An old example of this is porrigo, tinea, teigne, known still to-day in France and England as an isolated designation of disease of the hairy scalp, which originally were really used for as many peculiar diseases. As a modern counterpart may be mentioned the three diseases of impetigo simplex (Wilson), of sykosis simplex, and of furunculosis, which, according to Bockhart's researches, are caused by the known white and yellow staphylococci, according as the surface of the skin upon which they occur is covered by lanugo, by thick hair, or as the cocci find a good soil in the glands. The most important example for pathology is, however, that of the different forms of tuberculosis of the skin. We have on the hands and feet the relatively harmless species of papillomatous lupus, beginning as an anatomical wart and healing in its centre, progressing very slowly with peripheral papillary excrescences. We have tuberculous lupus and the very different sclerotic lupus; the former mostly appearing on the face, trunk, and upper extremities. There is the tuberculous lymphangitis of the skin, with the so-called tuberculous gumma and bubonuli, which lead to tuberculosis of neighboring lymphatic glands; further, the entirely flat lupus upon such cheesy glands if destroyed by ulceration; and, finally, at the termination of the tuberculous drama in the perfectly exhausted skin, those ominous tuberculous ulcers at the introitus of cavities, appearing in the lung and intestines much earlier. As many different forms of disease are presented by the lichen process, according to the degree of participation of the different parts of the skin. The modification by localization in the leg of the different skin diseases is known.

But enough of these examples; they demonstrate that we have to filtrate, as it were, the topographical, macroscopical, and microscopical differences of the normal skin from the manifold picture of a case before us, if we desire to arrive at an exact diagnosis. This is of special importance in those dermatoses which are localized in an unusual manner—*e.g.*, in an extragenital chancre; in a circular spot of lichen or psoriasis of the genitals, of a sykosis of the hairy scalp, in pointed condyloma of the capillitium. Another variety of skin disease depends on the typical change of symptoms in their course. This cause of polymorphy has produced historically most of the confusions, and continues to be a source of misunderstandings. The great dermatologists of modern times, Plenck and Willan contended with this difficulty without overcoming it. Their systems are attempts to embrace in the clinical forms of exanthems the true pathological types; and they knew, as appears from Bateman's preface to Willan's manual, that this one-sided presentation of the forms of efflorescences, for the object of classification, does not correspond well with the changeable character of most of them. They preferred, however, from practical reasons to give preference to this classification, which was based upon symptoms attracting the senses, and they were right. They did not imagine how much the future would rearrange in detail their order and reclassify it, partly through the discovery of finer anatomical distinctions, which rendered grouping untenable, as in lichen pilaris, lichen urticatus, lichen tropicus, and partly because it recognized remote forms of disease as a single one, as impetigo sparsa, and porrigo larvalis as eczema.

At this sore point of the older system, Hebra, the older, applied his critical lever; his clinical penetration permitted him to discover types of diseases even where entire series of different efflorescences make their appearance in the course of the process. The idea of eczema was considerably enlarged by the adoption of apparently heterogeneous forms of disease, to such a degree that the entire period after Hebra, according to the favorite diagnosis of the time, might be called the period of eczema, as there was previous to this one a period of scabies, and still earlier one of lepra. With the same excellent clinical instinct, Hebra limited the idea of lichen and of impetigo, and made, on the contrary, these diseases exclusive representatives of a distinct, anatomically definable efflorescent type. He thus overcame intuitively, without being a master of the anatomy and physiology of the skin, many difficulties, which the protean nature of many dermatoses had prepared for

his predecessors, but he has left to us, still, the task of classifying many new and well-known skin diseases.

External influences produce, as is well known, the most numerous variations in skin disease, and in no other organ are they, as a matter of course, of such importance as in the external integument. While formerly ths causes of external injurious effects which were considered of greatest importance, were generally regarded as mechanical, rarely as chemical, but at the present day these, although important factors, must give place to living parasites. If we know now with certainty that the normal epidermis in its horny layers is the nidus of an entire series of saprophytes, then it is a necessary consequence, according to what we know of the habit of such organisms, that the morbid epidermis provides a still better abode for ordinary saprophytes and a soil generally more favorable for the aggregation of true parasites, especially when the epidermis is abnormally moistened and contains decayed elements, pus cells, etc.

If mixed infections have a greater share in the production of diseases of internal organs than was heretofore believed, and if many deviations of the type of internal diseases prove to be, by accurate bacteriological investigation, secondary bacteriological invasions, we must assume *a priori* that in the exposed skin a secondary immigration of parasites forms the rule. This is confirmed, in fact, the more we collect experience in this direction. In most infectious diseases—*e.g.*, those invading the external integument, as variola, varicella, morbilli, and scarlatina—we have become acquainted with up to the most recent time such secondary invaders only, not, however, with the bearer of the poison proper. Perhaps we meet in van der Loeff's amœbæs, in Pfeiffer's sporozoides—the genuine parasite of smallpox-like diseases. All cocci found in smallpox only served to explain the puriform, secondary softening of the pox. We shall certainly have the same experience in many skin diseases. There is no doubt that, in acne vulgaris, the formation of comedones on the one hand, and the purulent inflammation of the follicle on the other, represent two processes internally absolutely foreign, externally simply combined, but existing independently of each other.

We observe that an originally purely nervous eczema, whose zoster-like vesicles on a previously healthy skin have suddenly sprung up, as in the dentition eczema upon the cheeks of the infant, after some time, begins to creep on like herpes tonsurans, instead of jumping over to remote parts of the skin in the track of nervous reflexes, as its nature demands. There is, then, no doubt that on the moist basis of nervous eczema, a parasitic—*e.g.*, seborrhœic eczema, has taken its seat, which now assumes the leadership, and dominates in the form of the disease. The joining of carcinoma in lupus is not otherwise to be explained. Even processes which we have been in the habit of considering as normal phases of well known dermatoses, as the suppuration of the zoster vesicles, have to be reduced to secondary infections. If we paint a beginning zoster immediately with iodoform, or some similar drug, the vesicles will develop as usual, but remain clear, the normal suppuration is suspended, and in the contents of the vesicles are found Pfeiffer's amœba-like organisms. How much more must we expect mixed infection where skin affections do not meet our eye in their typical forms.

In this is the next, most pressing task of the future; bacteriological analysis of skin diseases is, perhaps one of the most difficult of all bacteriological studies, but it is also one of the most interesting, and it does not require the gift of a prophet in order to see it develop from this study the germ of an entirely new conception of skin diseases in general; for clinical causes demand that we assume the parasitic origin of a larger number of dermatoses than many practitioners and colleagues of to-day are willing to admit.

Next to mixed infections are to be considered numerous external injuries, of mechanical, physical, and chemical nature for skin diseases. Let us simply think of the effect of cold and heat, of the variation of eczema in covered and uncovered parts of the body, in places which may be reached by the scratching finger and those remote from it, of the manifold peculiarities produced by the occupation of the patient, which can hardly be calculated in their extent; let us remember the complications produced by tight, rubbing, and compressing garments and ornaments on the affected skin, which may transform harmless eczema into dermatides accompanied by œdema, sugillations and vesicular formations. Let us pass before our minds the immense number of external and internal remedies which, in not desirable effect on the skin, give it an entirely new appearance, from arnica up to coal tar and chrysarobine. These external influences are so great, and admitted to be for so a long time, that the maxim was formed, under such circumstances confusing diagnosis, to permit the skin, under a protecting cover, to reflect the true nature of the affection.

Diametrically opposed to these external influences are the rarer but more difficult effects of internal nature, which must be ascribed to the individuality of each patient. Psoriasis and lupus vulgaris belong to skin disease easily diagnosticated, and yet there are individuals whose skin reacts upon these causes with such peculiar phenomena of irritation that extraordinary difficulties present themselves in diagnosis and treatment. The greater liability to these individual varieties is furnished by diseases under the influence of nervous affections: the simple nervous eczema, dermatitis herpetiformis (Duhring), varieties of herpes, erythema multiforme, and urticaria. Deviations from the ordinary type are observed in these instances, which threaten to displace and erase the character of members of this group, rendering exact diagnosis difficult. Disturbed circulation and cyanotic discoloring of the hands of working people may change existing eczema so considerably in appearance that even experienced physicians err in their diagnosis. The dermatologist has to make it a rule to himself, in rare affections, to examine the general constitution of the skin—above all, the circulation, the function of glands, and the condition of the epidermis—before he proceeds to the study of the morbid skin. And yet the causes of the varieties of skin diseases are not exhausted.

We have not spoken yet of those varieties induced by age and sex, country, climate, seasons, and race. The separate position of some skin diseases in children, compared with corresponding affections in the adult, is familiar to every practitioner. Every American physician knows of the great difficulties presented by the different pigmentation of races in the diagnosis of skin dis-

eases. I fear to tire you by entering more intimately into these points, and desire simply to point out in a few words the different *genius endemicus* of dermatoses in different countries, zones, and continents, and to the changing *genius epidemicus* in the same places. Lichen ruber acuminatus, Hebra's prurigo, are diseases almost unknown in America, as well as in England and France, in the place of which we have lichen planus and an eczema related to prurigo. Patients suffering from prurigo, transferred from the European continent to England and America, recover without medical aid more completely than they would at home with the best attention. There appeared in Hamburg, some years ago, a perfect epidemic of lichen ruber acuminatus, and disappeared again. At the present time there prevails there eczema seborrhœicum above all other eczemas, even psoriasis. Sycosis parasitaria slowly advances and diffuses, with herpes tonsurans of children, from England and France into Germany. But a few years ago the former was unknown in Vienna. The effect of tropical climates upon skin affections, especially eruptions caused by excessive sweating, has not been studied sufficiently. We shall probably meet here frequently old acquaintances in foreign dress and new names.

These scanty indications may suffice to prove that the study of the skin has to be an ethnological, climatological, and geographical one. By such comparisons we are, on the one hand, protected from the one-sidedness of some of the schools in different countries, and on the other, we obtain, by the collection of dermatological experience in all countries and zones, an extensive picture of the complete pathological functions of the skin.

In these facts, gentlemen, is embodied the explanation or, if you wish, the excuse that dermatology as a science has not yet attained the same high position of absolute knowledge as ophthalmology, or obstetrics. The complicated structure of the skin and its exposed position, render difficult an analysis of what is observed and will continue to make difficulties in the future.

More deductions may be made from these facts: We are in the first place directed with pressing necessity to minute analysis of the several symptoms of skin diseases, the first condition for a better understanding of skin diseases *per se*. This exact study of a single symptom, *e.g.*, function of perspiration, or of nerves —with all the auxiliary assistance rendered by physics and chemistry, by histology and experimental physiology, through all the regions of the skin, in all ages, in the normal skin of men, and in the greatest possible number of animals, in different morbid processes—that is what we want, and which we have heretofore had to do without almost entirely. Not the description of any new, heretofore unknown, skin disease is at present our most important problem, but the most penetrating understanding of the most common daily affections, like eczema, acne, and psoriasis. Strict analysis of the most usual symptoms must and will finally lead us to a firm basis of facts, accepted by all colleagues, and upon which a uniformly accepted pathology of the skin willarise.

We are then no longer, as in the times of Hebra, reduced to the clinical instinct of a single genius, but hundreds of active workers will successfully coöperate in building the common, solid structure. Then the faith in authorities will cease, and we shall not be compelled to explain to other professional brethren the mysteries of dermatology, but explain its facts. The divided national camps and schools among dermatologists will disappear, and it will be impossible to designate the same disease in Europe as a fungoid, and in America, or France as a constitutional disease of the blood. Then we shall do away with the rubbish accumulated during centuries, the superstition of the people and of physicians, which in spite of the glorious efforts of the Vienna school, still presses like a night-mare upon the unprejudiced study of skin diseases.

But this strict and minute analysis of all symptoms to the greatest extent will not benefit dermatology only, and this is my second deduction, but pathology in general. These two circumstances, complexity of the organ and its external position, rendering, on the one side observations difficult, make on the other side that which has been observed of importance for the entire pathology. The skin will become the touch-stone for every pathological theory of the future, far more so than the experimental organ in experimental pathology and therapeutics of the future. The eye only contests, in clearness of observation, with ex-perimentation on the skin, which is preferable as regards the animal body in most cases. For experiments in men we are reduced almost exclusively to the skin, and the few bacteriological experiments in this direction by Fehleisen, Garré, Bockhart, and others, have led to perfectly satisfactory, and explicit results. If all the parasites of the skin and their conditions of life were known to us, and we had learned their extraordinarily different pathological effect on the skin, from this limited chapter of experimental pathology and therapeutics a bright light would be shed upon the more obscure analogous processes of disease and treatment of internal organs.

The contest *pro* and *contra* concerning the trophoneurotic theory of disturbances will naturally be decided through the skin; the safe and broad basis of this theory was created by the eminent work of the American physicians Weir-Mitchell, Moorehouse, and Keen, during the War of the Rebellion. For observations of circulatory phenomena the external integument is indispensable, and especially for the sporadically appearing, and equally rapidly disappearing phenomena, only seen in the skin, like the angioneuroses, *e.g.*, urticaria. It is possible, even probable, that in other organs, *e.g.*, in the central nervous system, and in the mucous membrane analogous disturbances exist, which, as they never appear on the post-mortem table, can only be observed by means of the analogy of similar symptoms of the skin. The true nature of these skin diseases, heretofore treated by experimental research in a superficial manner, has certainly great value for general pathology.

I believe that these deductions are self-evident to such an extent that I need not prolong this connection of ideas. The entire pathology in the main, as the theory of inflammation and of tumors, has proceeded from skin symptoms; and it is still in every new definition of inflammation, the final touchstone, whether it can explain the four old cardinal symptoms: tumor, calor, rubor, dolor, originally applied to inflammation of the skin.

I would like to refer briefly to experimental therapeutics, to this interesting science of the future, the results of which have to supply or to confirm empirical

therapeutics. Numerous experiments on animals are considered to-day as the condition of recommendation of a new remedy supplied by chemistry, and yet we can make very rarely a final conclusion from the toxicological experiment in animals upon the therapeutical effect on man.

Experiment on animals is, however, not the only safe way to attain therapeutical knowledge. History teaches us quite a different road, viz., from the bold external to the careful internal application. The internal application of mercury was dreaded in antiquity. Dioscorides admonishes us expressly against its use. But when, at the end of the fifteenth century, with the appearance of syphilis, the mercurial ointment cure became popular, and by laymen more than by physicians was profusely applied as a remedy, occasional and isolated applications of its internal use occurred. In the beginning of the sixteenth century, pills containing mercury and turpentine, of the pirate Hayreddin, were in favor. At the end of the sixteenth century, with the mercurial ointment cure approved by physicians, internal mercurial preparations were administered. The balsam preparations had certainly already made this passage from external to internal applications, in antiquity. Well, this way is open to us to-day.

In illustration, I will quote an example from my own practice. I was experimenting with a sulphur remedy, which has received the name of ichthyol among laymen, in different skin affections, and found, among others, that in diseases of a distinctly nervous nature—*e. g.*, in certain nervous eczemas—it produced surprisingly good results by external application; I also found, however, that in continued external application this good effect changed to the opposite, and the idea then suggested itself to apply it internally in these affections; here I found its effect constant and satisfactory; it appeared that the domain of application of ichthyol, with respect to skin diseases, agrees partly with that of arsenic, but disagrees for the most part. In further experiment it surprised me as well as the patient, that certain complications of this eczema, especially nervous bronchial asthma, likewise disappeared under the use of ichthyol. Was it not natural when, later, other cases of bronchial asthma, not combined with eczema, were treated in the same manner, and the good results justified this supposition, that I considered ichthyol as one of our best remedies in bronchial asthma in general, and place it at the side of iodide of potassium. In a similar manner I have, proceeding from the skin, found the good qualities of this remedy—known to physicians—in chronic catarrhs of the stomach and intestines, and in chlorosis.

There is, therefore, an innocent, safe way for therapeutical experiments, which are not performed on the body of an animal, but the human skin, and as this tissue is, under proper treatment, very tolerant, I anticipate a large series of therapeutical acquisitions gained in this way. I expect not less beneficial effects from progressive dermatology or the future of surgery. Our specialty is properly situated between internal medicine and surgery, and bridges the wide chasm of both; sharing with internal medicine the gain of therapeutical effect, with surgery more the benefit of immediate diagnosis.

If we dermatologists have learned in general from modern surgery the blessings of the antiseptic method, in a limited sense, and the significance of the passive method, excluding all injuries, the time will come when surgery will long for a more active interference in surgical therapeutics, and then it will have to befriend itself with the results obtained by modern dermatology, which constantly studies the direct effects of chemical and physical agencies upon the tissues. The iodoform dispute of recent times has demonstrated that some surgeons still regard as identical the theories of antiseptic remedies, in the stricter sense, and surgical remedies in general, while according to our opinion antiseptics form only one part, an important one indeed, of surgical remedies. Iodoform has been saved this time, but even if all surgeons had turned away from it from fear, because iodoform does not destroy cultures of Staphylococcus aureus, we dermatologists would have continued to disinfect our soft ulcers with it and to esteem it highly, until a proper appreciation of the blessings of iodoform and the unimpeachable reasons for its being held in high estimation had been found by surgeons.

Permit me also here to give an example from my personal practice. We dermatologists, as well as physicians and surgeons, have to contend with one form of tuberculosis; viz., lupus. It may be a valuable direction to surgeons, that among all other local antituberculous remedies, above iodoform, pyrogallol, ichthyol, lunar caustic, salicylic acid has been approved, in pure form, as plaster-mull, or as a high per-cented salve, but especially the less painful mixture of salicylic acid and creasote. In tuberculosis of lymph vessels and lymph glands salicylic acid is equally excellent; whether it be for that of bones, further surgical experience must teach us.

I hope, gentlemen, that continuing this train of ideas, you will agree with me that the promotion of dermatology, as a special science, is in the interest of general medicine, in the interest of the naturalist, as well as in that of the practical physician. Such a promotion I see already in the increase of young practical physicians, who devote themselves with ideal enthusiasm to this branch, and happily there is no want of them at present. But essential encouragement ought to proceed from the Government and Universities. In France and England the entire burden of scientific research in this branch rests upon the shoulders of physicians and surgeons, who, simply from love for this branch, have devoted themselves to its special promotion. By special institutions this want is provided for in increasing extent in Russia, Germany, Italy, and the United States. Nowhere are so many chairs occupied by eminent savans in our branch as here in the United States, and yet the means for real progress in our specialty are not sufficient. The objects are so manifold, too confusing, too difficult for one individual, the extent of preliminary sciences to be acquired too extensive. Quite different results would be attained here by an association of investigators pursuing the same object, by a condensation of scientific means and methods, as they can be found only at a scientific central institution.

North America has, as no other country, produced citizens who have rendered themselves meritorious by founding rich scientific institutions. The first and oldest university of this country was founded, indeed, by a single man. A single American citizen will honor himself and

his country by the foundation of an institution, which elevates dermatology to the rank of one of the first medical branches, and, through it, places in view rich advances in general medicine.

ORIGINAL ARTICLES.

ON THE VACCINE OF YELLOW FEVER.[1]

BY DR. DOMINGOS FREIRE,
PROFESSOR OF ORGANIC AND BIOLOGICAL CHEMISTRY IN THE MEDICAL FACULTY OF RIO JANEIRO.

In 1880, I announced that yellow fever was due to the presence of an extremely minute organism, found in the blood and deeper tissues, and also in the liquids of the secretions, which caused, by its evolution, disorders often fatal. Since that time I have continued my investigations with the view of proving the transmissibility of the microbe, and also that I might transform it into a vaccine by attenuation.

I have published papers on these different subjects and, also, a report entitled, "Doctrine microbienne de la Fièvre jaune et les Inoculations Preventives," in which I have condensed all my ideas as to the pathogeny and prophylaxis of yellow fever. Two of these papers were made with the collaboration of Messieurs Paul Gibier and Ch. Rebourgeon, both distinguished pupils of the eminent scientist Pasteur, who were good enough to associate themselves with me during the present year while I was in Paris. Recently, at Rio Janeiro, I have continued the same investigations with Dr. Sternberg, who was sent by the United States Government to learn the result of my work. I now only fulfil a duty in expressing my gratitude for the interest and unflagging zeal shown by this learned physician, as well as for the efficient aid which he has given me.

The theory which I advanced as to the nature and prophylaxis of yellow fever, is the first of a long series of experiments assiduously pursued for a period of seven years. I hope that this will justify my assured confidence in the facts which I have observed, not only with reference to the etiology and pathogeny of the disease, but also with regard to the practice of preventive inoculations proposed by me.

My present communication I will divide into several parts, so as methodically to embrace the somewhat miscellaneous remarks which I have to offer.

II. *Natural history of the amarillus microbe. Its classification, evolution, and cultivation.* I have rejected the kingdom of the protista in attempting to classify this microbe, preferring to place it among the algæ, on the authority of scientists like Robin and Littré, Germain, St. Pierre, and others.

In 1880, when I discovered the amarillus microbe, I named it the cryptococcus xanthogenicus, because it seemed to me to have the general properties which characterize the genus cryptococcus. Recently the genus micrococcus has been created to designate the cellular or ovoid microbes, which are the cause of many infectious and contagious diseases. Many botanists, as I am informed by Dr. Pizarro, the distinguished professor of botany and zoölogy in the faculty of medicine of Rio Janeiro, consider this genus micrococcus the same as cryptococcus, the difference consisting merely in the method of reproduction, in the latter it being by spores, while the micrococci reproduce by budding.

The amarillus microbe is found in a monocellular form, commencing as a round point, almost imperceptible even with a magnifying power of 700 diameters, the points increasing little by little, strongly refracting the light and soon showing dark zones when the light is reflected on them at certain angles. These little cells are circular (spherical), surrounded by a grayish or black border, and contain in their interior masses of protoplasm. Reproduction, as I have many times seen, is effected, as it seems to me, by the rupture of the enveloping membrane.

The laceration of each cell may occur at a single point simulating a budding, but almost always the enveloping membrane breaks irregularly at several points. On the flaps resulting from the laceration there are seen colored viscous masses to which the germ cells adhere.[1]

These masses attaching themselves to the débris of the destroyed cells are often arranged in an almost symmetrical manner, sometimes in the form of a pear, of a pine cone, or of a pineapple, sometimes like long and more or less flexuous chaplets. The microörganisms measure from one to one and a half micro-millimetres.

At the time of proliferation there escape from each adult cell two different pigments, one yellow, which infiltrates all the tissues and produces the icteric color which gives the disease its name; the other black, insoluble, destined to be carried into the circulatory current and to produce either capillary obstructions, or blood stasis in the parenchyma of organs. The anuria is occasioned, at least in great measure, as the microscope shows, by the accumulation of microbes and their débris within the urinary canaliculi, exciting there, by their presence, colloid degeneration which transforms each uriniferous tube into a solid cord and thus prevents the renal infiltration.

The black color of the vomited matters is due to this pigment. This seemed strange at first, but since the publication of my earliest investigations it has been found that there exists in nature a great number of microbes which have been called *chromogenic*, and have the property of manufacturing pigments of different sorts, the coloring being sometimes very striking. In support of this I will cite the dark blue pigment made by the bacillus cyanogenus, another beautiful reddish-purple color given by the micrococcus prodigiosus and the micrococcus indicus. Besides, the presence of these pigments has been confirmed by many physicians, among whom I will

[1] An abstract of a paper read in the Section of Public and International Hygiene of the International Medical Congress, Washington, September 7, 1887.

[1] I call these germ-cells spores. Even admitting that the micrococci can only reproduce by budding, each bud forming a nascent cell can, strictly speaking, be only a spore.

cite Drs. Rebourgeon, Issartier, and Prof. Artigalas, of Bordeaux.

Prof. Cornil, in his *Traite sur les Bacteries*, has reproached me for having shown, in the illustrations of my book, *Doctrine microbienne de la fièvre jaune*, masses of pigment, "for," says he, "these pigments are accidental corpuscles, and not bacteria." I know very well that these are accidental corpuscles, but it should not be forgotten that such corpuscles are correlated with the life of the amarillus microbe. Convinced that the observer has no right to correct nature, and repress what she clearly shows, I thought it my duty to place in my illustrations the pigments met with in cultures, especially as these same pigments play a very important part in the pathogeny of the disease, the two phenomena, icterus and black vomit, being the symptomatic expression of their presence in the organism of the patient.

Prof. Cornil himself has not been indifferent to the great interest which many attach to these pigmentary matters, for he mentions them several times in his treatise already cited, and has therefore repeatedly verified the pigments which I showed in my illustrations. I am happy to say that he has also confirmed the presence of the amarillus microbe in organs sent from Brazil. When I was in Paris about four months ago, I had the pleasure of receiving a visit from that illustrious scientist in the Laboratory of Comparative Pathology of the Museum of Natural History, where I was carrying out my investigations together with Drs. Gibier and Rebourgeon. We had an opportunity of showing him liquid and solid cultures made after the methods of Pasteur and Koch, and were able to satisfy him that coloration was invariably associated with microbes which, in his treatise, he reproached me with not having shown. On this occasion he was able to compare the microbe in the fresh condition, which he had not before seen, and the dead microbe stained with the hydrochlorate of rosaniline.

I have made perfectly successful cultures of the xanthogenic microbe in beef broth, milk, and gelatine solutions. I prefer gelatine solutions made, not with distilled water, but with ordinary water, because the latter contains different mineral salts and even some organic matter useful to the microbe. All the details with reference to my method of carrying on cultures are given in the first part (Chapter III.) of my report on the *Microbian Doctrine of Yellow Fever and Preventive Inoculations*, published in Rio Janeiro in 1885.

Besides Pasteur's method of cultivating microbes, I also used, with my microbe, Koch's method of solid cultures. Experiment has showed me that the amarillus microbe is easily stained, much more easily than many others, by aniline colors, such as the hydrochlorate of rosaniline, methyl-violet, and Bismarck-brown. In a brief paper presented a short time ago to the Académie des Sciences, we pointed this out, and Drs. Gibier and Rebourgeon showed colonies of the xanthogenic microbe stained a violet color and perfectly visible by means of a Verick microscope, eye-piece No. 3 objective, with homogeneous immersion.

We have, besides, succeeded in cultivating the same microörganism by means of the method of Koch. Placed in tubes containing gelatine which has been previously perforated by a sterilized platinum wire and charged with a little drop of culture fluid, the microörganism, kept at a temperature of from fifteen to twenty-five degrees, forms colonies which take the form of a nail, the head being on the surface and the point buried below in the gelatine. The gelatine liquefies little by little in an irregular manner, and the liquefaction always takes place at the superficial strata, which indicates that the microbe is aërobic.

The amarillus microbe has the property of elaborating products belonging to the class of ptomaines (leucomaines of Gautier) at the expense of the albuminoid and other matters on which it feeds. These ptomaines are very poisonous. I have made numerous experiments with them on dogs and frogs, experiments which show that these alkaloids have a remarkable influence on the sympathetic and pneumogastric nerves. Many symptoms of yellow fever will thus be plausibly explained by the profound disorders which these poisons occasion in the cardiac apparatus and the vasomotor nerves. In the cultures themselves these ptomaines are formed. Gelatine having a neutral reaction becomes markedly alkaline after the microbe has been in it a few days, and by well-known methods we can extract from these cultures, ptomaines similar to those found within the body in cases of yellow fever.

II. *Inoculability of the amarillus microbe. Its attenuation.* I have made a great number of inoculation experiments upon animals in order to prove the transmissibility of the disease. I have remarked that not only do inoculations made directly with blood and with virulent cultures kill rabbits and guinea-pigs in from two to ten days, but that the same result occurs when these animals are kept in an atmosphere more or less saturated with microbes. Many animals died simply from breathing the air of the laboratory where I made my experiments and autopsies. Their organs showed many specific microbes. I have placed the inoculability of the microbe beyond doubt by injections, both hypodermatic, intravenous, and intravisceral. I have made many series of experiments which I am happy to announce have recently been fully confirmed by Dr. Rangé, physician of the first-class in the French Navy at the Salut Islands, French Guinea. The account of these experiments was published in the *Archives de Medecine Navale*, last year.

The transmission of yellow fever from individual to individual by blood which was in the first place virulent, and which loses none of its virulence by passing through different organisms, shows clearly that the agent which produces the disease is not dead matter, but living, and susceptible of reproduction by successive transmissions. This agent can be nothing else than the only abnormal element of definite form constantly and invariably associated with undoubted yellow fever cases, that is to say, the micrococcus xanthogenicus. These direct proofs having put beyond question the parasitic and contagious nature of yellow fever, I applied myself to the study of the attenuation of the microbe so as to

change it into a product which might be used for vaccination.

We know that yellow fever, except in very rare cases, attacks the same individual but once, a characteristic found in almost all transmissible diseases of a virulent nature. If we succeed, however, in attenuating the cultures of the xanthogenic microbes so that they produce only such slight disturbances and changes of composition in the blood and in the tissues as will confer immunity, we shall then obtain for yellow fever the same great desideratum which we have already obtained for smallpox, for chicken cholera, and for splenic fever in those animals which are susceptible to it.

Now I remarked that after a certain number of successive cultures the microbe became much less virulent, and guinea-pigs inoculated with it did not die, resisting an injection of from 50 to 100 cubic centimetres of attenuated culture fluid. They had slight fever, loss of flesh, and some other symptoms, which disappeared in a few days; besides, in a great number of the animals thus vaccinated, having made a few days later an injection of virulent blood, I proved that none of them died, although the same injection killed all those not inoculated with attenuated cultures.

The vaccine is prepared as follows: The blood of a patient, dead or about to die of yellow fever, is injected into the veins of a guinea-pig or a rabbit. A second animal of the same species is then inoculated with the blood of the first, and so on for six or seven animals. With the blood of the last cultures are made, which are transplanted at least four times; then I commence inoculations upon man, not, however, without having first ascertained, by experiments on animals, that the inoculations will not produce grave results. We thus obtain a tenth or twelfth generation from the primitive microbe, the virulence being notably diminished. The attenuation is caused by the new conditions with which the microbe is surrounded in passing through the organism of the guinea-pig, and its after-cultivation in sterilized test-tubes containg beef broth or gelatine.

Besides this, cultures attenuate of themselves gradually under the influence of air, so that a liquid at first virulent may be inoculated without danger in from seven to ten days afterward. These cultures once attenuated preserve their attenuation indefinitely until epidemic seasons, during which their activity almost insensibly increases. I, therefore, undertook experiments to ascertain how to renew the virulence of the cultures, and I can now, at any time of year whether during the epidemic period or not, keep up the virulence of these cultures, and change them at will from a toxic to an attenuated condition, and *vice versâ*, obtaining gradually the energy proper for vaccination and increasing it up to that which is infallibly fatal. I proceeded as follows in obtaining this important desideratum.

1. I practised inoculation by the hypodermatic method, injecting under the wing of pigeons or chickens 15 minims of attenuated culture fluid, used for the inoculation of patients.

2. Three hours afterward I killed the birds, in the blood of which the culture had been in a state of incubation or digestion, collecting the blood in sterilized flasks, conducting the operation with all the technical precautions necessary to prevent the introduction of foreign germs.

3. Immediately after, I inoculated small birds with this blood, allowing 5 minims to 7½ drachms weight of the animal.

All those used in this experiment died within seven days.

The experiment repeated fifteen times on *tiés* and *sanhassics*[1] gave identical results.

4. At the autopsy I found in the bodies of the birds lesions similar to those of yellow fever, and among the appearances I would would cite as of high diagnostic importance, matter black as writing ink in the gizzard and intestines. The blood of these birds examined microscopically shows the microbes characteristic of the disease.

5. The blood of the chickens and pigeons killed as stated in paragraph 2, preserved its deadly virulence for sixteen days, after which attenuation commenced.

6. Guinea-pigs inoculated with the same blood (the inoculation being intrahepatic, into the peritoneum or simply subcutaneous), even in a proportion of eight minims per one and one-quarter pounds weight of animal was also toxic, killing in from two to ten days. The anatomical lesions confirmed the diagnosis of yellow fever. The fluid of the stomach was very turbid and black, and the urine contained albumen.

7. If the blood from pigeons or chickens No. 1 is injected into one of the same species No. 2, 3, 4, or 5, the energy of the virus progressively decreases according to the number of transplantations made from one animal to another. We may thus always procure a series of cultures systematically graduated. When animals, either birds or guinea-pigs, are inoculated with attenuated cultures they obtain the immunity of vaccination and are no longer affected by fatal virus.

8. The specific microbe having its ordinary appearance is found in every case in cultures thus graduated.

9. Confining myself for the present to the statement of these facts, I will not now attempt to explain why the microbes remain unaffected in strength for some hours within an animal organism itself insusceptible to yellow fever, this agreeing with the observations described in my last work, and recently repeated, with an identical result by Dr. Rangé, of the French Navy.

The fact that an organism may not itself be affected by a morbid element, and may yet increase the virulence of that element, extraordinary as it may seem, may explain a great number of questions relative to the peculiarities of contagion during epidemics, as it may also explain many obscure circumstances relating to the hereditary transmission of various disorders

III. *Vaccinations upon man; practical results.* Only after the long experiments already described upon

[1] Names given to birds of the genus Tanagra which feed upon oranges, bananas, and other fruits.

the virulent power of the microbe of yellow fever, was I encouraged to inoculate the human organism with it. The first 400 vaccinations were made endermically, but I came to prefer the hypodermatic method as being much more sure and easier in practice.

The following is the method of procedure: The culture fluid is taken from the flask with every precaution against foreign germs, and preserved in small tubes containing from one to two drachms, these being sterilized by heat and stopped by emery. A few drops of the liquid are turned into a clean capsule, taken up by a Pravaz syringe, and then there is thrown under the skin, a quantity varying from two to fifteen minims, according to the age of the individual. The disturbances which result from the vaccination are like the prodromes of yellow fever. They are manifested by intraorbital headache, rigors, general lassitude, with heaviness of the limbs, backache, febrile action (99.5°, 100.5°, 102.5° F.), slight epigastric pain, and sometimes nausea, or even vomiting, all lasting not longer than two or three days without the use of remedies. There is no local cause for these phenomena, for there only appears around the puncture a slight reddish areola which quickly disappears.

I shall give a résumé of the results hitherto obtained from these vaccinations. The vaccinations have been performed gratuitously, and were authorized by Ministerial Decree No. 4546, of the Brazilian Government, Nov. 9, 1883.

During the epidemic of yellow fever which took place at Rio Janeiro in 1883 and 1884, I vaccinated 418 persons, not only before the epidemic but while it was raging with its greatest intensity. The number of unvaccinated persons who died of yellow fever was 650. Among the vaccinated persons there were *seven* who also appeared on the list as having died from the disease. Although there are serious doubts as to whether the diagnosis was correct, I will follow the counsel of my distinguished colleague, Dr. Trouessart, and not seek to suppress these rare cases of failure, especially in view of the imposing number (411) of successful vaccinations which I can put to my credit. This is an extremely favorable proportion, especially when we reflect that the patients in question belong to the working classes, and lived in *estalagens*, damp, narrow, and badly ventilated chambers in the most unhealthy quarter of the city, where the mortality among the unvaccinated, especially among foreign workmen, was great.

Among the 650 unvaccinated persons who died of yellow fever (October, 1883, to June, 1884) 577 were strangers, only 73 Brazilians. Now I vaccinated 307 strangers, the Brazilians who fill up the list of 418 all came from the interior and were therefore under the same conditions of susceptibility as strangers, the yellow fever being unknown in the interior of Brazil, and flourishing only on the sea coast. Not one of the Brazilians vaccinated died of yellow fever.

The results obtained the next year (January to August, 1885) by means of inoculations made, not by the lancet but by the hypodermatic method, were still more favorable. During this interval the number of deaths from fellow fever from among the unvaccinated at Rio Janeiro was 278, 200 strangers and 78 Brazilians, 44 only being born in that city. During this same period I vaccinated 3051 persons; 2186 natives, and 865 strangers. Among the 2186 natives, 625 were young children of foreign parentage, consequently as susceptible as strangers themselves. During the entire epidemic not one died. The immunity was absolute.

These figures speak for themselves, I think, but this is not all, for during the last epidemic which broke out at Rio Janeiro in 1886, the statistical results confirm their eloquence.

In fact, during this period we vaccinated 3473 persons: Brazilians, 2763; strangers, 710. Of the Brazilians, 489 were of foreign parentage, all quite young, and should really be added to the 710 strangers, as presenting the same degree of susceptibility as the latter. More than this; 222 came from different provinces of the interior and the south, and were therefore in a very favorable condition for contracting the disease. There were really 1421 vaccinated persons who should be added to those who cannot be said to be exempt from contagion by reason of residence. There remained 2053 Brazilian subjects, age varying from a few months to sixty years. In this group a large number, by reason of age or residence in quarters most subject to the scourge, were under the most favorable conditions for becoming victims. Among those vaccinated there were but eight who died of yellow fever, one of whom had been inoculated in 1885, although during the same period the mortality from the disease among non-vaccinated persons was 1389, thus divided: strangers, 1079; Brazilians, 310.

If we recapitulate the vaccinations by the hypodermatic method during 1885 and 1886, we obtain the following result:

First vaccinations in 1886	3473
Deaths of vaccinated persons	7
Second vaccinations in 1885	3051
Deaths of vaccinated persons	1
Total vaccinations	6524
Total deaths of vaccinated persons	8
Mortality of vaccinated persons	1 per cent.
Mortality in yellow fever cases of non-vaccinated persons according to official reports for the years 1885 and 1886	1667

Let us now arrange this so as to include the statistics of 1884, when we employed the endermic method; we have:

Vaccinated	6942
Deaths of vaccinated persons	15

Which gives us hardly two per cent of mortality of vaccinated persons.

Deaths of the non-vaccinated	2317

I here give but a short abridgment, the entire statistical details are given in a paper presented to the Academy of Sciences at Paris. Still, I think it is sufficient to show the real benefits which may result from a general use of the prophylactic method.

For all the statistical details the reader is referred to the following works:

1st. "Rapport sur les inoculations préventives de la fièvre jaune durant l'épidemie qui a regné en

1883 et 1884, à Rio Janeiro, presenté au Ministre de l'Interieur au Bresil." This report is annexed to my work entitled "Doctrine microbienne de la fièvre jaune."

2d. "Le vaccin de la fièvre jaune. Resultats statisques des inoculations preventives pratiquées avec la culture du microbe attenué, de Janvier à Août de 1885."

3d. "Statistique des vaccinations pratiquées avec la culture attenuée du microbe de la fièvre jaune de Septembre, 1885, à Septembre, 1886."

I also recommend the report made by Drs. Rebourgeon, Gibier, and myself to the Académie des Sciences de Paris, entitled "Résultats obtenus par l'inoculation préventive du virus atténué de la fièvre jaune." This paper was presented and read before the Academy of Sciences by the lamented Prof. Vulpian, who introduced it with some remarks very flattering to us, thus contributing to the success of our investigations.

MEDICAL PROGRESS.

TYPHOID FEVER CONTAGION IN THE ATMOSPHERE.—DEVALZ, of Eaux-Bonnes, France, recently reported to the Medical Society of the Hospitals a case of typhoid contagion in a hotel, where a guest brought the fever with him, and where three daughters of the proprietor were attacked. Bacteriological examination of the water was negative. The exhalations from the stools, which were not disinfected, are supposed to have been the medium of contagion.—*L'Union Médicale*, July 26, 1887.

SOLANINE.—GAIGNARD concludes an extensive investigation of the properties of this drug as follows:

Solanine is a glucoside which does not combine with acids to form salts. Acids decompose it into solanidine and glucose. It is insoluble in water; little soluble in alcohol, ether, and the oils. It is sparingly soluble in strongly acidulated water. It cannot be used hypodermatically; its acid solutions are too caustic. It is also caustic when held in suspension. It may be given in pills of 1½ or 3 grains. Daily dosage of 4½ grains to 6 grains is well borne. Its high price, unequal action, and large doses needed to produce an effect make it an undesirable and not to be recommended analgesic.—*Bulletin Générale de Thérapeutique*, July 15, 1887.

CASTOR OIL EMULSIFIED WITH CASEINE.—GASSICOURT has found the following a convenient combination:

R.—Ol. ricini	. . . .	15 parts.
Aq. lauro-cerasi	. . .	5 "
Aq. destillat.	. . .	100 "

Casein saccharat. q. s. to form an emulsion.—*Le Progrès Médical*, July 16, 1887.

FRACTURE OF THE HARD PALATE.—DR. E. HARRISON GRIFFIN, of New York, reports (*Medical Record*, July 21, 1887) a case, from injury by falling on an instrument in the mouth of a child thirty-two months of age. A portion of the hard palate was severed and hung down upon the tongue. The parts were readjusted and retained in place for two weeks by an obturator perforated for drainage, at the end of which time union was so complete that all marks of the injury had become effaced.

PRENATAL TUBERCULOSIS.—The *Centralblatt für klinische Medicin* of July 16, 1887, quotes the conclusions reached by FIRKET, who has written at length on the subject, as follows:

Infection through tuberculous semen the author considers doubtful, although Javi has found bacilli in the seminal ducts which had not, however, produced any changes in the epithelia of the prostate. Bacilli attacking the ovum would injure its development and produce monstrosities, which has not been observed. Bacteria, however, have been found in the placental circulation, which is only accessible through the maternal blood. Cases of general infection in which, besides the lungs, organs not in communication with the external world are implicated, are cited. In about half of the cases of pulmonary tubercle, however, local infection from without only exists. Tubercle has been found in the placenta, although doubted by some. Two cases of tuberculosis of the liver have been found in infants, and one case in young animals; which is explained by the important part which the fœtal liver plays in fœtal circulation.

Constitutional infection may remain long latent, and then attack the lungs.

HYDRASTIS CANADENSIS IN PILL FORM.—*Les Nouveaux Remèdes* for July 24, 1887, gives the following useful prescription:

R.—Extract. hydrastis canadensis	.	5ij½
Ext. ergot.	. . . . .	gr. 45
Ferri redact.	. . . . .	gr. 45

Div. in pil. 120 in nunc.—Sig.

From two to five pills every three or four hours.

THE DIAGNOSIS OF NEOPLASMS BY EXAMINATION OF THE BLOOD.—HAYEM is quoted by the *Centralblatt für die Medicinischen Wissenschaften* of July 23, 1887, as follows:

Taking as normal 6000 white blood corpuscles in 1 cubic millimetre of blood, the variations were as follows:

Mammary scirrhus, 13 cases, 7400 to 21,700; in 10 cases, over 10,000; in a 14th case, in an aged patient, the number was greatly reduced.

Medullary sarcoma of the breast, 3 cases, all above 10,000.

Scirrhus of the pancreas, 2 cases, 9400 and 9900.

Medullary sarcoma of the testis, 12,250.

Osteosarcoma, 7 cases, 19,500; one case of very rapid growth, 52,700.

Lymphosarcoma, from 11 to 20,000.

Epithelioma, an average of 7800.

Gastric cancer, in 7 cases, an average of 7600; in 5 cases, 17,600.

The influence of operations was shown to be—

Mammary scirrhus, 3 cases; before operation, 21,700, 11,500, 11,000; after recovery, 6200, 6200, 8400.

Medullary sarcoma of the breast, before operation, 10,000; after operation, 9000.

Lymphosarcomata and osteosarcomata showed a still greater diminution after operation.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, SEPTEMBER 17, 1887.

CATHETERIZATION OF THE URETERS.

AMONGST rare procedures for diagnostic and curative purposes may be mentioned catheterization of the ureters in the female. This operation has been developed chiefly by DR. KARL PAWLIK, of Vienna, and the publication of his method and results marks quite an epoch in the history of renal surgery.

One of the greatest obstacles to the performance of operations upon the kidneys is the great uncertainty as to the condition of the opposite organ, and some of the most lamentable results after nephrectomy have been due to the existence of unsuspected or undetermined lesions of the remaining kidney. The development of the operation of sounding the ureters has progressed to such an extent that, in the female at least, it is now possible to determine the exact condition of both kidneys in many instances. In the male, as yet, nothing has been done in this direction, as it is scarcely possible to reach the orifices of the ureters except by the performance of a perineal section, which has not been practised for this purpose, so far as we know.

Pawlik relates, in the *Wiener med. Presse*, the histories of ten cases in which he has sounded the ureters, and the value of the procedure is clearly shown. In the first case the catheterization resulted not only in the elucidation of the cause of the severe kidney colic, but a cure was effected at the same time. In this case it was found that mucus had been rolled up into a ball, which obstructed the ureter, and developed severe pain. The necessary dilatation was effected, and the condition relieved. In the second case the patient had previously submitted to double ovariotomy at the hands of Prof. Billroth, from which she recovered; but subsequently a discharge of urine occurred from the abdominal wall, and a uretero-abdominal fistula resulted. It was sought by sounding to ascertain the exact condition of the ureters, and it was discovered that one ureter was impervious, owing to parametric exudation. An attempt to dilate the ureter failed, and caused a renewal of the inflammation, for which reason it had to be discontinued. The opposite kidney was proved to be healthy, hence nephrectomy was performed for the cure of the urinary fistula. In the third case, one of wandering kidney, the exploration of the ureters proved that the opposite kidney was not sound, hence a contemplated extirpation was desisted from. In the fourth case, in which was a renal tumor, the soundness of the opposite kidney was demonstrated, and the diagnosis confirmed.

In the fifth case the diagnosis wavered between a tumor in a floating kidney, and an ovarian tumor with a long pedicle. The history spoke in favor of the first supposition, but the catheterization decided for the latter. In the sixth case the exploration confirmed the probable diagnosis of hydronephrosis, and at the same time the hydronephrotic fluid was evacuated, its further development hindered, and the normal function, of the not essentially diseased kidney restored. In the seventh case there was hæmaturia, the source of which was doubtful, and the sounding not only proved its renal origin, but, what was more remarkable, arrested the bleeding, which had lasted two months. This returned later, lasted three weeks, and again ceased after a repetition of the sounding. In the eighth and ninth cases the supposition of a renal tumor was proven to be correct, and the healthy condition of the opposite organ ascertained. Nephrectomy was accordingly performed in each case. In the tenth case an attempt was made to evacuate a hydronephrosis with the catheter, but it did not succeed, notwithstanding that the catheter clearly reached the renal pelvis, as the presence of hydronephrotic elements in the urine, after the exploration, showed. A renal fistula was then formed by the lumbar incision.

These results serve to draw attention to this procedure, as an addition to our methods for diagnostic purposes chiefly, but also, in some cases, as a therapeutical agent of marked value. There are probably other purposes which may be subserved by this operation, such as the dislodgement of an impacted calculus in the ureter.

Dr. Pawlik directs that the bladder should be filled with about 200 cubic centimetres (about 7 ounces) of fluid previous to undertaking any exploration of the ureters. When the bladder is filled to this extent, the orifices of the ureters are situated upon a prominent swelling which runs in a convex bow, from the basal angles of the trigonum toward the urethra. When the bladder is

further distended, this swelling disappears. Generally an arrangement of furrows is found upon the anterior wall of the vagina, which forms an angle, the apex of which is placed behind the urethral prominence, whilst its arms are separated from each other by the vaginal portion of the uterus. The orifices of the ureters are placed within this angle. The point at which the posterior bladder wall turns toward the uterus may frequently be recognized on the anterior vaginal wall, as a transverse line in front of the vaginal portion of the uterus. It forms with the above-mentioned angle a triangle which corresponds to the trigonum, and to a small portion of the posterior wall of the bladder when the latter is distended.

The most important guide for sounding is the prominent swelling of the ureter. The patient should be in the lithotomy position, whilst the perineum is retracted with a speculum, which exposes the anterior wall of the vagina, to view. The catheter is introduced into the bladder, and can be guided by lightly raising up the vaginal wall. Proceeding toward the corresponding ureteral orifice, if no obstruction is encountered, the catheter has been carried too near the middle line. When the opening of the ureter is reached, it is known by the fact that all resistance ceases, and a slight depression is formed in a circumscribed space on the front vaginal wall, the sinking of the handle of the catheter is hindered, and the instrument can be pushed further and further to the side. The catheter can be introduced as far as the pelvis of the kidney, if the ureter is not too tightly attached to the pelvis, or if the pathological changes in the cellular tissue have not fixed the ureter in the pelvis.

We have presented this notice of Dr. Pawlik's observations because they have an undoubted practical application. It may be that the knowledge to be obtained by the catheterization of the ureters will be but seldom required, but when serious surgical operations upon the kidneys are contemplated, information of the greatest importance may be gained in this manner, which could be obtained in no other way.

USEFUL MICROORGANISMS IN THE ALIMENTARY CANAL.

IN *L'Union Medicale* of August 23, 1887, are the records of some interesting results, obtained by PASTEUR, as to the influence of the microörganisms found in the alimentary tract of healthy persons, on the digestion of some of the common food stuffs. They throw much needed light upon this subject, and while these new views are still *sub judice*, they are worthy of the attentive consideration of both the physiologist and the general practitioner.

Pasteur, having first isolated no less than seventeen microörganisms of the mouth, including the micrococcus Pasteuri of Sternberg, and the coccus designated by the title *k*, of Pasteur, proceeded to add a given number of these microbes to various matters commonly taken as food, and the results are here expressed in the brief terms of the author. The addition of seven of these microörganisms to albumen dissolved that substance completely, while five caused it to swell and rendered it transparent. Ten of them added to fibrin dissolved it, while four rendered it transparent and swollen, nine dissolved gluten, seven coagulated milk, and six dissolved caseine. Three transformed starch into sugar and nine changed lactose into lactic acid; seven changed crystalline sugar; seven produced fermentation of glucose and transformed it partially into alcohol. These organisms also were found to possess the power of resisting the gastric juice for as long as twenty-four hours at the temperature of the body. In the fecal matters he recovered six of these microörganisms of the mouth, the bacillus mesentericus fuscus, the bacilus Coli commune, the bacillus *b*, *c*, and *e*, and the coccus *k*, and four other microorganisms. One of these last dissolved albumen, two rendered fibrin transparent, three dissolved gluten, one transformed potato starch, three transformed lactose to lactic acid, while two coagulated milk, and so on, with many of the various substances generally taken by man.

M. Pasteur, therefore, concludes that the microorganisms found in the normal human alimentary tract are important factors in aiding the carrying on of digestion. While it has generally been supposed that these microörganisms must have some functions to perform in the intestinal canal, so far as we are aware, these experiments are the first to place the supposition on anything like a firm basis, and the repute of the investigator gives assurance as to the accuracy of the deductions he has drawn.

Further experimentation may, and very likely will, give us still further data concerning this important matter, and the world, both professional and otherwise, may soon learn that the word microbe and microörganism is not always synonymous with some morbid process.

AN EMERGENCY SERVICE DURING THE CENTENNIAL CELEBRATION.

THE medical profession of Philadelphia will provide an emergency service modelled after the Geneva Red Cross Commission, which will have stations along the route of parade where the physicians on duty will be provided with ambulances and needed appliances for first aid to injured. When it is remembered that at the recent Jubilee of the Queen in London about 600 casualties occurred, the need for such precaution is apparent.

DR. ALONZO CLARK, one of the oldest and most eminent physicians of New York City, died at his residence in that city, on Tuesday, in the eighty-first year of his age. He had been in feeble health for some years past.

Dr. Clark graduated from Williams College in 1828, and received his degree of M.D. from the College of Physicians and Surgeons of New York in 1835. In 1848 he was elected to the Chair of Physiology and Pathology in his Alma Mater, and in 1853 he was transferred to the Chair of Practice of Medicine. He was for a long time Visiting Physician to Bellevue Hospital, President of the Medical Board at St. Luke's, and Consulting Physician to the Northeastern Dispensary. He belonged to numerous societies and institutions, among them being the State Medical Society, of which, in 1853, he was President; the Academy of Medicine, the County Medical Society, the New York Society for Relief of Widows and Orphans, and the New York Pathological Society.

THE New York State Medical Association will hold its fourth annual meeting at the Hotel Brunswick, New York, on September 27th, 28th, and 29th, under the presidency of Dr. Isaac E. Taylor, of New York.

THE Emperor of Austria has conferred upon M. Pasteur the decoration of the Order of the Iron Crown, with the title of Baron.

SOCIETY PROCEEDINGS.

NINTH INTERNATIONAL MEDICAL CONGRESS.

Held at Washington, September 5–10, 1887.

(Specially reported for THE MEDICAL NEWS.)

GENERAL SESSIONS

THURSDAY, SEPTEMBER 8TH.

THE Congress was called to order shortly after 10 o'clock, by the President, N. S. Davis, M.D.

INOCULATION AGAINST YELLOW FEVER.

The Associate Secretary, Dr. W. B. Atkinson, of Philadelphia, then read the resolutions adopted in the Section of Public and International Hygiene on the investigations of Dr. Domingos Freire, of Brazil. (See THE MEDICAL NEWS, Sept. 10th, page 320.)

ENTERTAINMENTS.

DR. A. Y. P. GARNETT, Chairman of the Committee of Arrangements, announced that as the time had been short for the change of tickets for the banquet in the evening, he feared many were not aware of the change, and that as a ticket would be absolutely required of those applying for admittance, he asked that the Chairmen of the various Sections would announce the fact from their respective chairs at the morning sessions.

THE ANNIVERSARY OF THE DISCOVERY OF AMERICA.

The following resolution was then proposed:

Whereas it is proposed to hold at the city of Washington, in 1892, an international celebration in honor of the four hundredth anniversary of the discovery of America by Christopher Columbus, and an exposition of the history, arts, and industries of all nations,

Resolved, That the International Medical Congress favors this patriotic movement, and commends it to the nations of the world.

This announcement elicited from DR. SEMMOLA an enthusiastic approval of the project. He spoke as follows:

"Gentlemen: There are things so great in the history of humanity that it is not possible to glorify them as much as they deserve. The discovery of America by Christopher Columbus is one of these. I have been educated from my infancy to venerate the memory of that immortal Italian, but I confess that now that I have crossed the ocean, even with all the facilities that steam and nautical science afford, it is the first time that I have been able to conceive a correct idea of the genius of Columbus, and to appreciate his enterprise, his hardihood, and the foresight which never failed him to the last day of his journey. So that now I prostrate myself before Columbus, and worship him as of divine emanation.

"Therefore, gentlemen, I rejoice with you, and congratulate you from the bottom of my heart for the noble sentiment that has inspired you in proposing an international testimonial in honor of the immortal son of Genoa; and be it as an Italian, or as a member of the Parliament of Italy, as a delegate of my Government to this Medical Congress, and even as one of its Vice-Presidents, with infinite delight do I associate myself with this proposition, and thank you most sincerely."

The following gentlemen were announced as having been appointed on

THE COMMITTEE TO SELECT THE NEXT PLACE OF MEETING,

in accordance with the resolution adopted on the preceding day

Argentine Republic—Dr. Villa, of Buenos Ayres.
Austria-Hungary—Dr. Farkas, of Buda-Pesth.
Belgium—Dr. Servais, of Antwerp.
Brazil—Dr. Freire, of Rio de Janeiro.
China—Dr. Boone, of Shanghai.
France—Dr. Landolt, of Paris.
German Empire—Dr. Martin, of Berlin.
Great Britain—Dr. Pavy, of London.
Italy—Dr. Semmola, of Naples.
Japan—Dr. Saiga, of the Imperial Navy.
Mexico—Dr. Alvarado, of Mexico.
Russia—Dr. Reyher, of St. Petersburg.
Spain—Dr. Laleardа, of Seville.
Sweden and Norway—Dr. Tillman, of Halinstadt.
Switzerland—Dr. Cordes, of Geneva.
Turkey—Dr. Post, of Beirût.
United States—Dr. A. L. Gihon, United States Navy.
Egypt—Dr. Grant (Bey), of Cairo.

DR. MARTIN, of Berlin, then took the chair.

DR. P. G. UNNA, of Hamburg, delivered a general address on

THE RELATION OF DERMATOLOGY TO GENERAL MEDICINE.

(See page 325.)

At the close of the address, SIR JAMES GRANT, of Canada, moved that a vote of thanks be tendered Dr. Unna for his very able and exceedingly interesting address. Adopted.

FRIDAY, SEPTEMBER 9TH.

PRESIDENT DAVIS called the Congress to order at a few minutes after 10 o'clock.

ENTERTAINMENTS.

Assistant Secretary, W. B. Atkinson, announced that the foreign delegates and their wives alone, would be admitted to the Government Steamer for the excursion to Mount Vernon at 10.30 A. M. to-morrow, and that the Grasslands entertainment was restricted solely for the foreign delegates and their ladies.

A COMMEMORATIVE MEDAL.

DR. J. M. TONER announced that it was known to most of those present, that there had been a movement to have struck a medal commemorative of the Ninth International Congress, similar to those of previous congresses. He was happy to state that the subscriptions already received were sufficient to warrant the issue of the medal, and that it would be struck at the United States Mint at Philadelphia. Two hundred have been subscribed for, but as it is probable that many more desire them, he made this announcement in order to give them an opportunity to subscribe and pay five dollars to the Treasurer.

THE NEXT MEETING OF THE CONGRESS.

The SECRETARY-GENERAL read the report of the Committee appointed yesterday, to select a place and time for the meeting of the Tenth International Medical Congress. The Committee reported that Dr. M. Semmola, of Italy, had been elected *Chairman*, and Dr. Assaky, of Bucharest, *Secretary*.

By a vote which was, with one exception, unanimous, Berlin was chosen as the place of meeting, and Prof. Virchow was named as President of the Congress.

DR. J. D. PHILLIPS, of London, then took the Chair.

DR. G. FIELDING BLANDFORD, of London, delivered a General Address on

THE TREATMENT OF RECENT CASES OF INSANITY.

The speaker prefaced his address by the statement that he had expected to read his paper before the Section on Psychology, and that had he known that he would be called upon to address an assemblage like the present one, he might have prepared something very different.

(This address will appear in full in the next number of THE MEDICAL NEWS.)

At the close of the address, DR. CORDES, of Geneva, arose and after complimenting the speaker, in French, on the high character of his address, moved a vote of thanks. The motion was seconded by Dr. Kretzmeyer, of New York, who spoke in German, and it was unanimously adopted.

RAILROAD ACCIDENTS.

The SECRETARY-GENERAL then read the following resolutions adopted by the Section on Public and International Hygiene:

Whereas, The whole community has been shocked by the almost daily occurrence of terrible accidents on many of the railroads, causing considerable loss of life, and by the neglect of the most elementary sanitary laws,

Whereas, This Section considers itself in a degree the guardian of public health,

Resolved, That the attention of this Ninth International Medical Congress be respectfully called to this most important question, and that it be requested to use its influence to obtain the necessary reform.

The President then announced that the Congress would meet at 9.30 Saturday morning, for the purpose of a formal adjournment.

Adjourned.

SATURDAY, SEPTEMBER 10TH.

At 9 30 A.M., about one hundred and fifty members and nearly fifty visitors met for the formal closure of the Congress, and a few minutes later, the assemblage was called to order by the President.

MISCELLANEOUS BUSINESS.

SECRETARY GENERAL HAMILTON read by title three sets of resolutions passed in the Sections of yesterday. The first was from the Section of Climatology in regard to the establishing of national bureaus of vital statistics; the second was from the Section of Military and Naval Medicine, and related to the prohibition of the use of explosive projectiles in naval warfare; and the last was a resolution from the Section of Public and International Hygiene, relative to the teaching of hygiene in the public schools.

THANKS AND CONGRATULATIONS.

DR. GRAILY HEWITT, of England, arose and said:

"I come before you as one of the foreign members of the Congress, and I have been requested to express in a few words the appreciation which is felt by the foreign members of this Congress of the efforts which have been made by the executive of the Congress for the furtherance of the object of this meeting, and to convey to them our thanks for the attentions that have been bestowed upon us, and our appreciation of the success which had attended their efforts. I desire also to express our sense of the hospitality, one of kindness and attention which we have received, both in public and private, at this great meeting—attentions which will contribute to make our visit to Washington a source of congratulation and a happy memory in the future. I beg to submit to you the following more formal expression of our ideas." Dr. Hewitt then read the following:

"On the part of the foreign visitors and officers of the Congress, we desire to convey to the President of the United States our best thanks for his presence at the ceremony of the inauguration of this Congress. We desire to express to the Executive Committee of the Congress, particularly to Dr. Henry M. Smith, Dr.

John B. Hamilton, Dr. A. Y. P. Garnett, Dr. Toner, and Dr. Arnold, our very high appreciation of the efforts they have made for efficient organization, action, and working of the Congress, which have rendered it so great a success. We would convey our warmest thanks to the citizens of Washington for the kind hospitality, both public and private, we have received during our pleasant visit to their beautiful city."

Dr. Hewitt's remarks and resolutions were loudly applauded.

DR. MARTIN, of Berlin, then expressed in German the gratitude which he and his fellows from abroad felt toward those having in charge the arrangements of the Congress. He had not come here without some doubts of the success of the Congress, but these had been all removed, and he now felt that it had taken a high rank with former Congresses. The names of the entertainers cannot, like those of the winners at the old Olympic games, be recorded in letters of gold, but we can express our sentiments by a sincere vote of thanks.

DR. LANDOLT, of Paris, next arose, and said in French:

"I have been commissioned to express to the President of the United States our sentiments of profound gratitude. Although feeling that I am unable to find words proper for the occasion, I accepted the honor, since the gratitude that springs from the heart had no need of eloquence to make it understood. Mr. President and gentlemen, we have already assisted at a series of International Congresses. We have been well received everywhere. The countries of Europe have rivalled each other in their zeal to make our stay with them agreeable in their most beautiful cities; but it has not often been our lot to see the chief of the State mingle in person among us and take part in our labors. The President of this great republic came among us to speak us welcome with his sympathetic voice. He invited us to his own home and gave to each of us a hearty grasp of the hand, significant of his most cordial hospitality. The sanction given President Cleveland to our Congress has given the greatest charm to our stay in this capital. Returning to our hearths we will preserve the most grateful and respectful remembrance of the President of the Republic, and we say to the whole world that the United States, already so favored, possesses above everything a chief who directs them surely in the way of progress and prosperity."

DR. EDMUND OWEN, of London, then arose and said he desired to second Dr. Hewitt's resolutions. He thought he was admirably qualified to discourse on American politics, as was entirely ignorant of the subject. In science they had no politics. "We are extremely happy," he said, "to have visited the United States during the presidency of Mr. Cleveland." He said he asked an American friend the other day, and a very intelligent man, if he voted for Mr. Cleveland, and the American said no. Then he asked the American if he were satisfied now, and the laconic answer was, "Guess I am." "If," said Dr. Owen, "that question was put to this meeting, 'are we satisfied?' I say, 'guess we are.'" A great man like the President might have found something else to occupy his attention, say, in the White Mountains about this time of the year; he might have been driven away by the doctors, but instead of that he remained here to welcome them. "When the history of his grand country is written," he said, "we trust President Cleveland will have a niche in the temple of fame side by side with those great men, Lincoln and Garfield. When you are in our country we love to hear you say, 'We admire your queen.' We can say to you with all truth we admire, we love your queen of beauty and grace, and in seconding this vote of thanks we simply express a prayer that Mr. President Cleveland and Mrs. Cleveland may long continue in strength and health to preside over a happy, a prosperous, and a united country."

PRESIDENT DAVIS said that it was hardly necessary to put a question of this character, but in order that it might be recorded, he would do so. The vote was unanimous.

A PRESENTATION.

There was then a pause of a minute, when the SECRETARY-GENERAL arose, and on behalf of the Section of Oral and Dental Surgery, presented to Dr. Hunt, of Washington, a handsome gold-headed cane as a token of the appreciation of his courtesy.

FAREWELL.

After another brief pause, DR. HAMILTON again arose and said:

Mr. President: I could not fail to be deeply sensible of the great kindness bestowed upon me, and the many words of encouragement received both during this present meeting and for the past six months. I am profoundly grateful for the expressions now placed upon record. But, sir, the success of this Congress is due to no one man. All on this side worked with the spirit and enthusiasm of Americans whose hearts were in the work, but all our efforts would have been in vain and the strongest would have failed had it not been for that noble army of scientific men abroad, who, deaf to all misrepresentations of disappointed factionists, came from old England, the universities and vine-clad hills of France, the seats of learning in Germany, the cities of the Alps, from sunny Italy, the lowlands of Holland, the fastness of the Danube, from far-off, but ever-near Russia, from the golden shores of China and Japan, from Cairo and the sands of Egypt, and the everlasting hills of Palestine, and I say to these representatives here assembled, that to them we owe a debt of gratitude which time cannot efface, and as these our dear colleagues have braved the dangers of the deep, and sustained, in some cases, the shock of calumny to be with us, so let us here say that when we again meet in Berlin in 1890, let it be to renew those friendships formed here, and to grasp once more the hands of those who have been true to us now.

DR. DAVIS, the President, then asked indulgence for a few words. After referring to his more than half a century of professional life, he said it had been one of the objects of his life to promote the harmony which should exist among all branches of medicine. It was to-day the happiest feeling of his life that he could now stand here in this Capital of the United States, and not only see the profession he loved united and working harmoniously, but to stand here among representatives from almost every country on the globe. He thanked those who had come across the water to attend the Congress, not only in his own name, but in the name of the profession in America, in whose name the Con-

gress had been invited to sit here. There were, he said, members of the profession from every State in this great Union assembled here to greet the foreign members. There is a larger gathering than there has been in any other Congress, leaving out the profession of the city in which they have been held. He thanked the members of the Congress for the courtesy shown him in sustaining him in the discharge of his duties. "Life with me," he said, "is not long, but if it is spared with sufficient health I shall take great satisfaction in meeting my friend, Dr. Martin, and all his comrades in Berlin in 1890."

He then declared the Ninth International Medical Congress adjourned *sine die*.

SECTIONS.

General Medicine.

WEDNESDAY, SEPTEMBER 7TH.

DR. JOHN A. OCTERLONY, of Louisville, read a paper on the

NATURAL HISTORY OF DISEASE.

He thought that the physician of to-day is too fond of prescribing medicines and not trusting Nature to do its duty. Nature possesses greater powers than we realize, and frequently the question must arise as to whether the patient died of the disease or his doctor. It is not to the discredit of therapeutics that nature is the greater power, it is rather the glory of this branch of medicine that it knows its own limits. As illustrative of his meaning he mentioned the various treatments which have been in vogue for the treatment of pneumonia, and said that the recovery of many of the cases simply showed that even the disease, and the doctor who aided the disease by bad treatment, could not withstand the tendencies of nature to promote a cure. In support of the truth of his theory that nature has such powers he mentioned cases he had seen of external cancer spontaneously cured. He advocated, therefore, to a considerable extent the "let the patient alone" doctrine.

DR. CRONIN, of Buffalo, spoke of the difficulty of leaving the patient alone with Nature, by reason of the distrust of the patient and his friends.

DR. SCOTT, of Cleveland, distinctly believed in the proper use of drugs in every branch of medicine.

DR. A. B. ARNOLD, thought there was a point to be reached halfway between too much medication and too little.

DR. PAVY, of London, supported Dr. Octerlony's views on the non-interference with nature, but did not enter into a discussion of the paper to any length.

DR. T. D. CROTHERS, of Hartford, then read a paper on the

DISEASE OF INEBRIETY AND ITS TREATMENT.

He believed the causes of inebriety to be as follows, namely: Heredity, physical shocks, structural changes of the brain, disturbances of nutrition, and certain acute or chronic diseases which develop into inebriety. Regarding the whole condition as one of an actual disease rather than a depression of moral sense, the author treated the subject from the standpoint of an alienist, and brought forward interesting data to show the limit of his remarks. Examination of records has shown that drunkenness passes over various countries in cycles. Thus, the proportion of drunkenness in Sweden and Norway is markedly increased once in every fourteen or fifteen years, in some other of the European countries in every eight years, and so over the whole world.

The disease inebriety may come on slowly or rapidly and may last or be transient. In some cases it simply remits, in others it comes, and goes never to return.

Statistics show that the number of moderate drinkers is decreasing, while the number of drunkards is increasing. He deprecated the misled efforts of those who advocate a treatment resting on a moral basis, since, as he before stated, inebriety is in reality on the border land of insanity, in many cases the sufferers are monomaniacs indeed.

He also thought that the present methods of treating drunkards in hospitals is wrong, since the food and surroundings of such institutions, and more particularly "reform" schools, is frequently absolutely harmful, in the depressed and perverted state of the inebriate's system, and, instead of placing his body in a healthy condition, leaves it in such a state that it wants more alcohol for support, and fails to bring the brain up to its proper standard.

General Surgery.

WEDNESDAY, SEPTEMBER 7TH.

THE discussion of DR. MACLEAN'S paper on

LAPARO-NEPHROTOMY

(See THE MEDICAL NEWS, September 10th, p. 313)

was first in order.

DR. HERFF, of San Antonio, Texas, agreed with Dr. Maclean that, in suitable cases, laparo-nephrotomy is the proper operation. Some years ago he had a case of a young woman who was newly married, and when about two months pregnant, she discovered a tumor on the right side, which was nearly as large as a child's head. She had no pain, and except that she had this tumor, she was in good health. The tumor, however, annoyed her very much, and she insisted on an operation being done. He, therefore, opened the abdomen in the median line, and removed the tumor. The remarkable thing about the case was that the tumor, which he thought was an ovarian one, proved to be the kidney and suprarenal capsule. From the lower end of the tumor the lower part of the kidney was hanging, while the upper part consisted of the suprarenal capsule enormously enlarged, sections of which presented under the microscope the appearance of the long cells of myrusa. The patient made a good recovery, and two years after the performance of the operation she was in perfect health. This was a case of both removal of the kidney and suprarenal capsule.

DR. HUGHES preferred the abdominal incision in all cases where it is practicable, and, as the result of his experience in these cases, would give the preference to the side, between the ribs and the crest of the ileum.

DR. LANGE, of New York, said that in a large number of these cases of tumors of the kidney, where there is fluctuation they are cases of pyonephrosis of usually very large size. He had operated several times for the removal of the kidney, and performed both the anterior and posterior operations. In the small tumors, and in

some of the larger ones, he preferred to make a small lumbar incision, empty the contents of the tumor out as far as possible, then wait until the remainder of the tumor lessens in size, which it will be very apt to do, so that it can be gotten out through even a very small hole or incision. Sometimes in renal calculi he had performed laparotomy, or rather the operation in the lumbar region, and then, after making this incision, by placing the patients in bed lying on their stomachs on a pillow, the kidney would float up where the wound was made, and could then be easily gotten up, and the calculus removed.

DR. M. H. RICHARDSON, of Boston, next read a paper entitled

GASTROTOMY FOR FOREIGN BODIES IN THE ŒSOPHAGUS,

in which he said that this operation was intended only for the removal of foreign bodies in the œsophagus which had passed so far down the œsophagus as to be lodged near the cardiac orifice. In regard to the length of the incision, it was not fixed; it might be only a very short one, or it might be large enough to put the hand inside the stomach, so as to reach up into the œsophagus, if that should be necessary, in order to extract the foreign body. The incision through the skin should be made over the cardiac end of the stomach, or might be made in the median line, and the incision through the walls of the stomach must be made in the cardiac end of the stomach. All the caution necessary in making this was to get the incision made without wounding the convexity of the lesser curvature of the stomach; and, in order to avoid this, the better way was to put the lesser curvature on the stretch.

He concluded that if the foreign body was lodged within six inches of the lower edge of the cricoid cartilage, it was best removed by an operation from the side or above, but if situated more than six inches from the cricoid cartilage, gastrotomy was the best thing to be done.

DR. F. S. DENNIS, of New York, then read a

REPORT OF AN AMPUTATION AT THE HIP-JOINT FOR THE REMOVAL OF A MALIGNANT GROWTH, SARCOMA.

This case was that of a young man aged seventeen years, who had no bad family history, and who had always been in good health until about five months prior to his admission to the hospital, when his weight was eighty-five pounds. Five months prior to his admission he had first noticed a dull pain in the thigh, and shortly afterward he discovered a swelling in the thigh. He had had no fall or blow.

About two months after the first appearance of the pain the tumor was aspirated, and about ten ounces of bloody fluid drawn off. The swelling was fusiform in shape, the skin was purple, and large veins were to be seen on the surface of the tumor, while the glands of the thigh and groin were much enlarged. The diagnosis was that it was a sarcoma of the femur, and amputation at the hip-joint suggested as the only means of saving life.

This amputation was done and the wound dressed antiseptically. The wound was entirely healed by the sixth or eighth day after the operation. After the patient left the hospital the wound reopened a little and discharged pus mixed with blood; this was found to be due to sloughing of the ligamentum teres, upon the removal of which the wound healed kindly, and the young man is now well.

DR. JASPER C. GARMANY then read a paper on the

SURGICAL TREATMENT OF EPILEPSY BY TREPHINING,

in which he related the case of a girl about eighteen years of age, struck on the head with a brick falling from a house-top and causing fracture of the skull. The skull was trephined and the splinters of bone removed, but some time after the wound had healed she began to have attacks of epilepsy, for which ordinary treatment was unavailing, and he finally operated on her with an entirely successful result. As a result of his researches on the subject he had found that lesions in the frontal and parietal regions are followed usually by the same symptoms, and that over fifty per cent. of the lesions in these regions are followed by epilepsy, which later on is complicated by insanity. Trephining at the site of the lesion and removing the cicatrix is usually followed by complete relief.

DR. SAMUEL BENSON, of London, read a paper on

FISTULA IN ANO OF THE HORSESHOE VARIETY.

Horseshoe fistulæ, as at present understood, are complete fistulæ, the external opening being situated on the opposite side of the bowel to the internal opening. This kind of fistula is rare, having been found five times in 750 cases of rectal disease. From these cases we gather that fistula in ano of the horseshoe shape may be complete or incomplete. Horseshoe fistula may be complicated with prolapsus. The most usual complication is anal ulcer. Sometimes polypus is also found. The average age of the patient is thirty-five years; males and females being attacked indiscriminately. The average number of days in bed is fourteen. If a correct diagnosis is made, the treatment consists in laying open the sinuses and paring the edges with scissors, dividing or paralyzing the sphincter muscle, and packing it systematically with cotton-wool to prevent the edges sticking together, and getting the wound to heal from the bottom.

A paper by ARTHUR TREHERN NORTON, F.R.C.S., of London, was then read by the Secretary in the absence of the author. It was entitled

REMARKS ON RODENT ULCER OF THE RECTUM.

In which the author declared that there is an ulcer of the rectum, persistent, unyielding to treatment, advancing to complete stricture of the rectum and usually appearing after thirty years of age. The ulcer begins immediately within the anus, after a time extending and completely surrounding the rectum; it is accompanied by a pain which is not usually severe and as it extends up the rectum contraction takes place with all the signs of stricture. Treatment by dilatation sometimes relieves for a time. From the clinical features of the disease and the microscopical characters the author was of the opinion that the disease is identical with rodent ulcer and suggested that further investigation into its pathology be made.

DR. GRANT (Bey), of Egypt, then presented a

REPORT OF SOME CASES OF LIVER ABSCESS AND THEIR TREATMENT,

in which he gave the opinion that in all cases of liver abscess we should first aspirate the abscess, and if that was not followed by cure then lay the abscess open by a free incision, and in extreme cases excise a portion of the ribs (one or more) over the site of the abscess, so that free access might be had for cleaning out the abscess cavity thoroughly with antiseptics.

DR. LEWIS H. SAYRE, of New York, then read a paper on

THE TREATMENT OF PSOAS ABSCESS BY POSTERIOR LUMBAR INCISION,

in which he strongly insisted on the early and free posterior and anterior incision in these abscesses and this to be followed by thorough drainage.

DR. EDWARD OWEN, of London, earnestly deprecated "ostrich surgery" in these cases and advised early opening of the abscess with free drainage.

DR. SPRENGLE, of Dresden, thought that in many cases there would be absorption of the pus if we waited for it and if we opened the abscess it was best to do it with an aspirator or fine trocar.

DR. LANGE, spoke of the constitutional treatment along with the surgical, and thought that he would not open these abscesses if he could avoid it until after the acute stage had passed.

DR. CHAVASSE, of Birmingham, England, thought it best to open these abscesses as soon as possible and give the sufferers a chance.

DR. E. ANDREWS, of Chicago, read a paper on

THE REMOVAL OF SEQUESTRA BY SOLUTION IN ACIDS,

in which he gave his experiments in detail and related a number of cases in which the sequestra had been removed by the use of acids without operation. He recommended that hydrochloric acid be used of a strength a little weaker than the officinal dilute acid.

Gynecology.

WEDNESDAY, SEPTEMBER 7TH.

DR. KELLOG, of Michigan, read a paper entitled

UTERINE DISPLACEMENTS CORRECTED BY MODIFICATIONS OF THE ALEXANDER OPERATION, WITH REPORT OF TWENTY CASES.

He still believes in the value of this operation notwithstanding unfavorable criticism. It is not only adapted to cases in which retroflexion alone exists, but also for those in which there is prolapse of the uterus, or of the uterus and ovaries. He believed it safe and effective if properly done, and much more likely to produce a cure than pessaries. The latter seldom result in radical cure, and are usually a source of annoyance and disgust to the wearers of them. It is also preferable to electricity as a remedial agent, though faradization may be employed in conjunction with it. The author had observed particularly the stimulating effect which it often has upon an enlarged uterus, producing great contraction and involution of the organ, as is frequently observed after the performance of Emmet's operation.

DR. A. MARTIN, of Berlin, said he had come to the Congress chiefly for the purpose of obtaining information concerning this operation. Though he was in the habit of seeing a very large number of cases in which displacement of the uterus existed, he had not yet seen a case in which this operation seemed indicated. His position was that which was held by most German gynecologists, for the operation had been done very few times in Germany.

DR. DOLÉRIS, of Paris, France, thought that Alexander's operation had been done only thirty times in France, twenty-four of the operations being his own. He believed that the operation was a logical one for prolapsus and retroflexion. An estimate of its value must be formed from both a technical and a practical standpoint. As to the former, the operation is not difficult, though sometimes rather tedious from difficulty in finding the ligaments and isolating them from surrounding tissues. The operation under antiseptic precautions is perfectly safe, even when the peritoneum is drawn up and stitched into the wound. The operation seemed to him much more satisfactory than the use of the tampon, or the pessary. When prolapsus is complicated with retroflexion, the operation is not indicated.

DR. TRENHOLME, of Montreal, objected to the general use of the operation. He believed it to be difficult, perhaps dangerous, and often ineffective.

DR. BOZEMAN then discussed Dr. Spanton's paper. He had observed as the most frequent causes of cystitis cicatricial contractions of the vagina, flexures of the uterus, and diseases of the urethra. For the first class of cases he had found dilatation of the contracted vagina as well as incision and division of bands useful, the vagina being packed with cotton-wool, while the patient is in the knee-chest position, by his so-called *columning* method. The same plan of treatment is applicable if a flexion causes the cystitis. If the disease arises from trouble in the urethra, as from redundancy of the mucous membrane, Emmet's button-hole operation in the inferior wall of the urethra may be performed, or a large opening may be made in the bladder. This operation of cystotomy was first performed upon the female in this country by the speaker in 1861, though Dr. Willard Parker had previously done it upon the male. The speaker's case was subsequently reported at a meeting of the New York State Medical Society.

DR. BALLS HEADLEY, of Australia, in discussing Dr. Hewitt's paper, advised, with the improvement of the general nutrition, the proper use of pessaries, or, if the organ were very large and the lips of the cervix everted, the performance of Emmet's operation.

DR. HEWITT, in closing, advocated preventive treatment in the way of suitable food and hygiene for those women whom he should consider predisposed to uterine displacement. If this were done, morbid changes in the shape and structure of the organ would not usually occur.

Therapeutics and Materia Medica.

TUESDAY, SEPTEMBER 6TH.

DR. HUGH HAMILTON, of Harrisburg, Pa., opened the Session with a paper on the

CHEMICAL PHILOSOPHY OF REMEDY,

which endeavored to prove that the therapeutist must

have regard for the ptomaines and like substances in treating disease, and use remedies capable of preventing their action.

Dr. J. G. Sinclair Coghill, of the Isle of Wight, followed with an interesting essay on

CHLORATE OF POTASH.

He was of the opinion that this drug has been unjustly and too hastily relegated to an inferior therapeutic position. The original researches of Wöhler and others seemed so unsatisfactory, in view of the undoubted therapeutic activity of the salt, that as far back as 1878 Dr. Coghill arranged a series of observations, the chemical part of which was conducted by Mr. Otto Helmer, F.C.S., with characteristic energy. He verified many of the experiments in his own person, and applied more than one novel process for attaining correctly the quantitative reduction of the chlorate as eliminated. The results were such as only to confirm the views of previous observers. It may be stated, generally, that the therapeutic properties of chlorate of potash are those suggested by its chemical constitution and properties. In all states of the system where the blood is impoverished either in amount or quality, where its nutritive efficiency, especially as regards oxygen, is impaired, the chlorate of potash is indicated, either alone or in such combinations as the complexity of the conditions present demand. In appropriate cases, its action, when judiciously administered in proper doses, will be found most potent. It is also a cardiac stimulant in small doses, and seems to exert an important influence on the nutrition of these tissues generally. Its action as an antiseptic, particularly in arresting chemical decomposition within the body, is to be considered as one of its most valuable properties.

Dr. H. A. Hare, of Philadelphia, called attention to some of the dangers of using chlorate of potash internally, and some of the popular fallacies regarding its action in the human body.

Dr. J. Solis Cohen, of Philadelphia, recommended its use very highly in diphtheria on account of its action on the passages involved. He spoke of the possible dangers under its administration, and thought that the condition of the urine should be constantly and carefully noticed during its administration, the drug being stopped as soon as decreased secretion asserted itself.

Other gentlemen spoke highly of the drug for its influence on all mucous membranes.

Dr. Traill Green, of Easton, Pa., spoke of its usefulness, but preferred chlorate of soda owing to its less irritating and depressing qualities. He also thought its solubility a word in its favor.

Dr. Charles D. F. Phillips, of London, England, then read a paper on the

INFLUENCE OF CERTAIN DRUGS ON THE ACTION OF THE KIDNEY, NOTABLY CAFFEINE.

He described the use of the ordinary oncograph, and detailed interesting results regarding the contraction and dilatation of the kidney under several diuretic drugs. His results with caffeine show that in large or too frequent doses it diminishes the secretion of urine, whereas small doses cause active diuresis.

The Section then adjourned until Wednesday afternoon.

Pathology.

TUESDAY, SEPTEMBER 6TH.

Dr. E. O. Shakespeare, of Philadelphia, reported an

EXPERIMENTAL INVESTIGATION ON THE CAUSE OF TETANUS.

He gave a detailed account of numerous experiments made between August 1st and September 4th of the current year, and offered the following conclusions drawn from these researches:

1. Traumatic tetanus of the horse and mule is at least sometimes, if not always, an infectious disease transmittable to other animals, and, therefore, possibly also to man; and during the progress of this disease a virus is elaborated and multiplied which is capable of producing the same infectious disease in some other animals when placed beneath the dura mater of the cerebrum.

2. This virus is contained in the medulla and spinal cord of the animal suffering the disease. It is capable of being strengthened in virulency by inoculation *sub dura cerebri*, from rabbit to rabbit, like the virus of hydrophobia, and, as in the latter disease, is also capable of attenuation by exposure for a sufficiently long time to the action of dry air at a temperate or summer heat; and, again, like rabic virus, its effects are far more intense when it is inserted *sub dura cerebri* than when injected under the skin or between the muscles of the body.

3. The author reserves his conclusions concerning a prophylactic effect of inoculations of the attenuated virus until the completion of experiments which are at present in progress.

He then drew the following conclusions from his own experiments correlated with those of Nicolaier, Carle and Rattone, Rosenbach, Ferrari, Flügge, and others.

1st. Traumatic tetany of the lower animals and of man, at least sometimes, possibly always, is a specific infectious disease due to the action of a specific infectious virus, which exists in the tissues at the seat of infection, in the blood, and in the central cerebro-spinal nervous system.

2d. In view of the experimental evidence which we possess at present, and of many unassailable observations of surgeons and veterinarians, there seems to be ample warrant for the admission, that not infrequently tetanus in man is acquired directly or indirectly from some of the domestic animals, notably the horse, which surround him.

Drs. D. E. Salmon and Theobald Smith, of the Bureau of Animal Industry of the U. S. Department of Agriculture, presented a report of some

EXPERIMENTS ON THE PRODUCTION OF IMMUNITY BY THE HYPODERMATIC INJECTION OF STERILIZED CULTURES.

The experiments were carried out as follows: Culture tubes containing about 10 c.c. of beef infusion 1 per cent. peptone, were inoculated with hog-cholera bacteria and placed in the incubator at 93.2° to 96.8° F. After a certain number of days, varying from three to ten, the tubes were exposed to a temperature of 136.4° to 140° F., for about one hour. Inoculation of fresh tubes showed that the bacteria had been destroyed. This test was always resorted to, to make sure that no living bacteria

were injected. From 1 to 1.5 c.c. of this culture liquid was injected with a hypodermatic syringe beneath the skin of one pectoral muscle. This injection was repeated once or twice. Some days after the last injection, the bird was inoculated with living bacteria. About ¾ c.c. of a beef infusion peptone culture was injected beneath the skin of the other pectoral or into the superficial layer of muscular fibres. The vaccinated pigeons remained alive and well, the control pigeons nearly all died.

The conclusions drawn from these experiments were as follows: The birds are protected by the injection of sterilized cultures so as to resist a fatal dose of living bacteria. The sterilized cultures contain only the products of bacterial growth. Among these the ptomaine-like bodies—some of which we now know owing to the researches of Brieger, are very likely the agents that produce immunity.

Diseases of Children.

TUESDAY, SEPTEMBER 6TH.

DR. VICTOR C. VAUGHAN, of Michigan, read a very interesting paper on

THE USE OF COW'S MILK IN THE FEEDING OF INFANTS.

He pointed out the necessity of resorting to cow's milk; the care of milk used in infant feeding; the fermentations that occur in milk; the development of poisons in milk, such as tyrotoxicon; the preservation of milk; the chemical differences between the milk of woman and that of the cow; and the proper use of prepared milk foods.

In regard to the use of digestive ferments in cow's milk, he thought that in strong children they need not be given, that in weak children they must be used, but only partially, since all the work must not be taken from the stomach, which in that case would soon loose its power.

In reply to an inquiry, whether he preferred to use milk from a herd or from a single cow, he replied that the milk from the herd is perhaps the best. He called attention to the fact, however, that one diseased cow's milk would, in the course of a few hours, change that of the whole herd into an equally poisonous mass.

DR. BOOKER, of Baltimore, advocated sterilization by heat, before using milk obtained in cities.

DR. J. LEWIS SMITH, of New York, asked Dr. Vaughan his opinion in regard to the use of farinaceous matters in cow's milk to prevent too solid clotting of the casein.

DR. VAUGHAN expressed himself as unable to make any reply to this question. He believed that cholera infantum is probably, in many cases, due solely to the presence of tyrotoxicon, developed either before or after the introduction of the milk into the stomach. He detailed experiments on cats, in which, after the administration of the poison, symptoms closely resembling those of cholera infantum asserted themselves.

DR. W. P. NORTHRUP, of New York, read a paper on the

ANATOMICAL CHARACTERISTICS OF MEMBRANOUS CROUP AS OBSERVED IN FATAL CASES IN THE NEW YORK FOUNDLING ASYLUM.

He analyzed a series of cases observed post-mortem in the Asylum, with reference to the onset of the affection and the location of the membrane. The cases cover a period of five years. The greatest mortality was between two and three years, at which age 36 died out of 90 cases. Most of the cases showed an extension of the membrane into the bronchi. Autopsies in intubated cases showed only a rubbing off of the epithelium of the surface. In some cases the wearing of the tube for two or three days caused ulceration of the mucous membrane opposite the lower end of the tube, in some cases even the cartilages being affected. The ulceration is due to frequent friction and intermittent pressure due to swallowing. Some cases died from pulmonary collapse because of bronchial occlusion. Sometimes death was due to pneumonia caused by an extension of the inflammation by continuity. The best test for diagnosis of pneumonia post-mortem is to attempt inflation of the affected tissue; if it inflates, collapse is indicated; whereas, if it remains solid there can be no doubt of pneumonia. He did not believe that septic pneumonia was occasioned by the use of the O'Dwyer tube. He experimented with milk and bone charcoal, causing intubated patients to swallow these and finding no evidence of either in the lungs of the cases that died. This shows that there is little or no probability of producing living inflammation by food falling through the tube into the trachea and producing pneumonia. He summarizes his views as follows:

The cases here studied are 116 in number, 90 of which were sporadic and 26 epidemic. They all occurred in the New York Foundling Asylum, an institution which has the constant care of 1800 children from the ages of a few weeks to five and seven years.

2. In the sporadic cases, the larger, great tube of O'Dwyer caused no ulceration worthy of consideration.

3. In the epidemic cases, numbering 26, there were 5 serious ulcers.

4. The causes of death have been mostly extension of pseudo-membrane to the bronchi and pneumonia.

5. He had been able to find *no* evidence that milk or other foreign material has found its way into the lungs. The pneumonia is broncho-pneumonia and not "schluck-pneumonie."

DR. JOSEPH O'DWYER, of New York, then made some remarks on

INTUBATION OF THE LARYNX.

He began his experiments, he said, with intubation in 1880. He was induced to devise his tube because of the prejudice against tracheotomy at the institution with which he was connected, and the inability of the staff to present a single tracheotomized case that had recovered. "Like hundreds of others before," he at first used the flexible catheter and gradually shortened it for convenience and comfort to the patient. An essential principle in making them self-reta ning is to have them larger below than at the glottis. He then exhibited the tubes, and showed how to introduce them. A large, tightly fitting tube will be self-retaining because of firm and equal pressure from all sides. It was by using such a tube that Bouchut had no trouble in its insertion. The same kind of a tube, because of the great pressure it exerts on the surrounding parts, gave Trousseau the only reason founded in fact, that could be adduced

against intubation. The small tube formerly used is objectionable for two reasons: one being the danger of its slipping into the trachea, and the other from overlapping of the upper end of the tube by the swollen mucous membrane. The present tube with the large shoulder prevented both these accidents. The advantage of the backward curve on the lower end of the tube, is to prevent the ulcerations found at the base of the epiglottis, which straight tubes have been known to cause.

He favors small tubes. When first seen they are supposed to be too small to allow of comfortable respiration. They are, however, ample. The objection to the large tubes is the danger of ulceration from pressure. He steadily reduced the antero-posterior diameter of the tube to the present size, until he no longer noticed laryngeal ulceration as a sequel of its use. It is not necessary, for comfortable breathing during rest, to have the respiratory channel as wide as it is normally found. He spoke of the mechanism of cough and the necessity for closure of the glottis and compression of the intrapulmonary air before its expulsion, so as to give it force enough to produce sufficient friction to carry away the material on the surface of the bronchial mucous membrane. Coughing or nose-blowing is impossible, unless preceded by closure of the glottis. In case of dyspnœa in an intubated case, removal and reinsertion of the same tube give marked relief, and if a larger tube is inserted credit for the relief is awarded to the larger tube. This is evidently incorrect. There are still two very serious defects to be overcome in intubation: 1st, difficulty in swallowing food, and 2d, difficulty in the elimination of membrane.

When established, perfected, and matured, this operation will remain unsatisfactory, from the complications and very nature of the disease itself. The first results, if good, will create enthusiasm; if bad, distrust.

He showed three instruments made for the extraction of false membrane, but has only tried one and that on the cadaver of a child. His was made on the principle of Otis' urethrometer. On introducing the tube it is important to have it so firmly attached to the introducer as to make them appear as a single unjointed instrument. He has never developed as much enthusiasm for the operation as others have. Thinks better results have been obtained by the conjoined use of the bichloride of mercury and intubation, than by intubation alone. The best results on record were obtained by Dr. Frank Huber, of New York, in this way. This paper was read on June 7, 1887, before the New York Academy of Medicine.

Intubation is better than tracheotomy because it avoids cutting, and can, therefore, be earlier and more frequently performed and thus save more lives.

Dr. F. E. Waxham, of Chicago, then read a paper on

INTUBATION VERSUS TRACHEOTOMY IN THE TREATMENT OF CROUP.

Modified and new intubation instruments were exhibited in connection with this paper. A laryngeal dilator composed of diverging blades or bent scissors shanks was shown and has been successfully employed to dilate the glottis temporarily in place of the tube. An automatic rubber epiglottic attachment was shown attached to one of the tubes. A statistical table of operators, number of operations, and number of successes and failures was read in detail. Out of a total of 1007 cases 269 recoveries had taken place.

Dr. C. G. Jennings, of Detroit, said his experience had been the reverse of that of the readers of the papers. Has performed 37 primary and 3 secondary tracheotomies. 26 of the 37 primary recovered. He had had 9 intubations and all have died. Of the 3 secondary operations after intubation, all died. He was compelled to favor tracheotomy in preference to intubation, yet he was forced to admit that Dr. Waxham's statistics spoke better for intubation than they did for tracheotomy.

In tracheotomy there is the advantage of having direct access to the diseased locality. In intubation this is not so. Deglutition is easier after tracheotomy than after intubation. Tracheotomy is particularly successful in those cases in which it is performed toward the end of the disease, and where the membrane has extended into the larynx. He has found after treatment in intubation cases fully as arduous as after tracheotomy.

Dr. J. Lewis Smith, of New York, asked if all of Dr. Jennings' intubation cases had been relieved promptly of their dyspnœa.

Dr. Jennings said they had with two exceptions.

Dr. Smith asked if intubation did not allow more time for tracheotomy.

Dr. Jennings replied that he thought it had to precede tracheotomy with the use of the tube.

Dr. W. P. Northrup, of New York, said that in 33 cases he never had any trouble whatever. One of his cases that had the most trouble of all in swallowing, recovered, while some of those that died could swallow perfectly. He thought that the interference with deglutition is the only drawback to intubation.

Dr. T. J. Pitner, of Jacksonville, Ill., though a believer in the operation of intubation, did not think Dr. Waxham justified in saying that all of those that recovered by this means according to some of his statistics would otherwise certainly have died. That was something no man could say.

(To be concluded.)

AMERICAN GYNECOLOGICAL SOCIETY.

Twelfth Annual Meeting, held at New York, September 13, 14, and 15, 1887.

(Specially reported for The Medical News.)

First Day, September 13th.

Morning Session.

The Society was called to order at 10.30 by the President, Dr. A. J. C. Skene, of Brooklyn.

Thirty-one Fellows were present, and about fifty invited guests, among whom were Doctors Ferrier, Doléris, and Apostoli, of Paris; Dr. Grant Bey, of Cairo, Egypt; Dr. Bauga, of Bombay; Drs. Graily Hewitt and Bantock, of London, England; Dr. Simpson, of Edinburg; Dr. Martin, of Berlin, and Dr. Cordes, of Geneva, Switzerland.

Dr. Fordyce Barker, of New York, made the following

ADDRESS OF WELCOME.

Mr. President, Fellows of the American Gynecological Society, and friends who honor us with their presence:

The pleasing duty has been assigned to me by our Committee of Arrangements to welcome you in behalf of the resident Fellows of New York and Brooklyn, and in behalf of the Academy of Medicine, and of our affiliated societies having the same aims and objects.

I feel warranted in referring to the success of our Society in one of its aspects. It has brought its Fellows into intimate relations of warm personal regard. It has made us acquainted with, not only the mental calibre and acquirements of our Associate Fellows, but it has made us to know their winning and lovable personal qualities.

Our discussions have not been wanting in sharp criticisms or freedom in pointing out supposed errors in the statement of facts—or absurdities in reasoning—or fallacies in deduction—or the futility or danger of suggested plans of practice or operation. But not in a single instance that I have known has there appeared in our discussions anything bearing the semblance of personal rancor, of the sting of venom, or a desire to wound, or of an ignoble ambition to triumph by sharp personal repartee, but the courtesies of debate have always been maintained on a high level. Neither has the time of our meetings been wasted in listening to profitless and wearisome discussions of personal claims to priority. All of our Fellows seem wisely to have decided in their own minds, that their present and posthumous reputation will rest on the aggregate of good work they accomplish, and not on the single merit of being the first to suggest a plan of treatment or a special operation. All know that now claims to priority of whatever nature are sure to be contested, and possibly to be confuted at no very remote period, although perhaps after the claimant "has joined the majority," and is no longer able to defend or explain his claim. If by referring to these merits, I lay myself open to the charge of assuming that the American Gynecological Society is made up of gentlemen, I confess to the justice of the charge, and shall "die impenitent," appealing to the record of our discussions in the ten volumes of its transactions in proof of the validity of my assertions.

As modesty is well known to be our most prominent national characteristic, I have felt justified in saying this much, in order that our distinguished foreign guests who have honored us by accepting our invitations, and have come more than three thousand miles to do so, may better know the company they are to meet. To them I will say, many of you are well known to many of us personally. All of you are well known to all of us by the good work that you have done. We give you a warm welcome, with the anticipation that the interest of this meeting will be largely enhanced by your participation in its work. We hope that you will find our hospitalities acceptable and agreeable, and we feel assured that you will leave behind you a warm place in our hearts, which will bind us in as close affinity in our personal affections as we now are united in sympathy in our professional work.

We welcome also our friends of this city and from other parts of the country, whose interest in the subjects to which we are devoted, brings them here to watch our proceedings and to stimulate us to our best efforts. Your presence serves to imply a knowledge through the medium of our published *Transactions* of the work which the Society has done before, and an approval of it. We trust that your interest will be increased by this meeting.

DR. THOMAS ADDIS EMMET, of New York, then read a paper entitled

A STUDY OF THE CAUSES AND TREATMENT OF UTERINE DISPLACEMENTS.

He stated that he had long before pointed out that in every woman there was a "health line," or normal plane for the uterus; as long as the organ occupied that plane the circulation was unimpeded and the veins did not become over-distended. The disturbance due to prolapse of the uterus might also be produced by lifting the organ above the health line. Both ante- and retroversion, not due to inflammatory processes, might be unaccompanied by marked discomfort—in fact, a retroversion pessary with a long posterior curve, while it actually increased the anterior displacement, gave relief simply because it elevated the cervix to a higher plane. In short, the suffering in cases of displacement was not due to the displacement itself, but to extraneous causes, especially to periuterine inflammation. Whether the uterus was raised or lowered in the pelvis in consequence of the cicatricial contraction following inflammatory processes, the traction was always exerted at the only fixed point—*i. e.*, the neck of the bladder, whence the frequent desire to urinate. Prolapse was the usual displacement because of the increased weight of the uterus resulting from the impeded circulation.

Since the Fallopian tubes were attached to the fundus uteri at a higher point than the attachment of the broad ligament to the side of the pelvis, an inflammation confined to the peritoneum covering the tube would shorten the line and thus depress the uterus in the pelvis; if the inflammation extends from below upward the reverse would be the case, *i. e.*, the resulting adhesions would tend to elevate the organ. An inflammation of the connective tissue between the folds of the ligaments would result in destruction of that tissue, and extending to the peritoneum forming Douglas's pouch, would form adhesions which would raise the uterus; as the folds of the ligament on one side became separated, the organ would be drawn to that side, thus causing a lateroversion. If, on the other hand, the peritoneal covering alone was involved, prolapse and retroversion would result. Inflammation confined chiefly to the peritoneal covering of the utero-sacral ligaments, caused elevation of the cervix and anteversion.

In retro-displacement, the fundus was usually movable and could be replaced with the finger; after restoring the uterus to its supposed normal position, the operator would be able to feel a pulsating vessel, which showed that the circulation was obstructed in consequence of the adherent peritoneal surfaces and vessels being put on the stretch. If now a sharply curved pessary was introduced, there would soon be so much pain that it would be necessary to remove it; but if an instrument with a moderate curve was used, which simply corrected the prolapse, it could be worn longer, and would relieve the traction on the neck of the bladder, but in the end both pessaries would certainly cause peritonitis if allowed to remain long *in situ*.

In anteversion, from inflammatory shortening of the utero-sacral folds, we might indeed relieve the patient by means of a retroversion pessary which corrected the prolapse, but here, too, fresh inflammation would be the consequence of prolonged pressure on the affected liga-

ments. What then was the general practitioner to do? It was better not to attempt to correct the displacement, but to be content with hot water injections and the application of iodine and glycerine pads. Such cases were better treated in a hospital.

He then called attention to the peculiarities of the pelvic circulation, and to the fact that traction on the tortuous veins sufficient to straighten them results in dilatation of these vessels. Artificial traction on a healthy uterus causes an obstruction of the circulation; when the uterus is entirely procident, compensatory dilatation of the veins occurs. The arteries also lose their tone in consequence of extreme traction, and their calibre becomes diminished, thus relieving the over-distended veins. The pelvic connective tissue supports the vessels; a local peritonitis, by exerting undue traction on the connective tissue at one point, impairs its elasticity at another, and thus weakens the vascular support. He referred, in this connection, to so-called laceration of the perineum; the pelvic fascia is so injured that the vessels lose their proper support by reason of the general relaxation of the connective tissue. No operation on the perineum can give relief unless the normal tension is restored.

The object to be aimed at in fitting a pessary is to give just enough support to the over-stretched connective tissue to relieve the obstruction to the circulation. If a non-adherent uterus is replaced and the fascia is sufficiently supported, the natural elasticity of the periuterine tissues will keep the organ in position. He is accustomed to introduce a few cotton pledgets, simply to elevate the uterus to its normal plane, and thus to relieve the congestion; but he disapproved of the practice of introducing a large quantity of cotton, with the patient in the knee-chest position, since this is more likely to increase the existing irritation.

He stated in conclusion that, although he had pointed out the limited range of usefulness of pessaries, he is anxious that his views should not be misrepresented. In suitable cases nothing can take their place, but they should not be used without a clear understanding of just what they are intended to accomplish. A displacement of the uterus is rather to be regarded as a *symptom*, the cause of which must always be sought for. If this is done in every case, much less harm will result from the ignorant use of pessaries. Gynecologists were too apt to omit to search for evidences of pelvic inflammation, and to use the sound recklessly to correct a displacement, when the uterus can be replaced just as well with the finger.

DR. GRAILY HEWITT, of London, on being invited to discuss the paper, said that the subject of uterine displacement had occupied his attention for several years. He agreed with the spirit of Dr. Emmet's paper, but it seemed to him that there must be some difference between English and American women with regard to the relative frequency of pelvic cellulitis in cases of displacement. He had not detected it in many of his own cases, or else he had overlooked it. With reference to the causes of displacement, he thought that the reader had given a limited view of the matter, since he had touched on inflammatory causes only; but he inferred from the latter's book that he believed in the existence of others. Dr. Hewitt thought that the general causes were highly important, especially with regard to the prophylactic treatment of uterine affections. Dr. Emmet had explained the sufferings of patients as due mostly to the pelvic inflammation. He thought that an important fact was the influence of flexions as causing obstruction to the circulation, and hence pressure on the nerves. The mere straightening of the uterus relieved the patient, perhaps more than the elevation of the organ. The speaker had met with cases of flexion in which there was extreme sensitiveness at the region of the os internum, and this pain was removed on straightening the uterus with the sound. It must be that the relief was due to the removal of the flexion. The speaker agreed with Dr. Emmet as to the unjustifiability of using pessaries when there was acute inflammation; but, when old indurations were present they might be valuable in removing such exudations. No man should use pessaries unless he thoroughly understands them. It was necessary to be familiar with the past history of the patient, as well as with the present local condition, before good could be done with these instruments.

PROFESSOR SIMPSON, of Edinburgh, said that the question of uterine displacement was especially interesting to teachers of gynecology. Dr. Hewitt had said that American and English women differed as regards the frequency of pelvic inflammation. The speaker differed from him, he believed that the diagnosis of gynecologists was modified by their individual opinions, since one man found inflammation very often, and another seldom. Dr. Emmet had taken a limited view of uterine displacements, since his paper dealt only with the condition in women who had borne children. Many sterile women had displacements. Pain was not the only symptom. In many cases it was necessary to replace the uterus in order to favor impregnation. We must not forget that in a certain class of cases no history of inflammation could be found. There seemed to be a growing disposition to abandon pessaries entirely; but, at the same time, even those who decried them, had certain cases in which they could not dispense with them.

DR. HEWITT explained that he did not express any positive opinions as to the difference between English and American women.

DR. BANTOCK, of London, said that he had been deeply interested in the paper, but he did not agree with the reader as to the frequency of pelvic inflammation. He thought that, as Dr. Simpson had said, a good deal depended upon the personal bias of the examiner. It had been shown that many cases of supposed pelvic cellulitis were really cases of salpingitis and peritonitis. The speaker was pleased to find that Dr. Emmet did not reject the use of pessaries. There was no advantage in trying to find out the exact cause of a uterine displacement; the patient wished to be relieved of her symptom, and in most cases this could be done by the *proper* adjustment of a pessary. Many men who used pessaries did not understand how to adjust them. In retroversion, following childbirth, no other instrument was necessary except the introduction of a pessary. The speaker always replaced the uterus with a sound, unless the organ was very tender, when it was necessary to relieve the inflammation first. When it was adherent, the pessary would not only be useless, but even injurious.

DR. EMMETT closed the discussion by saying that he

had not intended to disregard the ordinary causes of displacement, but only to discuss one which was little recognized. The failure to recognize cellulitis was due to the fact that patients were not examined by the rectum. He said that he had used the word "honest" purposely. He believed that many men used pessaries in this country who did not understand them and did more harm than good. No man used pessaries more than he did, but it was important to be able to distinguish cases which were unfit for them. He believed that there *was* more pelvic inflammation here than there was abroad. This was due to the fact that young women in America went into society earlier and were more exposed. Pelvic peritonitis was very frequent in young women and led directly to sterility. Displacements were common in young married females and often corrected themselves under the use of hot injections alone.

Dr. Samuel C. Busey, of Washington, read a paper on

CYSTOKOLPOCELE, COMPLICATING LABOR AND PREGNANCY.

Cystokolpocele, or prolapse of the bladder, might be partial or complete, the latter blocked up the vaginal outlet. The size of the tumor depended more or less on the amount of urine in the bladder. Little attention had been given to this condition as a complication of labor. The literature was very scanty, only six cases of cystokolpocele complicating pregnancy having been reported in detail; one of these had occurred in the practice of the author.

He was called to attend a patient advanced in pregnancy and on making a vaginal examination was unable to find the cervix, the fingers entering a large, soft, blind pouch. The woman had not passed any urine since the previous day. On emptying the bladder, the tumor disappeared. The true condition ought to be sus ected when there is dulness over the suprapubic region associated with the presence of a soft fluctuating tumor in the vagina, which disappears on emptying the bladder. Cases of cystokolpocele complicating labor were more numerous, the reader having collected thirty-five. The first stage was rendered long and painful, exhausting the patient. Errors in diagnosis are frequent. The bladder has been tapped under the supposition that it was a hydrocephalic head, and the bag of waters.

The etiology of the condition was mainly multiparity. The relaxation of the pelvic viscera led to vesical prolapse, but there must be some other cause. Hard work, muscular effort, etc., were active factors. Pendulous abdomen, relaxation of the vaginal canal, and retention of urine should also be mentioned. In a few instances cystocele had existed before pregnancy. Contraction of the pelvis had been mentioned as a possible cause. Lingering labor was the principal symptom, the pains being sharp and frequent, but ineffectual, the pain being referred to the bottom of the stomach. Straining and tenesmus characterized the pain, as distinguished from ordinary labor-pains. There was usually a frequent desire to urinate. There might be no enlargement above the pubes. As labor advanced, the patient experienced severe pain and dragging sensations in the lower part of the vagina. On making a vaginal examination, a soft, fluctuating, tender tumor was felt in the anterior vaginal wall, which became relaxed during the interval between the pains. Sometimes the os could be felt above the tumor. In lateral displacement a tumor would be felt on the lateral wall of the vagina, which would not block up the entire canal. The cystocele might assume an hour-glass shape, when the diagnosis was often difficult. Discharge of the contents of the tumor through the urethra was the only positive evidence of its character. The cystocele might refill during the labor.

The condition was to be distinguished from the amniotic sac, a hydrocephalic head, pyokolpocele, vaginal cysts, and ovarian cysts. Evacuation of the bladder by means of a soft catheter at once reduced the obstacle to delivery. It might be necessary to elevate the cystocele with the finger. No special treatment was necessary after delivery.

Dr. Goodell, of Philadelphia, said that he had met with two cases of cystokolpocele, one before and one during labor. He was completely deceived in the first instance, thinking that he felt the child's head, and that labor was in progress. There was severe vesical tenesmus, resembling uterine pains. On making a second examination the os uteri could not be reached, and the diagnosis was then clear. The bladder was rapidly emptied.

In the second case the pain was very severe, and the tumor was so large as to obstruct the passage of the head. It was impossible to pass the catheter until the head had been elevated by means of forceps. The speaker believed that in these cases there was some contraction of the pelvis, so that the sacral portion of the head was arrested, and the pubic portion, revolving with each pain, carried the bladder down before it.

Afternoon Session.

Dr. William M. Polk, of New York, read a paper entitled

ARE THE TUBES AND OVARIES TO BE SACRIFICED IN ALL CASES OF SALPINGITIS?

Salpingitis is to be defined, he said, as "the disorder whose most marked clinical expression is found to be those periuterine inflammatory masses so commonly met with when palpating the pelvic contents, which, until recently, were regarded as the sign manual of cellulitis." It is the affection heretofore treated as an inflammation of the periuterine cellular tissue. The inflammation is similar to that in the pleura, and results in either a serous exudation, which is absorbed, sometimes leaving slight adhesions, a sero-fibrinous exudation, which leaves numerous firm adhesions; or, finally, a collection of pus. The ultimate results of this salpingitis are determined by the strength and distribution of the resulting adhesions; if these are slight, the damage is slight. Displacement and imprisonment of the uterus and its appendages is the most important result whereby their functions are impaired.

The changes in the tube are endo- and peri-salpingitis, with resulting pyo-, hydro-, and hæmato-salpinx; while in the uterus there may be simply chronic endometritis or areolar hyperplasia. The ovaries, if buried in adhesions, may present interstitial changes, which finally lead to atrophy. But the ordinary form of salpingitis

maims, rather than destroys, the tubes, the maiming being due not so much to the primary disease as to the resulting adhesions.

The clinical evidences are those of localized peritonitis, which are followed by special symptoms resulting from the impairment of function in the organs involved.

These statements, the reader added, were based upon observations made both at the bedside and in the dead-house. In fifty cases, after making a careful physical examination, the abdomen was opened and the pelvis was then examined both from above and below, one finger being within the abdominal cavity and the other in the vagina. In fifty other cases the pelvis of the living subject was carefully examined, and then the results in the two series were compared, when it was shown that the local condition in both corresponded to the same disease—in short, the condition was that described in text-books as "pelvic cellulitis and peritonitis."

As regards the prognosis of salpingitis, it may be said that the majority of the cases recover, the death-rate being small in non-puerperal cases. Of course, recovery means restoration of health, not necessarily restoration of the function of the affected organs.

It was formerly said, that a woman with pyosalpinx was in danger of her life; but no distinction was made between the slighter and more serious cases. A year ago he would have performed laparotomy in all these cases. Since then he had met with numbers of specimens in which the *adhesions* were the principal trouble. The principal symptom was severe pelvic pain or dysmenorrhœa; recurrent peritonitis was not particularly frequent. It seemed as if the adhesions were the principal cause of the suffering, and that the pain might be relieved by freeing the adhesions. These might re-form, but if the uterus and appendages were so altered as to separate the ends of the adhesions, Alexander's operation has accomplished this result in the hands of the reader. Is it wise to leave an occluded tube without removing it? In certain cases this can be done. The reader had operated eight times, breaking up the adhesions around the displaced uterus and appendages, and restoring the organs to their normal position, where they were kept by shortening the round ligament.

In conclusion, the author said that he did not deny the value of the removal of the tubes and ovaries in proper cases, but he would confine the operation within narrow limits.

Dr. Martin, of Berlin, said that he was pleased to see that the reader spoke of salpingitis generally as inflammation of the tube. Ten years ago, the speaker had called attention to the different forms of inflammation of the tube. The tube was rarely the seat of neoplasms. Carcinoma was rare, probably because of the absence of glands. Simple catarrh, being most frequent in the uterus, was also the most common inflammation in the tube. Recently micrococci had been found in the tube; gonococci were rarely discovered. Tuberculosis, as was shown by Hegar, was occasionally present. In general, the inflammations of the tube could be regarded as innocent; occlusion or adhesion to surrounding parts occurring early; but in only a small number of cases did the inflammation become general. Out of a large number of cases of salpingitis, the speaker had found it necessary to operate in only a small minority. Only after a long course of anti-inflammatory treatment should we resort to an operation. Among eighty operations he had rarely found that the principal trouble was in the tubes. He was accustomed to puncture the tube in every instance before removing it, so as to prevent the contents from entering the cavity.

Dr. Barker said that he was deeply interested in Dr. Martin's reference to the good results of general treatment. In reply to a question from the last speaker, Dr. Martin said that in cases of acute inflammation he used ice-bags on the abdomen, with opium to relieve the pain. In chronic cases he applied iodine and peat-compresses. The general health was cared for, and massage was employed. Great care must be exercised not to set up fresh inflammation.

Dr. Emmet said that he had always taught that in the majority of these cases the patient should have all the benefit of palliative treatment before an operation was performed.

Dr. Goodell said that he agreed substantially with the speakers. He was accustomed to resort to general treatment before operating. He did not understand how a collection of pus could be dispelled, even if a catarrhal inflammation could. He believed in Dr. Polk's pathological teachings, but he thought that his treatment was too heroic. After opening the abdomen, and liberating the ovaries and tubes, why not remove them, instead of trying any experiment? The patient could not become pregnant, and her instincts would not be removed by removing the organs. The speaker had thought long and anxiously on the subject. He often had gratifying results from the rest-treatment; but, on the other hand, he had been compelled to operate often against his will. He confessed that he could not tell what constituted exactly enough disease in an ovary to warrant its removal.

Dr. Bantock said that his views coincided with those of Dr. Martin. He had come to the conclusion that ordinary cases of catarrhal salpingitis did not require operative treatment. But in pyosalpinx an operation would be necessary, sooner or later; even the latter cases might be cured spontaneously. The patient's symptoms were generally due to the surrounding peritonitis. Death was seldom due to rupture of a pyosalpinx. Hæmatosalpinx was more serious than pyosalpinx. The speaker had come to be very cautious in removing the ovaries, since, in several instances, he had seen pregnancy occur in women whose organs were apparently hopelessly diseased. He did not approve of Dr. Polk's operation, since, if adhesions had once been formed, there was no reason to think that they would not reform. If the appendages were so buried in adhesions, they were probably so much diseased that they ought to be removed. In reply to a question as to his method of general treatment, Dr. Bantock said that during the acute stage of inflammation he kept the patient absolutely quiet, administered hot douches, and gave opium.

Dr. Sutton, of Pittsburg, said that the subject of tubal pathology was still *sub judice*. He thought that if we laid down the rule only to operate when there was a tumor we should certainly neglect cases in which an operation was urgently needed. If pus was present in a tube, that tube should be extirpated just as an abscess anywhere else in the body ought to be incised. How

many abnormal conditions of the tubes and ovaries would be cured spontaneously we could not tell. We must take into account the entire condition of the patient. We could not say what the result of an operation would be until months had elapsed. If the patient suffered from the presence of an ovary and tube, what was the use of leaving it? It is not necessary to discover just what the disease was; if the patient was cured, that was the main thing.

Dr. Emmet thought that in many of these cases the trouble was really due to anæmia and general depression. The woman was better after removal of the appendages, but it was due to the fact that the menopause was induced. It was a reflection on the profession to think that we must remove the ovaries in order to cure anæmia.

Dr. Wylie, of New York, said that he did not dread cases of salpingitis as he did seven years before, when he first began to operate. He selected his cases carefully, not operating in more than one out of ten. He had not ventured to perform the operation described by the reader, although in two instances he had opened the abdomen and simply broken up adhesions, since the appendages were not diseased. Constitutional treatment was not enough in these cases.

Dr. Polk closed the discussion with the remark that he had not desired to give prominence to the question of laparotomy, but to that of *mutilation*. Women had a right to retain organs which did them no harm. The main point in his paper was that the tubes and ovaries were crippled by adhesions, and were not functionally useless. He did not oppose extirpation of the organs in proper cases, but it was important to discover some way in which women could be spared if possible. None of his patients had died after the operation, so that the question of safety could not come in. Nor did the performance of Alexander's operation, in addition to the laparotomy, entail any extra risk. Every woman had the right to take the chance of saving her ovaries.

Dr. Paul F. Mundé, of New York, then read a paper entitled

DRAINAGE AFTER LAPAROTOMY.

He made the prefatory statement that, while general surgeons were unanimous with regard to the advisability of draining secreting cavities, he was surprised to find on reviewing the literature of the subject, as well as by reference to his observation of operations performed by prominent European laparotomists, how widely diverse were the views as to the necessity of abdominal drainage after the removal of adherent tumors. Some operators invariably used a drainage-tube in such cases, while others, who obtained just as good results, rarely or never employed one; among the latter were Olshausen, Martin, and Tait. Hegar omitted drainage except in cases of extensive oozing or exudation, where a quantity of septic fluid escaped into the peritoneal cavity, or when it was probable that ligated adhesions or cyst-remains might become gangrenous. Olshausen was strongly opposed to drainage, considering it directly responsible for septicæmia, tedious convalescence, and subsequent abdominal fistulæ. He, himself, had seen excellent results in Martin's clinic in cases of extensive adhesion when the tube was dispensed with. Referring to his own experience, he said that he had employed drainage in twenty-three out of sixty laparotomies, with twelve deaths, while of the other thirty-seven, in which no tube was used, only three died.

The following questions were proposed for discussion:

1. In what class of cases does drainage seem to be theoretically necessary?

2. What are its advantages, and what its dangers and disadvantages?

3. What form of drainage is the best and least dangerous?

4. What substitute can be offered for drainage, or how can the necessity for its employment be averted?

The original object aimed at by Dr. E. R. Peaslee, who first introduced the use of glass tubes after laparotomy, was to favor the escape of blood and serum from the abdominal cavity; this purpose was still effected, but practically we find at the present day that it is not always necessary to remove the exudation, which is most apt to accumulate in cases where extensive adhesions have been separated. If by our modern antiseptic methods this fluid can be rendered innocuous, drainage may be dispensed with, since the peritoneum is able to absorb it without injury to the general system. However, as long as there remains any doubt as to the aseptic character of the fluid, drainage is indicated, at least theoretically.

Concerning the justifiability of drainage, there could be no question that it was criminal negligence to allow septic fluid to remain within the peritoneal cavity, when it could be removed. In considering the dangers we must bear in mind how much more serious a matter it is to drain the peritoneal cavity than an ordinary surgical wound. It is true that a wall of lymph was easily formed around the tube, thus separating it from the surrounding intestines and protecting the latter against external influences, but there was ample time for septic infection before this protecting lymph was thrown out. It could not be denied that the presence of the tube prevented the perfect closure of the abdominal wound, and thus added to the danger. He had often been glad that he had introduced a tube, because of the quantity of bloody serum that escaped soon after the operation; but might not this fluid have been innocuous if it had remained? Was not the danger from its presence more than counterbalanced by the added risks of septic infection, traumatic peritonitis, and subsequent intestinal adhesions entailed by the presence of the tube, as well as the alarm and annoyance caused to the patient from the frequent removal of the accumulated fluid? The tube, certainly, causes more or less irritation; in fact, he had noted the occurrence of reflex vomiting in one case, which ceased as soon as the tube was removed. After the first forty-eight hours, when the fluid had become merely serous in character, it was better to dispense with it. Abdominal fistulæ and ventral hernia sometimes resulted directly from the use of the tube.

The simplest form of glass drainage-tubes were the best; lateral perforations were objectionable, since omentum, or even small intestine, might be imprisoned in the holes. Mikulicz used a strip of iodoform gauze. The fluid could be removed from the tube by means of a rubber tube attached to a syringe; it was seldom necessary to examine the tube within twelve hours after the operation. He thought that it was often left in too

long, from forty-eight to ninety-six hours being the limit. The formation of a permanent fistula was prevented to some extent by introducing a deep suture at the site of the tube and tightening it as soon as the latter had been removed.

While he substantially agreed with Olshausen in his condemnation of drainage after laparotomy, he did not think that the latter was correct in advocating the shutting up of a portion of an adherent cyst within the cavity without providing for the escape of the fluid which must inevitably be secreted; there could be no safer plan than that of stitching the adherent sac into the abdominal wound, packing its interior with iodoform gauze, and allowing it to close by granulation. Was there any substitute for drainage? Some authorities claimed that it was unnecessary if rigid antisepsis was observed during the operation and the peritoneal cavity was carefully cleansed before closing the wound; they affirmed, and with reason, that the presence of the tube really kept up the serous exudation. Schröder, Martin, and Olshausen had found that if large raw surfaces were placed in contact they would become agglutinated without much oozing or exudation. Moreover, a small quantity of pure blood, bloody serum, or cyst fluid might safely be left within the peritoneal cavity, *provided all possibility of septic infection from without was prevented;* prophylactic drainage in these cases was not only unnecessary, but it introduced an element of danger. Where it was desirable to drain, the reader suggested the employment of a strip of gauze, which could be pushed up through the vaginal roof into Douglas's pouch. Two indispensable conditions must be observed if drainage was to be omitted, viz.:

1. The peritoneal cavity must be thoroughly cleansed by careful sponging, the viscera being protected by means of flat sponges or layers of sublimated gauze, and by washing out the pelvic cavity with an antiseptic solution poured from a pitcher.

2. Rigid antisepsis must be observed in all the details of the operation.

Dr. Martin, of Berlin, said that he did not employ drainage in ordinary cases of ovariotomy, but only where there was some complication. He used it in cases of supravaginal amputation, vaginal hysterectomy, and where large sloughing surfaces were left after the removal of adherent tumors. In the latter case, he always drained through the vaginal fornix, using a rubber tube, but he did not use injections.

Dr. Bantock said that he had long been interested in the subject. He was so confident of the value of drainage that he used it whenever there was the slightest excuse—*i. e.*, when there had been many adhesions, or there was much fluid in the cavity. He used simple warm water for washing out the abdomen, having long given up so-called antiseptics. He substituted perfect cleanliness for them. Of his last 104 cases, he has lost only three, and this success he attributed to the frequent use of the tube. He used the ordinary straight glass tube introduced through the abdominal wound, and emptied it every two or three hours. The tube should not be removed until the serum became clear and free from blood.

Dr. Gardner, of Montreal, had used drainage-tubes extensively, and was thoroughly convinced of the value of Dr. Bantock's teachings with regard to leaving them in for a long time.

Dr. Wylie called attention to the fact that the drainage-tube was useful as giving an early indication of hemorrhage after laparotomy. He agreed with Dr. Bantock in preferring a straight glass tube.

Dr. Goodell said he was sceptical as to the value of the drainage-tube. He had had several cases of ruptured colloid cyst in which the abdomen was not washed out, no drainage was employed, and yet the patient recovered. He agreed with the last speaker in regard to the value of the tube as furnishing indication of hemorrhage. At the end of twenty-four hours the drainage was imperfect, as described by the reader.

A NEW LABORATORY FOR BACTERIOLOGY AT KING'S COLLEGE.—MR. EDGAR CROOKSHANK, M.B., has been elected Professor of Bacteriology, and the plans for a new bacteriological laboratory, to be built during the vacation, have been decided on.

VACATION COURSES IN VIENNA ABANDONED.—The vacation short courses of practical instruction for medical men, which have been held for many years past during the months of August and September, are about to be stopped. The prospectus of these courses, numbering more than fifty, had already been published when this decision was arrived at.

HYPNOTISM IN TEMPERANCE REFORM.—At Soissons, France, a drunkard of local fame for inebriety, was hypnotized by a mesmerizer, and was obliged, by the "suggestions" of the latter, to refrain from drink. Whether the "suggestions" of convivial friends arising later did not undo the temporary reform is not stated.

INSANITY AND INTEMPERANCE.—There were 1626 persons of both sexes in the insane hospitals of Pennsylvania for 1886. Of this number only 2 were dipsomaniacs, 8 were opium cases, 1 of cocaine inebriety. 123 are put down to intemperance.—*Quarterly Journal of Inebriety*, July, 1887.

IN MEMORIAM.—At a special meeting of the Auxiliary Faculty of Medicine of the University of Pennsylvania, held September 5, 1887, the following resolutions were adopted:

Resolved, That this Faculty has received with the profoundest sorrow the intelligence of the sudden death of their esteemed colleague, Doctor Nathaniel Archer Randolph, late Professor of Hygiene in the University of Pennsylvania.

Resolved, That in the demise of Professor Randolph this Faculty has been deprived of a most faithful and zealous co-worker, endeared to them by the uniform courtesy and gentleness of his deportment; and that the University has lost a Professor of great merit and of brilliant promise, and one most acceptable to the students under his charge.

Resolved, That this Faculty begs to tender to the widow and family of their late colleague the sincerest sympathy and condolence in this afflictive bereavement.

NOTES AND QUERIES.

IPECACUANHA IN LABOR.

To the Editor of THE MEDICAL NEWS,

SIR: When I was a medical student, in 1879–80, my father, Dr. D. O. Baird, of Pickens County, this State, taught me the use of ipecacuanha as a uterine motor stimulant, and he informed me quite recently that he has so used it for fifteen years, and has had no cause to be displeased with its action. He considers it specially indicated when there is a full habit and rigid os. He gives it in two to three grain doses.

Respectfully, W. J. BAIRD.

BIRMINGHAM, ALA., September 7, 1887.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM SEPTEMBER 6 TO SEPTEMBER 12, 1887.

BANISTER, W. B., *First Lieutenant and Assistant Surgeon.*—Granted leave of absence for one month, with permission to apply for an extension of one month, to take effect upon the arrival at Fort Lowell, of Assistant Surgeon J. B. Girard.—*S. O. 91*, par. 4, *Headquarters Department of Arizona*, August 29, 1887.

BYRNE, C. C., *Major and Surgeon.*—Detailed as a member of the Army Retiring Board in Washington City, vice Captain Washington Matthews, Assistant Surgeon, relieved.—*S. O. 208*, par. 2, *A. G. O.*, September 7, 1887.

O'REILLY, R. M., *Major and Surgeon*, U. S. Army.—Ordered to proceed to Fort Niagara, New York, on public business, and on completion thereof, to return to his proper station, Washington, D. C.—*S. O. 205*, par. 10, *A. G. O.*, September 3, 1887.

PEELEY, H. O., *Captain and Assistant Surgeon.*—Ordered to accompany battalion of the Twenty third Infantry from Fort Wayne, Michigan, to Chicago, to participate in the International Military Encampment, to be held in that city in October next.—*S. O. 191*, par. 1, *Headquarters Division of the Atlantic*, September 8, 1887.

SUTER, WILLIAM N., *First Lieutenant and Assistant Surgeon.*—Ordered to accompany Battery E, Third Artillery, from Washington Barracks, D. C., to Philadelphia, on the 14th instant, to participate in the military parade, during the celebration of the Centennial of the Adoption of the Constitution, September 15, 16, and 17, 1887.—*S. O. 191*, par. 3, *Headquarters Division of the Atlantic*, September 8, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING SEPTEMBER 3, 1887.

DEAN, RICHARD C., *Medical Director.*—Detached from duty as a member of the Examining and Retiring Boards, and ordered to Hospital, Chelsea, Massachusetts.

FLICK, GEORGE, *Medical Director.*—Orders as delegate to the International Medical Congress revoked.

SIMONS, M. H., *Surgeon.*—Detached from the "Constellation," and ordered to the Naval Academy.

ROGERS, E. F., *Surgeon.*—Detached from the Marine Rendezvous, New York, and ordered to the "Alliance."

FIELD, JAMES G., *Assistant Surgeon.*—Detached from the "Vermont," and ordered to the Marine Rendezvous, New York.

HENRY, C. P., *Assistant Surgeon.*—Ordered to the "Ossipee."

LUMSDEN, G. P., *Passed Assistant Surgeon.*—Ordered to the "Boston."

ATLEE, LOUIS W., *Assistant Surgeon.*—Restored to duty.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

NINTH SESSION, WASHINGTON, 1887.

THE TREATMENT OF RECENT CASES OF INSANITY IN PRIVATE AND IN ASYLUMS.

An Address delivered in General Session, September 7, 1887.

BY G. FIELDING BLANDFORD, M.D., F.R.C.P., OF LONDON.

HAPPY is the psychologist who is not concerned with his patients till he receives them within the walls of his asylum. Many of the physicians of our large public institutions are thus fortunate. They do not see or hear of those they are about to treat till they are admitted. They have not to advise removal, to write certificates, to plan means of conveyance. They receive them only in hospitals filled with the best contrivances for the care and cure of disease of every kind, and they can apply themselves without drawback or hindrance to the task.

Very different is the lot of a consultant summoned to see a patient who has become insane at home, or to chase him from place to place and examine him, perhaps in an assumed character, in order to advise a plan of treatment. Although anxiously consulted by the friends, his advice is as often opposed as adopted. Every conceivable objection is urged against his proposals and he is supposed to carry about with him some potent elixir which, without any restraint, will speedily disperse the cloud and bring back the sunlight of reason.

The object of this paper is not to discuss the treatment of the chronic or incurable insane but that of recent cases only, which are for the most part somewhat acute, not admitting of question as regards the insanity, but in which prognosis rather than diagnosis will play the most important part. We have to consider, when called to an acute case of mania, whether it is likely to be of brief or of lengthy duration, and where and how we can deal with it.

Recent insanity is a very curable disorder, as statistics from all quarters prove, and it behooves us to place the sufferer under such conditions that the cure may be effected as surely and speedily as possible. To the majority of cases a well ordered asylum affords the best means of treatment, for many it is a necessity, and removals ought to be urged in the strongest terms. But from time to time patients come before us whom, for various reasons, we wish to save from the stigma which, rightly or wrongly, is attached to one who has been an inmate of an asylum. This point is sure to be strongly brought up by the friends, and it is one not lightly to be put aside. Many fathers of families may be seriously damaged in position or prospects, or may even lose the post they hold. Some may be lads, or young girls at the outset of life, others young mothers in their first confinement. The reputation of having been in an asylum will never be lost by any one of these. The public attaches but little importance to a person being sent away ill to the country, or the seaside. If sent to an asylum it is quite another matter. In a practice of some thirty years I have seen many recover from a brief, though acute, attack of insanity, either at home or in a lodging or house suitable for treatment. My time does not allow me to enumerate even a fraction of such cases in anything like detail, but I wish to state very briefly some points which may help us to determine the prognosis and afford a hope that the malady will soon pass away. That this passing mania is recognized by psychologists is certain. Its name, *mania transitoria*, is adopted by many and well expresses the fleeting nature of the attack.

The chief point of prognostic value is the suddenness of the attack. It may come on, with scarcely any warning, in the course of a few hours, and in that brief time may develop symptoms of a very violent and acute character. There may or may not have been premonitory symptoms. This will depend very much on the cause—an exciting cause—lighting up the disorder in a brain prone to "instability" or "explosiveness." The illness comes on suddenly; we may hope that it will, if not as suddenly yet at any rate in a short time, pass away. I have known a young lady pass into chronic and incurable mania of the worst kind, whose malady commenced in the most sudden way and who was at once placed in an asylum. It was not, therefore, for want of skilled treatment that she did not recover.

Some guidance may be derived from the cause of the attack, if we are so fortunate as to be able to put our finger on it. If the cause is recent, not spread over a long period, but definite and rapidly producing its result, it is to be hoped that by removal of it, the effect may in a brief time subside.

Such a cause may be a sudden mental shock or fright; the loss of a relative, or a surgical operation. Here the suddenness of the event upsets the unstable equilibrium of the individual, and, although the cause may not be removable, as some are, yet the equilibrium is regained by the mind becoming by degrees able to contemplate the event, or being distracted therefrom by change of scene or surroundings. Another potent cause is religious excitement. Probably most of my hearers have seen women—aye, men too—attacked by hysterical mania after attending revival meetings and exciting religious services of all kinds. We may hope that in such persons the symptoms will quickly abate. I have seen several women, not young, but elderly, who have had sharp attacks of mania after a hot course of spiritualism, attendance at spiritualistic *séances* and the like. Two I have encountered lately. They were as violent cases of mania as one often meets with, but both got well in the course of two or three weeks without ever being removed from their own houses.

Another cause of sudden maniacal attacks, which I

have gone with several times, is protracted fatigue, an unduly long walk or exposure to a hot sun for a long period.

This was to my opinion the cause in the case of an officer who had been attending the autumn manœuvres in Germany and had, for want of a horse, walked many miles in the sun on a hot day. Travelling back day and night to his command he thoroughly knocked himself up and developed an irritability which culminated in a violent and public quarrel with his superior officer, with outrageous conduct, exaltation of ideas, great personal conceit, and unmeasured and at times obscene talk. I was summoned from London, and asked to bring certificate papers for his removal to an asylum. By the time I got there he was in restraint, having been taken in charge by the authorities as a dangerous lunatic. On hearing a little about his previous history, I anticipated that the attack would not last long. So, as we had him in safe keeping, we carried him to the railroad, took him to his home in London, whence, in a fortnight, he went convalescent to the seaside.

A very long walk produced an attack of acute mania in a lady of very nervous temperament, who had had a similar attack on a previous occasion. This entirely subsided in a few days.

Very acute maniacal symptoms occasionally arise in the course or the decline of an acute disease, such as measles, scarlatina, erysipelas, pneumonia, and typhoid fever; and my friend Herman Webber has, in the forty-eighth volume of the *Medico-Chirurgical Transactions*, published the particulars of seven cases of this form, to which he has given the name of the delirium of collapse. He remarks that the delirium commences almost always on waking from sleep, and at a time when the disorder is declining, not when the temperature and the fever symptoms are most prominent. In his experience, the mania lasted for a short time—from eight to forty-eight hours—and all recovered. My own experience has not been quite so fortunate, and I have seen some who have not recovered quite so quickly, but still the majority do, and we may give a favorable prognosis. The occurrence of such mania, just as an illness is declining, is an alarming event, and the ordinary sick nurse is probably very unfit to cope with it, but removal from home should not be thought of until sufficient time has elapsed to show whether the mental symptoms will be brief, or prolonged.

And here I may mention those curious cases of mania which occur in connection with gout or rheumatism. Sudden maniacal symptoms may present themselves in a man, or a woman, and the case assume the appearance of the greatest gravity, and all this may as suddenly disappear on the supervention of an attack of acute rheumatism, or gout in some joint. It is always worth while in patients with such a history to try to develop an attack of gout by the application of mustard to the feet and the administration, rather than the withdrawal, of a liberal diet.

Brief and very violent attacks of mania may follow epileptic seizures. Here we shall have the history of the case to guide us in the majority of instances. But it sometimes happens that no one has seen the epileptic fit or known the patient's previous history. It lately happened to me to have a patient sent to my hospital, who for a few days was one of the most troublesome that I ever encountered. He then rapidly recovered, and his whole term of residence was only a fortnight. It was impossible to keep this man in his own home, and his means being small, no temporary abode with requisite attendants could be provided for him.

We are all familiar with the acute alcoholic delirium to which is given the name of delirium tremens. It is not uncommon and is easily recognized. It is a transitory mania, and generally terminates within a week in recovery or death. But besides these, we occasionally see symptoms of insanity produced by drink, delusions and hallucinations very like those of ordinary insanity, but which pass away quickly if the drinking has not been prolonged. Two cases have come before me lately, and one last year. One of the two was a young lady, between twenty and thirty, who suddenly showed alarming symptoms, which subsided after two good nights, produced by chloral and bromide. The second was an old lady, whose hallucinations of hearing were said to have been produced by chlorodyne; I suspected, however, that she mixed it with a good drop of brandy. The lady was last year so bad that I thought she would have to go to an asylum. She came to me from the country, and her relatives at first concealed the fact of her having drank, but she suddenly got well in about a fortnight, and the secret came out. We shall derive great aid in our prognosis if we are able to ascertain that the patient has had previously similar acute attacks, which have passed off in a short time.

These sudden violent accessions of mania are just what we should expect to find in persons of such an unstable nature that they are ready to explode at the least thing which opposes them. Thus we see so many who are driven into furious gusts of passion by mere trifles, and for a time are hardly responsible persons. I know several who habitually have accessions of mania. One, a gentleman of great intellectual ability but nervous to a degree, has had three within my knowledge. On one occasion he was speedily placed in the asylum, which converted a brief attack into one most prolonged. The last time I saw him he was not violent, but in a kind of cataleptic seizure, unable to speak or take food. I warned his medical attendant that it would pass away, and it did entirely, in forty-eight hours or less. The officer of whom I spoke had had something of the kind before, which prompted me to keep him at home and not send him to the asylum. Of course, after repeated attacks, recovery may not, probably will not, be so speedy as after the first or second, still we may reasonably expect it to occur without any removal, or other special treatment.

In two highly nervous individuals the attacks have been more melancholic than maniacal, being of the nature of intense panic, with delusions of fear—fear that every one about was conspiring to inflict some injury, or traduce and take away their character. Two cases have lately come under my notice and both terminated almost suddenly, but owing to different causes. Each tried to escape from his imaginary persecutor, the one by running away, the other by suicide. The former succeeded and got away to his friends on the continent. Feeling himself safe in the hands of his friends, his fears and delusions vanished, and he returned after a short time to his home and business. The other gentleman

took poison, but only succeeded in making himself horribly sick, which cured him. In consequence of the suicidal attempt, the authorities packed him off to the nearest asylum. He was well, however, before he started, and wrote me a letter telling me all about it. I saw him the next day and he seemed absolutely recovered and sane.

What is there in the physical condition of the patient to aid us in our prognosis and determine the brevity, or length of the attack? The temperature will not give us much assistance. Neither in transitory nor in prolonged mania do we find any great rise in temperature. The pulse will tell us rather more. It may be quick when great excitement, violence, singing, and shouting, are going on, and when the paroxysm is over, and all this noisy excitement occurs in paroxysms, it may fall very considerably, and the pulse be not much more rapid than normal. If it does not so fall, but on the contrary remains rapid, even when the patient is comparatively quiet, the chances are the mania will be a prolonged attack, and we shall have to treat it not for days but for weeks.

The tongue, too, will give us some help. In very violent attacks it often happens that this will remain moist and clean, presenting no abnormal appearance. On the other hand, if it becomes dry, more and more furred and brown with that coat which is so indicative, not of stomach derangement, as we so often hear, but of acute nervous disorders, then we can hardly hope that it will pass away in two or three days.

There is often a great deal in one of these maniacal attacks, which, for want of a better name, we may call hysterical. As a rule they are characterized by noise and violence, rather than by fixed delusions. They begin suddenly, or after a very short period, and delusions have not had time to take definite shape. Now, in the hysterical attacks, between the intervals of violence, there is often a good deal of consciousness and attention directed to what is going on. If these increase, we may hope for a speedy return of rationality. If they decrease, if incoherence and inability to converse increase, and if delusions are manifest, then the prognosis of speedy recovery will be unfavorable. This hysterical state and these hysterical symptoms will last some time, not varying very much and without any increase of the graver symptoms. Yet we know certainly that they will pass away, because there is so much reasoning power at one time, though with great excitement and violence at another. We may have reason to suspect that a good deal of the latter is put on and is to be met by moral control.

Treatment will often aid us in the prognosis of these cases. Sleeplessness is a main feature in many of them, and it not infrequently happens that, after a long sleep produced by a narcotic, the patient wakes recovered, or so nearly so that we are no longer anxious about him, precisely as we see men recover in delirium tremens. Now for the producing of sleep, what a number of medicines we have at hand! When I began to practise, there was nothing but opium and its compounds, and to administer opium, or morphia to a patient in this stage would almost certainly have the effect of not producing, but of preventing sleep. But now there are the bromides, urethan, paraldehyde, chloral hydrate, hyoscine, hyosciamine, and others with which you are acquainted. If a usual dose of one of these produces a refreshing sleep, and the sufferer awakes with his mental symptoms lessened, his mind clearer, and excitement diminished, our hope of a speedy termination may be strengthened accordingly.

But if the maniacal attack does not subside in a few days, or in a week, and it appears probable that it will be an affair not of days, but of weeks, or months, what are we to do? The friends may be altogether against us in our purpose to send the patient to an asylum, and will profess their willingness to consent to any other alternative. The question, we find, resolves itself chiefly into one of cost. There are many patients, uneasy, delirious, and excited, who are not homicidal, or suicidal, or dangerously violent. By good attendants they may be nursed through an attack of mania, if the friends will defray the expense, by the orders of the physician. In nine cases out of ten they must be removed from home. Home surroundings and the appearance of near relatives are prejudicial, so that a house, or rooms must be taken and made suitable for such a case. The windows must be made safe. Bedsteads and furniture must be removed. The bed must be made on the floor, and the services of several good attendants must be secured. To harness the patient to the bedstead by his ankles and wrists and to keep him thus day after day and week after week is not treatment, though, unfortunately, it is, even now, occasionally met with and acquiesced in by friends who disdain the services of a lunacy doctor, and put up with anything rather than listen to what they know would be the advice of such a specialist. And not only will it be necessary to have suitable rooms for the patient. There must be the means of giving him air and exercise, but not in the streets of a town, but in a garden, or country fields. All this involves considerable expense, but where the case is suitable and money no object, it is often worth while to try to effect a cure by this method, and so save the stigma of an asylum and the subsequent feelings of the individual. Of course, it often happens, that the friends, although at first professing that they will do anything rather than consent to an asylum, do in time get tired of the heavy expenditure and the trouble which the management of the attendants and servants give them. Being, too, often very nervous people and born with the same temperament they cannot stand the racket any longer, and to the asylum the patient goes. But he may get well without.

There are some patients, however, who are to be sent at once, whom it is useless to treat in a single house, and who will become more dangerous by such treatment. These are persons affected, not by uneasy and active mania of recent origin, but by delusions which have gradually deepened until they are dangerous to a degree to those about them. Such cannot be kept in one room with sick patients. They require considerable exercise, the vigilance of many attendants, and the authority of a superintending physician. They demand moral control and coercion. The discipline of an asylum and the loss of liberty act beneficially upon the disorder, and the example of others is frequently of the highest service. We see, also, many patients whose malady we recognize as chronic and incurable, being often of long standing. It is a pity to let these, or their friends be impoverished by the expense incidental to a

residence outside an asylum, when to the latter they must come at last, and to one less comfortable if all their money has gone.

There is, too, one large class of moral patients, and generally paralytics, whom it is very difficult to treat out of an asylum, except in rare cases where quiet imbecility sets in at once. The restless, exalted, and often angry excitement which characterizes the early stages demands a larger room and space than a private house affords; and the feeling of intense self-satisfaction and happiness prevents their feeling restrained or chafing at their surroundings.

Passing from the acutely excited and maniacal patients, I may consider for a moment the treatment of the depressed, or melancholic. The non-asylum treatment of such has probably been tried in most instances before a resort is had to specialists. They have been sent away from home; have had rest from work, and more or less medical treatment; but the gloom has deepened, and special advice is sought. Are we to send them to an asylum? Here the question of suicidal propensity will come in. Many I hear say that the asylum is the only place for a suicidal patient. But an asylum is not an absolute safeguard against suicide, as the reports of our Commissioners show. Nothing but the persistent vigilance of good attendants will prevent it; and vigilance may be applied both out of and in an asylum. There is more than one kind of suicidal patient. Some there are who will not make the attempt unless they have a tempting opportunity, and are left alone by those who should look after them. But others will try and injure themselves all day long, even in the presence of others will they try to gouge out their eyes, throw themselves out of bed and break their bones, and, in fact, damage themselves in every conceivable way. So, again, some will refuse food, but will eat on complusion, or will allow themselves to be fed with a spoon. Others require to be fed by force, either by nasal or œsophageal tube, entailing the efforts of several people. Clearly some of these can only be treated in an asylum, while the less acute may be kept in a suitable house and, by vigilant attendants and judicious companions, nursed back to health. The attack of this melancholy, however, is very different from the short and acute attacks of mania which I have spoken of before. It is the most tedious of all the curable forms of insanity. We have to carry out the treatment, not for days or weeks, but for months. Consequently expense becomes a serious question, and poor patients have to go to the asylum, because they cannot afford the cost of a house and attendants. It is useless to attempt to cure such at home. The sight of home and home-surroundings intensifies the gloomy ideas and urges the sufferer on to suicide. It is intense egotism, self-feeling, selfishness, or whatever we choose to call it, which distinguishes so many. They will tell us that there never was such a case before, that they never can get well, that we are altogether unable to comprehend their individual symptoms. One of these patients will completely upset his home, and we order him away; but placed in a house with attendants and companions, or in a doctor's house, he may still be able to make himself seen and fix everybody's attention, and his self-importance is fostered and not diminished by the move. Place this man in an asylum of, say one hundred patients, and make him the one-hundredth part of the unit instead of one important unit, and the effect is often wonderful. Possibly he has been refusing his food and has required to be fed with much coaxing and entreating. Seated in the midst of twenty others, he takes it because they do, and no one seems particularly to care whether he takes it or not. The best medicine for these people is what I term judicious neglect.

To cure a patient's insanity without having to send him to an asylum, is a matter of great satisfaction both to one's self and to the friends of the sufferer. It is akin to the feeling of the surgeon when he saves a limb after a severe accident, or heals a diseased joint without having recourse to amputation. But I am not one of those—and this I wish clearly to enunciate—who think that all or nearly all acute cases of insanity can be treated in private dwellings.

We hear from every one who is capable of forming an opinion that early treatment is necessary, and that if a case is not treated early it will in all probability become chronic and confirmed. With these I cordially agree, and when I have spoken of mania cases treated successfully out of an asylum, it is because I wish to point out that there are some such, and that in practice we not infrequently meet with them, recognizing them amidst many others for whom an asylum is the proper place and alone can afford the proper treatment. Many must go because they have no funds and no friends. Taken care of by the State, they must go to a public institution. If we do not send the case thither it must be because we think that we can treat it as well and as successfully outside, and if our method fails and it is plain that the patient is getting worse and not better, we ought to bring it to an end and have recourse to an asylum, by overcoming the reluctance of the friends who so constantly think, not of the patient but of themselves.

It will be obvious that the limit of time allowed here does not give more than the briefest outline of the subject, which, to treat in full, would demand a chapter far exceeding that which I am able to set before you. It is impossible to enter upon the treatment of such cases, but American physicians are perfectly conversant with this, and I need not enter upon it, even if time allowed.

There is another matter connected with it, namely, the law. How far are we justified in treating our patients outside an asylum without having recourse to lunacy laws and all the apparatus of medical certificates, and orders? I am glad to be spared all reference to this question. In this country, I believe, the laws differ in different States. I can say, however, what the law ought to do. It ought to enable us to treat a case for a certain time outside an asylum, without having recourse to certificates, just as we should treat any ordinary case of illness, as the delirium of fever, or delirium tremens. In Scotland there is this power; in England there is not, and I fear that there is not much hope that there will be. I hope that here such provision exists, and that, if it does not, it will at no distant date.

I have thought fit to bring this subject before you because it is often thrown at us that lunacy doctors wish to send every patient to an asylum and have no other method of treatment. As there are many who impera-

tively demand the care of an asylum, not only that they may be kept in safety, but for cure, so are there others whose recovery may be brought about without being so sent. It is our duty to discriminate so far as we can between them. Those who suffer from transitory mania are not the dangerous class who should be sent to an asylum as speedily as possible. The delay of a few days will often not materially interfere with the after-treatment if the asylum is eventually necessary, and in this period recovery will take place. I cannot hope to have assisted you much within the limit of this paper in the diagnosis of such cases; but, at any rate, I may claim to have directed your attention to them.

ORIGINAL ARTICLES.

ON DIABETES.[1]

By F. W. PAVY, M.D., F.R.S.,
Senior Physician to Guy's Hospital, London.

Diabetes has always been regarded as an incurable disease, and although it has elicited much study, there are still many points open for investigation. The nature of the affection may be stated in very precise terms. It is simply a faulty assimilation or a faulty disposal of certain elements of our food. If we look to the food of man, we find that the chief elements of it are nitrogenous matter, fatty matter, and carbohydrates; that is to say, the large group consisting of starch, cane sugar, grape sugar, dextrine, etc., behave in the system the one exactly the same as the other, so that it would be better to employ this general term.

In diabetes there is no difference in the behavior of the carbohydrates: starch behaves the same as cane sugar, the same as dextrine. It is this group of principles in connection with which there is a faulty disposal or a faulty assimilative action. The disease consists essentially of that. A healthy person, for example, takes one or another of the carbohydrates, and it is lost sight of in the system; we know nothing more with regard to it, and we assume that the processes of life are such as to lead to the transformation of this carbohydrate in such a manner that it shall be susceptible of utilization in the system. That is the case with the carbohydrates. That is the condition of health; but what is the condition of diabetes? In diabetes, one of these carbohydrates may be taken, and in proportion as the carbohydrate is taken, so is sugar eliminated in the urine. We may therefore say, and it is merely the expression of a fact, that in the diabetic there is a want of assimilative power, there is a want of the power to dispose of what carbohydrates may be taken into the system as food. Thus far, I think, we have to deal with facts.

In diabetes the sugar reaches the general circulation in a manner that it should not do. In a state of health analysis shows that only a trace of sugar exists in the contents of the general circulation—in the small proportion of 0 6, 0.7, 0.8 per thousand, so that when a carbohydrate is taken as food, it is stopped before it reaches the general circulation. Not so with diabetes. Here sugar exists to a large extent in the general circulation. In proportion to the severity of the case will be the quantity of sugar contained in the general circulation. The carbohydrate which is taken as food does not stop before reaching the general circulation, but in proportion as it is taken, so does sugar appear in the urine. The sugar appears in the urine in proportion as it exists in the blood, and, therefore, the urine may be said to be the index of the diabetes.

The amount of sugar in the urine stands in direct relation to the amount of sugar in the blood. You cannot possibly keep sugar in the circulation; it will not remain there, but it will make its appearance in the renal secretion. Now I have at present only given expression to facts that may be observed.

But why does sugar thus get into the general circulation in diabetes? That is the important point. I think it is generally admitted that the liver constitutes the assimilative organ for the carbohydrates. The liver it is that stops the sugar, or the carbohydrate in its passage to the general circulation. The sugar is so changed by the liver that it is not permitted to arrive in the general circulation. Sugar in the organism is transformed into glycogen, and leads on to the production of fat. Its office may be demonstrated in the lower animals. If you want to fatten an animal quickly, feed it on an abundance of sugar. This, I think, demonstrates the use of sugar in the production of fat. The liver, then, I think, is a steatogenic organ, transforming the sugar into glycogen, and afterward into fat.

It seems to me in health that this is what occurs; that the carbohydrate absorbed from the intestine is stopped by the liver, converted into glycogen and then into fat, instead of being passed through the organ and appearing in the general circulation. If, however, it passes through the organ, we have diabetes. But, what is at the bottom of this faulty process? It seems to be a wrong condition, apparently arising from a faulty condition of the venous blood. The liver is differently placed from other organs, in its large supply of venous blood and its proportionately small supply of arterial blood; and the blood which reaches it should be in a good venous condition. If it be not in a good venous condition, we have the chemistry of the liver immediately altered, and sugar appears in the urine.

This alteration of the portal blood may be produced in a number of ways, it may be produced by disease or by experiment; in the first place, by the injection of defibrinized arterial blood into the portal circulation. In a very short time after arterial blood from which the fibrin has been removed has been introduced into a vein of the portal system, we find sugar in the urine. The blood may be rendered saccharine by over-oxidizing the systemic blood. Experiments—not only my own, but those of others—have demonstrated this, that the carrying on of respiration in the lower animals more actively than normal, the heart's action continuing, will lead to the production of

[1] A communication to the Section of General Medicine, of the International Medical Congress. Stenographically reported for The Medical News, and revised by the author.

saccharine urine. If oxygen exist in the portal blood to an extent to which it ought not to exist, you will have saccharine urine.

How does this apply to diabetes? If you get a vaso-motor paralysis of the arteries of the body you will have that condition. If, as may be witnessed, we have a vaso-motor paralysis of the vessels of one side of the head and neck, we find that the veins of the region become distended, not with venous blood, but with semi-arterial blood. As a result of such, the blood will arrive at the liver without being fully de-arterialized; in other words, in an imperfectly venous condition. If the arteries of the abdominal organs, of the chylopoietic viscera become enlarged so that the blood in them does not become perfectly de-arterialized, you will find the chemical action of the liver becoming changed so as to permit the carbohydrates to pass through it and get into the system, and so charge the general circulation with sugar. The worst forms of diabetes I have met with are those in which there is a dilated condition of the vessels of the mouth. For the production of diabetes, it is only necessary, I consider, for us to have a dilated condition of the vessels of the chylopoietic viscera. But the worst cases of the disease, as I have just said, are those in which this dilated condition of the vessels, due to vaso-motor paralysis, has extended from the chylopoietic viscera and visibly involved the mouth. In these cases we have the presence of an exceedingly red tongue.

Again, puncture of the floor of the fourth ventricle, that celebrated experiment of Bernard, leads to the presence of sugar in the urine. Now what did Bernard himself observe in connection with the animals thus experimented upon? A dilated condition of the vessels of the chylopoietic viscera.

One of the first points to attend to in a case of diabetes is to test for sugar. Sometimes discordant opinions are expressed with reference to cases; one physician, for instance, will say that the patient is suffering from diabetes, while another physician will say that he is not suffering from the disease. Sometimes that depends upon the test made, at other times it depends upon its being a mild case of the disease, which presents varying conditions under the influence of food. If the patient has partaken freely of carbohydrates, sugar exists in his urine, and, if examined then, it is to be detected. Then he goes to another physician after he has not partaken so largely of the carbohydrates, or perhaps after a fast, and there is no sugar present.

We want a test that will give us a decided and reliable indication. I believe that the most reliable test for sugar in the urine is the copper test. What is ordinarily used is known as Fehling's solution. But there is this objection to Fehling's solution, namely, that it is apt to get bad after being kept, because, if kept for a long time it will throw down a precipitate; and again, the stopper of the bottle, unless used often, is apt to become fixed, and when you want to use it you cannot get it out. Some time ago I came to the conclusion that it would be well if we could get the Fehling's reagents prepared ready for use in a solid form. I found, however, that when thus prepared the agents rapidly deliquesced and decomposed. Here, however, is a pellet which I have had prepared in which the difficulty has been overcome. It is composed of the copper sulphate, Rochelle salt, and caustic potash. It must be made in a certain way with the materials in an anhydrous state. The sulphate of copper is to be placed in the die first, then some Rochelle salt, next the potash, and finally some more Rochelle salt to complete the mass. If now we dissolve one of these pellets in a little water, we have first produced the greenish color of the copper, but, later, as the potash is reached, it becomes blue, as is characteristic of Fehling's solution. If these pellets are kept in well-stoppered bottles they will keep for any length of time. And there is this advantage about the pellet, that if it does become bad from the absorption of moisture, it becomes so bad that it cannot be used, and therefore there is no danger of its leading to error. It will, if exposed to the atmosphere, become altered, but it then turns black, so that the change is readily recognized, and it cannot be used. If I now add to this solution a little liquid containing sugar, and boil the mixture, the oxide of copper becomes reduced to the state of suboxide, just as in the ordinary testing with Fehling's solution. These pellets are now considerably used in England.

I do not think that a case of diabetes can be satisfactorily managed unless a quantitative analysis of the urine is made, and the amount of sugar contained in it is determined. I do not consider that a person can get along satisfactorily without knowing the amount of sugar that is being eliminated by the kidneys any more than he can get along in a case of thoracic disease without knowing, by the aid of the stethoscope, exactly the amount of disease existing there. In my own practice, I desire that two specimens be brought to me; one passed in the evening and the other upon rising in the morning. By an examination of this kind you can discover errors of diet in your patient that would otherwise escape you. You do not need to ask the patient at all what he has been eating; you can can tell him. Errors of diet can be detected at once. You can not only detect that the patient is not following your instructions, but you can tell at what meal the error has been committed. Under ordinary circumstances, if the person is passing sugar (of course, if he is not passing sugar you cannot tell anything about it) you may find in the night urine a considerable quantity of sugar, and in the morning urine none at all. The sugar in the night urine has been derived from the carbohydrates taken during the day. The morning urine has been derived from the blood during the night, and therefore in the interval of digestion, and thus may contain no sugar. The urine of food may be quite different from the urine of fasting.

I remember once a patient whom I had treated for some time, coming to me with a bottle of night urine containing an unexpectedly large amount of sugar. I could not account for this sudden increase of the amount of sugar in it. I got him to enumerate the articles of food he had taken the evening before. Among the articles enumerated

he named blanc mange, but he had frequently taken that before without injury. I told him to inquire, and that in all probability he would find that it had not been made in the usual manner; and upon doing so, he learned that it had been made with corn flour (corn-starch) instead of in the manner that had formerly been done, viz., with isinglass and cream. In another instance I was able to tell a patient that she had taken her breakfast in bed. I found in this case that the night urine contained no sugar, while the morning urine was loaded with it. She had arisen late, and the only way of accounting for these conditions observed was on the supposition that she had eaten before arising, and this I found was actually the case.

Now we want some means of easily and precisely determining the amount of sugar contained in the urine. This can be done as follows: As we know and have just seen, in testing in the ordinary manner with the copper solution, the suboxide of copper is precipitated. In the method that I shall show you, instead of this, the solution remains clear, and becomes colorless, and the sugar is estimated from the amount of liquid being examined, that is required to decolorize a given quantity of the solution. The solution is made with the sulphate of copper, Rochelle salt, caustic potash, and water of ammonia. Into a given quantity of this the liquid containing sugar is dropped. It is best in testing urine to dilute it with twenty or thirty parts of water in order to make the test more delicate. The diluted urine is placed in a graduated burette, from which it is dropped into the ammoniated copper solution after the latter has been heated to the boiling point, letting it flow drop by drop until the color has just entirely disappeared. The dropping of the liquid into the test solution is guided by means of a screw adjustment affixed to the tube, which can be set so as to permit the escape of forty, fifty, eighty, or one hundred drops per minute. The beauty of the test is that the exact terminal point of the reduction can with the greatest surety be determined, for there is no precipitate to obscure the view of the reduction. You observe now in the apparatus before me that as the saccharine liquid drops into the boiling test solution the color is gradually disappearing and the liquid remains perfectly clear.

Sometimes albumen is found in addition to sugar in the urine of the diabetic. Not infrequently you will find that when the patient first comes under your observation he has a considerable quantity of albumen in his urine, and that after he has been under treatment for the disease for a while the albumen disappears. This will permit me to bring to your notice a convenient test for albumen. This consists of citric acid and the ferrocyanide of sodium, the ferrocyanide of sodium being used because it makes a looser pellet than the ferrocyanide of potassium, and therefore more quickly dissolves. There is this advantage about it, that as a clinical test you require nothing more. If albumen is present, you are sure to get a precipitate; and if you get a precipitate, you are sure that albumen is present. It is also a test of an exceedingly delicate nature. It is a test that requires nothing to check and nothing to corroborate. You can carry it with you in your pocket like a pencil-case or pocket-knife. No matter whether I need it or not, I always have my albumen test in my pocket with me. I have here, as you see, a very compact tube containing all that is required. I will show you the method of using the test with this liquid, which contains albumen. The citric acid pellet must be used first. It very speedily dissolves. Sometimes citric acid will bring down a precipitate of uric acid, or it may be of oleo-resinous matter; but, as it is not the citric acid which is the test, we do not rely upon that. If the citric acid brings down a precipitate of uric acid, a dilution of the urine will redissolve it. On the addition now of the other pellet, consisting of ferrocyanide of sodium, you have a definite and reliable precipitate of albumen produced. This test has now been out several years, and, so far as is known up to the present time, nothing under the circumstances will occasion a precipitate with the pellet of ferrocyanide of sodium besides albumen, so that it is a test upon which you may rely alone.

I will speak now of considerations bearing more particularly upon the disease itself. There are different grades of intensity probably as marked in diabetes as in any disease we have to deal with. Let us start with a healthy person. Even a healthy person has not an unlimited power of assimilating the carbohydrates, but the first step toward disease is where the assimilative power is below the normal. This kind of person will not, under ordinary circumstances, pass sugar in his urine. If, however, he partake freely of preserves, or other articles of food containing large quantities of sugar, he will pass saccharine urine. Then you come to persons who, when partaking moderately of food containing carbohydrates, will pass sugar. They may take carbohydrates to a certain extent without showing evidence of abnormality, but as soon as the limit is passed, sugar will appear.

Age influences largely this complaint. Severe cases are in young subjects, mild cases are in old subjects, and the more advanced the age, the better the prognosis. I know of no disease in young subjects that is more grave. The ordinary length of life in young subjects afflicted with diabetes may be said to be about two years. In middle-aged or elderly persons the prospects, happily, are of a different nature. If they follow proper management they can keep the disease under. The unsatisfactory cases are in the young, the satisfactory cases in the elderly.

The age at which the disease is most common ranges between forty and sixty years. Preparatory to the meeting of the British Medical Association a few years ago, I went through my case book and tabulated 1360 cases, and I found that the cases occurring between forty and sixty years of age made up fifty-six per cent. of the whole.

Sometimes the disease commences in mild form, and may run along for several years before it is recognized. You may say, What authority have you for making such an assertion? How do you know that the disease has run for some time without having been recognized? There is this way of knowing it: saccharine urine leaves white spots on articles of

clothing, and in micturition the trousers are apt to get splashed. The "boots" at hotels are able to recognize diabetic guests. They find the spots on the legs of their trousers very difficult to brush out. I have had patients come to me who were able, when asked, to hunt up old trousers on which these spots were found, and could remember the annoyance occasioned by them for a long time before. Such are the grounds for being able to say that the disease may have existed for some time without having been recognized.

It runs in families to a considerable degree. I do not say that it is hereditary in the same way as gout and phthisis are; but it runs in some families in a striking manner. I was asked to see a patient suffering from diabetes, who belonged to a family of five, the eldest of whom was not more than eighteen or nineteen. The mother had died of diabetes and the grandmother had died also of the disease. One of the children was brought to me, as I have said, and sugar existed in the urine. I desired to have a specimen from each of the remaining children. In four of the five the urine was saccharine.

There is one point with reference to the disease to which I would like to call your especial attention, and ask you to give it the benefit of your own observation. It is only somewhat recently that my own attention has been fixed upon the matter, and the number of cases I find to be affected in the manner I am going to mention is striking. The remark does not apply to young subjects, but to persons beyond the middle period of life. I used to come across persons who complained of pain in the legs, put down as cases of gout or rheumatism; and I took it as simply coincidental to the diabetes, without anything important in it. But I so frequently met with it that my attention became aroused, and now I find many subjects of diabetes beyond the middle period of life thus affected. There is also more or less ataxia. It is not exactly the pure form of ataxia that is seen in locomotor ataxia, because I have noticed that these persons can stand, maintaining their balance fairly well with their eyes shut. Yet they walk with some difficulty. They cannot properly maintain their balance. They feel often compelled in walking to pull themselves together and make an effort to walk steadier, lest persons behind them may think they have been taking too much. This is what has occurred to me over and over again to hear.

Then, again, with this, there are usually associated some anæsthesia, and hyperæsthesia, and various forms of paræsthesia. Persons feel as though they were walking on pebbles. The flesh is tender, so that when the leg is grasped it gives pain. This comes oftener in the legs than in the upper extremity; sometimes, however, it affects the upper also. Then there is an aching of the bones. The patient complains of it especially at night, in bed. The condition appears to be due to peripheral neuritis.

Treatment.—In young subjects, all we can do is to endeavor to stay the disease for a time. You cannot possibly cure it. At an early stage of the disease in the young subject, you diet the patient—the sugar is removed, and the patient thinks he is cured. Sometimes you are called upon to treat a patient who has been brought to an extreme state of emaciation and weakness, by a sudden and severe invasion of the disease. Placed under proper treatment, the change appears like a resuscitation. He goes on getting better, his hopes are raised, and he thinks he is well. But unfortunately this is not the case. It is a progressive disease. It is a disease which seems to progress in the same way as progressive muscular atrophy or locomotor ataxia, but its advance is uneven. As it advances, the diet and other methods of treatment which succeeded in removing the sugar at first no longer do so; the patient now loses ground and becomes weaker and weaker. You are able at first to keep down the symptoms and the excessive flow of urine; but soon you lose your power to keep them down, and finally something occurs to throw your patient off his balance, and to lead up to diabetic coma, which is the ordinary mode of death in these cases.

It would be a hard and oppressive life to devote one's self only to the treatment of diabetes occurring in young subjects. But the successes obtained in treating the disease in patients of a more advanced age compensate in a measure at least for the failure in young persons.

We must first avoid feeding the disease, and whilst doing this endeavor to convert the wrong action of assimilation into a right one. I lay the greatest stress on diet. I do not think that we can get along in the management of these cases without strict attention to diet. There must, then, be the proper articles of food provided. It is easy enough for the patient to avoid taking some articles of food, as sweets, pastry, puddings, potatoes, etc., but it is not so easy in the case of bread. What he may take may be summed up as consisting of any kind of meat, fish, poultry and game, with eggs, butter, cheese, the various forms of green vegetable food, and a prepared substitute for bread. Milk should only be taken to a limited extent. Some authorities have recommended the free use of milk. But milk contains sugar and milk-sugar behaves in the system exactly as any other form of sugar. I have found that where milk has been taken in large quantity, the sugar has been kept up in the urine; whilst when the quantity of milk was reduced, the state of the urine improved. Certainly it is a hardship for a patient to abstain from bread, and you want to make it as easy as possible for him, by substituting something else of a palatable nature for the article prepared from wheaten flour. I do not think bran, which is often used, is a good substitute, because it contains from 40 to 50 per cent. of carbohydrates and very little else that can be digested and applied. Gluten is better, but it contains a considerable amount of starch. If the gluten is good, it contains only from 30 to 33 per cent.; but I have found some specimens containing 70 to 80 per cent. Perhaps there is no article of food better suited to the diabetic than the almond. There is nothing which seems to supply him better with what is wanted. The almond, rich as it is in nitrogenous material, rich as it is in oily material, is just the article of food to meet his requirements, and palatable products, as a substitute for bread, may be prepared from it.

Medicinal Treatment.—As far as my experience goes, nothing contributes so much to arrest the disease as opium, morphia, and codeia. It is difficult, of course, to say, when you are treating a case with one of these remedies in conjunction with diet, whether the good result you get is not solely the result of dieting. But my own experience is to the effect that my practice, ever since I have been giving these, has been much more satisfactory than it was before I gave them. Clearly these agents appear to exert some power in controlling the disease. It is my custom when I get a patient of forty-five to fifty years of age to put him at once on small doses of opium, morphia, or codeia, and gradually increase. The sugar in the urine diminishes and usually disappears. After a while I permit the patient to take a little bread—say, two ounces a day. If he takes this without a return of sugar I let him gradually increase the quantity until he takes four or six ounces per day. Then I say to him you had better let well alone and stop at this, knowing how readily harm may be done by going beyond what can be taken without occasioning the passage of sugar. As long as sugar does not exist in the urine there is nothing to interfere with a healthy state being maintained. The patient is, to all intents and purposes, in a natural condition as regards his general state. It is only with the voidance of sugar that we get the symptoms of the disease and untoward results.

PRIMARY EPITHELIOMA OF THE ANTERIOR VAGINAL WALL, AND SUPERINVOLUTION OF THE UTERUS.

BY MILES F. PORTER, M.A., M.D.,

PROFESSOR OF GENITO-URINARY SURGERY AND SURGICAL ANATOMY IN THE FORT WAYNE COLLEGE OF MEDICINE.

I VISITED Mrs. P., in company with Dr. J. E. Stultz, whose patient she was, on April 16, 1887, when the following history was obtained: age fifty-eight years, born in England, mother of four children, family history unimportant, menstruated first at seventeen years, menopause at forty years. When fifty years of age, she felt as though a foreign body were in the vagina; and when her bowels moved, or when she urinated, she noticed that some blood "passed," which she supposed to be caused by "piles." This condition continued for some time, finally stopped for some months, when about December 25, 1886, while bathing, she noticed a growth on the external genitals.

Shortly after this, a profuse hemorrhage came on suddenly. These hemorrhages recurred at irregular intervals, until within the past two weeks, since which time no blood has been lost.

No bladder symptoms at any time, except for the past four or six weeks she has had to wait on the vessel a longer time than usual, before the flow would start, though the stream was always full size, and lately, to use the patient's language, "the water scattered."

About the time of the first severe hemorrhage pain commenced, and has been severe ever since. The patient was much emaciated, cachectic, pulse rapid and feeble, temperature 102° Fahr., no appetite, and on lifting the clothing for the purpose of making a digital examination, a fearful odor was perceived.

Digital examination convinced me that we had to deal with an epithelioma, which involved the anterior vaginal wall, and also the anterior part of the external genitals; that the upper extremity of the vagina was not involved; that there was no involvement of the pelvic or other glands; that the proper course to pursue, in view of the pain produced by the examination and the patient's history and condition, was to etherize her, make a more thorough examination, and if no contraindications were developed, to remove the growth as thoroughly as possible, with a view of stopping the fever, which was evidently septic in character, ameliorating the pain, preventing hemorrhage, and thereby prolonging life.

I was unable to discover any trace of the uterus by this first examination, but was able to define distinctly with the finger a depression or opening at the vault of the vagina, which would almost admit the tip of the finger.

The patient was etherized, and the growth removed with the scissors, knife, and curette, after a thorough examination had been made, which confirmed the conclusions drawn from the first, and revealed the further fact that the disease involved the peri-urethral tissues from the meatus to the neck of the bladder, though the urethra proper was not involved. The labia minora, anterior one-half of the mucous surface of the labia majora, clitoris, and anterior half of the vaginal wall for a distance of two inches from the vulva, were completely removed, while the urethra was dissected from the surrounding tissues up to the neck of the bladder, about one-half inch of the distal extremity cut off, and the extremity of the remaining portion brought down and fixed with silk sutures.

Careful examination by Drs. Myers, McCullough, and myself, both before and after the operation, failed to elicit any traces of a uterus, except the depression at the vault of the vagina noted above.

No probe was used, for fear of entering the abdominal cavity. As far as touch and sight could reveal, the growth was completely removed. The woman recovered slowly from the ether and the shock, and for three days was unable to control her water, after which time she had perfect control over it, and passed it without any difficulty whatever. Since the operation she has been free from pain, has had no fever since the fourth day, her appetite is good, and at present writing (May 14th), there has been no return of the growth, though I do not anticipate a permanent cure by any means. Strict antisepsis was observed in the operation, and in so far as possible, in the after-treatment. Hemorrhage was controlled by forceps, no ligatures being required.

The case is important, chiefly because of the rarity of primary epithelioma of the anterior vaginal wall, and because of the extreme degree of atrophy of the uterus. I can find in the literature at hand no record of a case which approaches this one in this respect.

How much of this atrophy is due to the process, called by Simpson super involution, how much to senile changes, and how much, if any, to the disease present in the vagina, are interesting questions which I will leave for others to discuss. Inasmuch as the meatus urinarius was involved in the disease, it is also rather singular, considering the duration of the malady, that the trouble had not travelled along the urethral mucous membrane to the bladder. I should have added, while speaking of the results of the operation, that there is at present but little discharge, and what there is, is free from any unpleasant odor.

A microscopical examination made by Dr. H. McCullough proved the diagnosis, as to the nature of the growth, to be correct.

106 Fairfield Avenue.

MEDICAL PROGRESS.

Antipyrin in Pregnancy.—Cheron reports the case of a young woman seven months advanced in pregnancy, who was attacked by typhoid fever. Antipyrin was given to reduce a temperature of 108° F. in two doses of seven and a half grains each, at intervals of five hours. The temperature fell rapidly to 94.1° F., attended by cramps, difficulty of speech, obscured sight, and general intellectual oppression. Heat and diffusible stimulants were required to rescue the patient from this condition. The remedy was again tried in six grains given in eight doses, at intervals of three hours; the collapse repeated itself. Still smaller doses were without either good or bad effects.—*Journal de Médecine*, July 31, 1887.

Iodoform Wicking.—Gersung, of Vienna, has found wicking impregnated with iodoform an excellent material for tampons in the drainage of wounds whose secretion is moderate; in Billroth's clinic wicking saturated with tannin and iodoform is used with excellent results. Its removal is much less painful and inconvenient than that of gauze.—*Centralblatt für Chirurgie*, July 30, 1887.

A New Peptone for Hypodermatic Injection.—Raynaud gives the following formula for a peptone made from blood, especially adapted for intravenous, or hypodermatic injection:

Pure blood albumen	gr. 75.
Dialyzed pepsine	gr. 12.
Distilled water	℥ 2ij.
Hydrochloric acid	gtt. ij.

The whole should be digested seventy two hours at a temperature of 110° F.—*Bulletin Général de Therapeutique*, July 30, 1887.

The Pupil as a Guide in Giving Chloroform.—Neilson considers the condition of the pupil a reliable indication of a patient's condition under chloroform anæsthesia, and concludes from his experiments as follows:

1. The effect produced by chloroform on the pupil is at first dilatation, varying in degree and duration, then contraction as the narcosis becomes profound, and dilatation again when the sensibility is returning. If the administration be still continued, with the pupil strongly contracted and motionless, the pupil will also dilate, but in this case more suddenly and completely, and will be coincident with a state from which it will be difficult or impossible to resuscitate the patient. This latter is the dilatation of asphyxia.

2. So long as the pupil dilates in response to excitation by pinching, etc., the patient is not sufficiently narcotized for the operation to be proceeded with, unless the latter is slight and does not require complete anæsthesia.

3. When the pupil becomes strongly contracted and immobile, no more chloroform should be given until it begins to dilate again. If, then, further anæsthesia be required, a little more chloroform should be given till the pupil again contracts.

4. The occurrence of sickness causes dilatation similar to, but more sudden than, that which happens when sensibility is returning, and the efforts of vomiting have the effect of arousing the patient.—*British Medical Journal*, July 30, 1887.

Neisser's Calomel Injections for Syphilis.—Harttung reports good results in ninety cases of syphilis from hypodermatic injections of calomel and olive oil, 1 to 10. Few abscesses, and trifling reaction followed.—*Centralblatt für klinische Medicin*, July 30, 1887.

Thymol as a Tænifuge.—Dr. Numa Campi has used this remedy successfully in ankylostoma duodenalis, which so frequently produces anæmia, especially among the miners of Italy. It is given as follows: The evening before its administration, after the last meal, ℥ss of castor oil is taken. The following morning, ℈2 of thymol are divided in twelve doses, at intervals of a quarter of an hour, followed by a second dose of oil. Should symptoms of depression arise from the thymol, a stimulant may be combined with it. Its action was always successful.—*L'Union Médicale*, July 14, 1887.

The Results of 1881 Cases of Diphtheria and 1000 Tracheotomies.—Guth, in an extensive collection of statistics, shows that from prior to 1882 the performance of tracheotomy in these cases has fallen from 71.3 per cent. and 68.6 per cent. to 49.5 per cent. at the Lazarus Hospital, in Berlin. Of those tracheotomized prior to 1882 from 65 per cent. to 83 5 per cent. died; since 1882 from 76 per cent. to 58 per cent. have died. The lessened rate of tracheotomy is owing to a milder epidemic; the improved results of tracheotomy are due to the adoption of Langenbuch's procedure; the insertion of a cotton-iodoform tampon, to which a ligature is attached, through the tracheal wound as far as the larynx.—*Centralblatt für Chirurgie*, July 30, 1887.

The Action of Eucalyptol on the Tubercle Bacilli.—Chabannes and Perret have made experiments with a five per cent. solution of eucalyptol to test its action upon tubercle bacilli. Sputum from the tuberculous was treated with the solution, and animals were then inoculated with it. Their experiments showed that eucalyptol has no effect upon tubercle bacilli; the animals died after inoculation with virulent tuberculosis.—*Centralblatt für Bacteriologie und Parasitenkunde*, Band ii. No. 5.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE. . . . . $5.00.
SINGLE COPIES. . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, SEPTEMBER 24, 1887.

SOME NEW OPERATIONS UPON THE INTESTINAL TRACT.

ONE of the most noteworthy incidents of the International Medical Congress was the reading of a paper by DR. SENN, of Milwaukee, entitled "An Experimental Contribution to Intestinal Surgery, with Special Reference to the Treatment of Intestinal Obstruction." The address was so voluminous, and dealt with so many different topics, that it is difficult to comprehend it in its entirety until we shall have an opportunity of studying it in print.

As the title implies, the work was entirely experimental in character, and while much is to be learned by comparative methods, still we cannot rely implicitly upon information gained in this manner, as the dog seems to be much more tolerant of intestinal mutilation than is man. It seems to us, however, that this work of Dr. Senn is of the very highest importance, and it reflects great credit upon him. It is not possible for us to do more than to notice a few of the problems which are sought to be elucidated.

It is well known that several operators have removed large portions of the small intestine without causing any special disturbance of the digestive functions; thus Kocher excised $5\frac{1}{2}$ feet, and Koeberlé $6\frac{1}{2}$ feet of bowel, the patients surviving and not experiencing any bad effects from the mutilation. One of the questions which Dr. Senn has sought to settle is, How much of the intestinal tract can be excised safely? He found that when more than six feet of the small intestine was resected the dog invariably perished from the immediate effects of the trauma, and that not more than four feet of bowel could be removed without causing such disturbances of digestion and nutrition that the animal soon succumbed. One dog upon which resection of a large portion of the small intestine was practised, lived some months, eating incessantly, consuming enough to feed ten dogs, and emaciating progressively until he died of inanition. Curiously the same impairment of nutrition does not follow the physiological exclusion of an equal length of bowel from the intestinal tract, as follows resection, and fecal accumulation does not occur in the excluded portion. The practical lesson to be deduced from these observations is that better results will follow the formation of an artificial communication between contiguous portions of bowel, in cases in which the obstruction may be allowed to remain, as a cicatricial stricture, for example, than will follow the performance of circular resection.

As every one who has had experience in intestinal surgery knows, time is a most important element. Many patients succumb to shock on account of the length of time required for the performance of intra-abdominal operations, who would survive if the duration of the exposure could be materially shortened. Not only does the long operation expose the patient to increased danger from the anæsthetic, from the chilling of the peritoneum, and from the extensive manipulation required, but the longer the exposure to the atmosphere, the greater the danger from sepsis; hence every effort to shorten the duration of these procedures is a move in the right direction. Owing to the length of time required for the proper execution of the Czerny-Lembert suture in cases of circular enterectomy, Dr. Senn has devised a modification of Jobert's invagination suture; the bowel having been cut squarely across: the intussusceptum is lined with a narrow, flexible rubber ring, and this being introduced into the intussuscipiens, the peritoneal surfaces of the latter are inverted by means of two catgut sutures, until they are in contact with the peritoneal surface of the intussusceptum, and firm union is effected in a few hours. In order to prevent any danger from perforation of the bowel, a graft, two inches in width, taken from a non-vascular portion of the omentum, is laid over the entire line of suture; this graft forms adhesions in twelve hours, and becomes vascularized in twenty-four hours. We believe this idea to be entirely original with the author, and is rational in its aim, and promises to be a great advantage in these cases. Perforation peritonitis has been the cause of death in a number of cases of pylorectomy, and other intestinal resections, and it is for the purpose of preventing this that the omental graft is recommended.

One of the most interesting portions of the address was in regard to the formation of intestinal anasto-

moses. This idea originated with Dr. Woelfler, of Vienna, who sought to overcome the effects of a carcinomatous stenosis of the pylorus, by forming a fistula between the stomach and small intestine; this operation, now known as gastro-enterostomy, has been performed thirty or more times with most satisfactory results in some cases, but the great length of time required for its performance is a very great disadvantage. Lücke, who has had the best results with gastro-enterostomy, consumes from one and a half to two and a half hours in its performance. Senn, in speaking of this operation, said it was a procedure which an expert might perform in an hour, but that by means of the method devised by himself a novice could do it in ten minutes. Starting with the idea that it is only necessary to bring broad surfaces of peritoneum together in order to have union occur, and that this union occurs quicker when the tissues are irritated by scratching with an aseptic needle, he effects apposition by means of two partially decalcified bone plates with a lumen corresponding to that of the fistula which is to be formed, and these are secured with four silk sutures. An incision is made into the stomach, and a bone plate slipped in, and each of the four sutures is passed directly through the stomach walls with needles. A similar opening is made into the intestine, a plate slipped in, and the threaded needles passed through its walls. The corresponding sutures are tied, and the stomach and bowel are brought into accurate contact. The plates eventually become absorbed, and the threads are discharged, leaving a permanent fistula. The same principle can be applied to the formation of an "intestinal anastomosis" in any portion of the tract, and this recommendation is a distinct advance in the treatment of many of the surgical affections of the intestine.

This operation is recommended in all cases in which it is either impossible or unadvisable to remove the obstruction, provided the cause of the stenosis is not *per se* a source of danger. In some cases a lateral implantation of the small intestine into the large intestine is recommended, which is performed as follows: a slit is made in the colon, and the cut end of the small intestine, which has been lined with the rubber ring previously mentioned, is slipped into the slit and secured with a few sutures; thus we may have an ileo-colostomy or ileo-rectostomy, and this method is applicable to all parts where the resected portions do not correspond in calibre. As has been stated, these procedures have only been practised upon animals, but if it shall be found that they are equally as successful upon man, a revolution in the treatment of intestinal lesions is bound to follow. Let us hope that this desirable result will be effected.

YELLOW FEVER VACCINATIONS.

The profession will await with great interest the report of Dr. Sternberg, the Government expert, recently sent to Brazil to study the methods of vaccination against yellow fever introduced by Dr. Freire, whose most recent communication we presented to our readers in last week's issue. It is satisfactory to note, in the first place, that he has been able to demonstrate the microbe to so reliable an authority as Professor Cornil, of Paris; for there have been serious, and not unnatural doubts, whether he was dealing with any definite microörganism. Certainly the figures of the plates of his large work, published in 1885, were in themselves sufficient to discredit the entire research, and we are not surprised at Cornil's reproach, to which he alludes. There were indications, then, of an untrained, unscientific mind, and the confusion expressed in the present paper between *cryptococcus* and *micrococcus* is astonishing in any one professing to be a skilled bacteriologist. It is claimed that the organism is a chromogenic micrococcus (?), producing two different pigments, one yellow and the other black, the former staining the tissues, the latter appearing in the vomit. The description which he gives of it, is exceedingly indefinite, and in no particular will Dr. Sternberg's work be more welcome than in a clear and accurate definition of the structure and relations of this organism.

The vaccine is prepared by first passing the virus through six or seven guinea pigs, and then cultivating in beef-broth or gelatine. At the tenth or twelfth generation from the primitive microbe the virus is found to be sufficiently attenuated for purposes of vaccination. The practical results of the investigations are of extreme interest, and the figures which he gives of the vaccinations during the years 1885 and 1886, impress us much more than any other part of his work. A mortality of only 8 in 6524 vaccinations, means that either insusceptible persons were the subjects, or else that we have here in reality a mitigated virus capable of protecting against this terrible scourge; and let us hope that Sternberg's researches may confirm this latter view.

FLANNEL VERSUS RUBBER BANDAGES.

There are contingencies constantly arising in which it becomes necessary to apply a bandage, and it depends much upon the skill with which it is applied, as to whether beneficial, negative, or positively bad results are to follow. A properly applied bandage gives comfort, and in numerous instances exerts a positively curative effect, and this effect may be materially influenced by the fabric out of which the bandage is made. It is not a matter of indifference as to the material used for the bandage. In many instances muslin torn into narrow strips is used for

all purposes; but it is as rational to use one drug exclusively in the treatment of any given disease as to use the same material in every case in which it is desirable to apply a bandage.

For the retention of wound-dressings, thin materials, as gauze, or cheese-cloth, are much preferable to muslin, as they can be applied better, and do not slip so easily; whilst for the retention of splints, in the treatment of fractures, there is a tendency to replace bandages with adhesive plaster, which holds more firmly, and has the advantage of leaving the seat of injury open to inspection. When firm compression is desired, as in the treatment of ulcers of the lower limbs, muslin is generally used; but of late years it has become fashionable to use Martin's pure rubber bandage, especially when there is a varicose condition of the veins; and it must be admitted that, in many instances, admirable results are obtained by its use. It has, however, some very great disadvantages, due to the fact that the secretions of the skin cannot pass through the bandage, and the limb is constantly bathed in perspiration. This is not only unpleasant, but—in hot weather especially—the parts become offensive, and unless great care is exercised, and even when every precaution is taken in some cases, an eczematous condition is produced, which is distressing to the patient and aggravating to the local affection. Aside from these objections, the heat of this bandage is very unpleasant during the summer. For these reasons we prefer a good quality of flannel to any other material for bandaging the limbs.

Flannel absorbs the perspiration, and neither produces nor aggravates an eczematous condition of the skin; it is sufficiently elastic to supply the pressure which may be desired, and the roughness of its surface effectually prevents its slipping. It is the coolest bandage which can be effectively applied, owing to its capacity for absorption, and, in our experience, has answered a better purpose than any other material.

The Volunteer Medical Corps during the recent three-days' Constitutional Centennial Celebration at Philadelphia reported 384 casualties, of various degrees. The list includes a fatal fracture of the skull; a fatal fracture of the ribs and sternum; a fracture of the wrist and ankle; 7 lacerated wounds; 1 uterine hemorrhage; 20 cases of epilepsy; several quotidian agues; numerous cases of syncope and exhaustion from overexertion; and 1 case of acute dementia. In view of the large number of people who were collected on the line of the procession, the relatively small number of accidents speaks well for the character of an American crowd, and is in marked contrast with the 600 casualties reported on the single day of the Queen's Jubilee in London.

Great credit is due to Medical Director Cleborne and his efficient staff for the admirable manner in which the details of the medical service were carried out. The presence of the medical officers with their ambulances, stationed at short intervals along the route, gave a feeling of security to the spectators and added in no small degree to their peace of mind.

The new building of the College of Physicians and Surgeons of New York, will be inaugurated on next Thursday, with an Historical Sketch of the College by Dr. J. C. Dalton, and an Inaugural Address by Joseph H. Choate, Esq.

The subscriptions toward founding the Pasteur Institute at Paris now amount to 1,872,625 francs.

The late French journals announce the death, at Paris, of M. Giraud-Teulon, one of the most eminent of French ophthalmologists.

SOCIETY PROCEEDINGS.

AMERICAN GYNECOLOGICAL SOCIETY.

Twelfth Annual Meeting, held at New York, September 13, 14, and 15, 1887.

(Specially reported for The Medical News.)

Wednesday, September 14th.

Dr. C. D. Palmer, of Cincinnati, read a paper on

THE THERAPEUTIC VALUE OF SOME MEDICINES IN THE TREATMENT OF HEMORRHAGIC CONDITIONS OF THE UTERUS.

Referring to the fact that gynecology has assumed a decidedly surgical tendency, he said that too little attention has been paid to the less brilliant medicinal treatment. Uterine hemorrhage can often be treated advantageously by means of drugs, such as ergot, digitalis, cannabis indica, bromide of potassium, arsenic, and gallic acid. Ergot is especially useful in cases of chronic hyperæmia and subinvolution of the uterus, attended by menorrhagia, where the organ is soft and relaxed, and of interstitial and submucous fibroids. Hemorrhages due to fungous endometritis, ovarian and parametritic inflammation are not favorably affected. Digitalis is useful in uterine hemorrhage due to cardiac disease.

Cannabis indica is an uncertain drug, acting rather upon the nervous system. Bromide of potassium is a sedative in ovarian irritation and congestion and thus is useful in certain forms of menorrhagia, as well as in the treatment of hemorrhage from subacute and chronic pelvic peritonitis.

Arsenic acts by improving the general condition, and hence is of value in the menorrhagia of young women and at the climacteric, also in malarial conditions. He gave Fowler's solution in three minim doses. Active cathartics often exercise a favorable effect in checking uterine hemorrhage, especially if there is evidence of obstruction to the circulation from habitual

constipation. In general, the administration of iron during the intermenstrual period is not advisable, unless the patient is markedly anæmic.

Hydrastis Canadensis has been highly recommended as a hæmostatic in uterine hemorrhage from any cause. Garrigues has obtained good results with *gossypium herbaceum*, especially in cases of fibroid tumor. Hamemelis is inferior to ergot for the relief of sudden hemorrhage, but is useful in the treatment of long-continued flux, where the hemorrhage being of a passive character, the uterus is soft and flabby.

DR. FORDYCE BARKER said that he had found arsenic to be a valuable drug in the treatment of hemorrhages, of excessive flow at the time of the menopause, where vasomotor irritability was especially prominent. It exerts a direct influence upon anæmia of vasomotor origin. He is accustomed in treating such cases to administer full doses of the bromides during the time immediately preceding the flow, giving arsenic during the intermenstrual period.

Hydrastis Canadensis is of most value if given after the flow has begun. If there is marked vasomotor irritability he adds five or six minims of the tincture of nux vomica. Viburnum is a useful drug in menorrhagia and metrorrhagia, where the hemorrhage is of a passive character, especially in early pregnancy, and in threatening abortion; it is a valuable uterine sedative.

He agreed with the author as to the importance of relieving the portal circulation, which was accomplished by the use of mercury and saline laxatives. In cases where the uterus was large and flabby, iron and opium should be administered during the intervals between periods.

DR. LLOYD ROBERTS, of Manchester, said that he did not have much confidence in any drug but ergot in the treatment of passive hemorrhage from the uterus. It is important to use a good preparation. He inferred that the author did not reject local treatment. He had often found that by giving ergot in the intermenstrual period more good was accomplished than when it was administered only during the fever. He thought that quinine was more useful than arsenic in menorrhagia of malarial origin. Gallic acid is the next best remedy to ergot in hemorrhage from mucous membranes. Might not its value be directly due to its local effect? Bromide of potassium is only useful in ovarian congestion, or in conditions where the nervous element is prominent.

DR. BALLS-HEADLEY, of Melbourne, thought that it was important that prominence should be given to the medicinal treatment of pelvic affections. He did not see how the remedies acted *per se*. For instance, in the case of fibroid tumors, the vessels around the exterior of the tumor are so large that it is difficult to see how they can be affected by muscular contraction, since the muscular fibres cross in so many different directions. We must know exactly where the tumor is located, else there may be danger that the tumor will be expressed into the peritoneal cavity, instead of into the cavity of the uterus. He had given ergot for years, and did not have the slightest faith in it. We must consider the natural history of these tumors; some remain stationary for years. He had tried local applications of ergot without result. He had used the tincture of the chloride of iron in half-drachm doses thrice daily with good effects.

DR. GRANT (Bey), of Egypt, reported a case of uterine hemorrhage, in a syphilitic patient, which was cured by mercurial treatment after all other hæmostatics had been tried in vain. The patient had a large fibroid tumor which also disappeared under the administration of mercury.

DR. H. R. C. WILSON, of Baltimore, had little confidence in any uterine hæmostatic. In young girls with irregular and excessive menstruation it is necessary to care for the general health. Obstinate constipation is a common cause of uterine hemorrhage. He depends most on ergot when the uterus is flabby and relaxed.

DR. CHADWICK, of Boston, had found chian turpentine to be especially valuable. In one case, a young lady had been flowing for two years, and had been treated without effect. Under six grain doses of the turpentine, repeated thrice daily, the hemorrhage ceased promptly. He believed that it is better to give ergot between the periods, and aromatic sulphuric acid at the time of the flow.

DR. REID, of Glasgow, said that in flabby, anæmic patients, where no marked local disease could be found, he had given twenty grains of alum daily with good results. He had used gallic acid, but without benefit. The iodide of arsenic had been useful in his hands.

DR. PALMER closed the discussion by saying that he had been surprised at the indiscriminate way in which these remedies had been employed. He had endeavored to lay down a few rules which might serve as a guide in using them.

DR. DOLÉRIS, of Paris, delivered, in French, an address on

ALEXANDER'S OPERATION,

of which the following is a very brief abstract:

He first described the normal supports of the uterus. These are twofold, the tissues forming the pelvic floor, and the uterine ligaments, the former being the principal support. According as these supports are weakened, displacements of the organ may occur, which vary in their degree from simple retroversion to complete procidentia. The minor degrees of prolapse may be cured by restoration of the pelvic floor and vaginal outlet alone; this is also true of cases of prolapse combined with anteversion. For the other displacements shortening of the round ligaments, combined with posterior kolpo-perineorrhaphy, offers an efficient means of restoring the organ to its normal position and retaining it there. He alluded to the results of his experiments on the cadaver, and to the success which had followed his operations on the living subject. From his early position as a sceptic on the subject, he had come to place great confidence in the operation popularized by Alexander.

DR. REID, of Glasgow, said that he had no doubt of the value of the operation in suitable cases, but we should remember that the *position*, not the *condition* of the uterus was altered. Months might pass before much benefit was felt. He thought the external ring should be clearly exposed, then, by pressing on the canal above, the fat and fibres of the cord would be found.

He had never failed to find it in fourteen cases. The after-treatment is very important; the patient must be kept in bed for six weeks, and must wear a pessary for at least six months more.

DR. MARTIN, of Berlin, said that the operation had been done only a few times in Germany, perhaps not more than a dozen. He was pleased to see that M. Doléris had changed his opinion favorably with regard to the operation. He would himself perform it in a suitable case, but he had had a large experience with prolapsus and had found that in most of the cases the patient had no serious symptoms. He did not believe that the round ligaments alone support the uterus, since the pelvic floor is the true support. Hegar was the first to point out that only by restoring this floor could the displaced organ be kept in position; his operation on the posterior wall accomplished this.

DR. LUSK, of New York, said that he had been very slow to accept the operation, but after watching Dr. Polk operate he had been led to perform it several times. It was free from danger, and there was no reason why it should not be employed in the case of workingwomen, where pessaries had been tried in vain. The paper was especially valuable in laying down positive indications for the operation. There was no doubt that in aggravated cases anterior and posterior kolporrhaphy did not keep the uterus in place. He had performed Hegar's operation for several years, but it was not sufficient.

DR. H. MARION SIMS, of New York, said that he had performed Hegar's operation a number of times with good results.

DR. LEE, of New York, had performed Alexander's operation nineteen times, and had found it particularly useful in cases where pessaries could not be borne, by reason of chronic salpingitis, and where the uterus was large and procident. In the latter cases it is absolutely indispensable to perform Emmet's operation on the perineum simultaneously. He highly endorsed the operation in properly selected cases. Hysterorrhaphy is useful where the uterus is adherent, but it is much more serious than Alexander's operation and can never take its place.

DR. LAWRENCE, of Bristol, England, had not performed the operation himself, but had seen a number of cases in which, after the lapse of several months, the patients were little, if any, improved.

DR. KELLY, of Philadelphia, thought it was folly to expect a heavy uterus to be suspended by the round ligaments alone, when the vaginal canal was patent. When there was a large, heavy uterus an operation must be performed first, in order to narrow the vagina. When this has been done, the fundus could be held in position by a slight attachment. The trouble in the Alexander-Adams operation was that, in lifting the heavy, procident uterus, its entire weight was thrown upon the ligaments; the same was true in cases of old retroflexion. He had recently performed hysterorrhaphy successfully, and twelve successful cases had been reported in Germany.

DR. DOLÉRIS, in closing the discussion, repeated that when the uterus was anteverted and procident, the plastic operation on the vagina was sufficient, without shortening of the ligaments.

DR. ALEXANDER J. C. SKENE then delivered the

PRESIDENTIAL ADDRESS.

Just twelve years ago, he said, the American Gynecological Society was organized in the Academy of Medicine, Dr. Fordyce Barker presiding. The idea of founding such a society had been conceived by Dr. Chadwick, of Boston. The results had been highly gratifying, since the organization could now compare with any in the world. It had served to promote not merely an interchange of ideas on scientific subjects, but social intercourse among its Fellows. The fact that men of science were becoming united in one grand family was proved by the fact that there were present at the meeting representatives of nearly all parts of the civilized world, a circumstance which was not possible in the past.

He alluded to the fact that modern gynecology was not much more than seventy-five years old, yet wonderful progress had been made in it, especially in the department of surgery. At least ten of the most heroic operations in surgery were gynecological; over 780 gynecological instruments had been devised, exclusive of the different varieties of needles and sutures. About three hundred different pessaries were in use. During the last three-quarters of a century about six thousand books on diseases of women had been published, and in the past eight years seven thousand five hundred and five journal articles and pamphlets on this subject had appeared.

The new antiseptic method had added remarkably to the successful results of surgical gynecology. Surgery still held too prominent a position, however; but it would eventually find its true position. The time would come when enthusiastic surgeons would stop and consider what was the real value of their work, while greater prominence would be given to the medical treatment of functional and organic diseases.

DR. GEORGE GRANVILLE BANTOCK, of London, then read a paper on

THE TREATMENT OF THE PEDICLE IN SUPRAVAGINAL HYSTERECTOMY.

He said that in his first case of hysterectomy he had divided the pedicle by means of the cautery, according to Baker Brown's method, but, on removing the clamp, the hemorrhage was so profuse that it was necessary to ligate the broad ligaments separately. The stump was then tied in two portions and secured at the lower angle of the abdominal wound, but was left within the peritoneal cavity. The ligatures slipped, oozing into the peritoneal cavity occurred, and the patient died of septicæmia on the fourth day, in spite of the strict observance of antiseptic details. This manner of treating the stump is the very one so strongly commended by Sänger and Schröder, but he had been so impressed with its fallacy that he resolved never to try it again. In the next case he used Cintrat's serre-nœud, but found it inefficient, and was obliged to substitute Koeberlé's for it, which he subsequently changed for the instrument which he now uses. He had found that fine, soft iron wire was preferable to either copper or steel.

Several cases were cited at length, showing the efficiency of the serre-nœud in completely controlling the hemorrhage during the removal of large tumors. In

one instance the reader neglected to apply the supporting pins before excising the fibrous mass, and, although the stump was encircled by the wire of the écraseur, it slipped through the loop and fatal hemorrhage occurred. In one successful case the pregnant uterus was removed together with a fibrocyst weighing thirteen pounds. In his forty-fifth case he applied the serre-nœud just below the level of the ovaries and partially tightened it, then included the broad ligaments in long hæmostatic forceps, thus securing the large vessels. The peritoneal covering of the uterus and tumor was then divided three inches from the wire loop and was reflected toward the latter. After tightening the loop, the pins were inserted an inch from the wire, and a second serre-nœud was applied just behind the pins, after which the first was removed. In this an additional half-inch was gained in the pedicle, and the strain on the broad ligaments was relieved.

In a subsequent case this method was still further modified by first reflecting the peritoneal envelope, while temporarily securing the broad ligaments, and then applying the loop; the ovaries were subsequently ligated separately. Where the broad ligaments were redundant, and were thrown into folds in tightening the loop, it was important not to trim it away until it was secured by several hæmostatic forceps, preparatory to stitching it over the stump, otherwise the divided fold might escape from the loop and give rise to hemorrhage. By uniting the edges of the peritoneum across the stump, this retraction was prevented, when from the shrinking of the tissues the loop became loosened.

The treatment of the stump after supravaginal hysterectomy is a very different thing from that of the ovarian pedicle, yet the two have been regarded as identical. The differences are great. He had no fixed prejudices in the matter, but simply spoke from the results of his own experience, when he said that the intraperitoneal method has been as uniformly disastrous as the extraperitoneal has been successful.

To summarize, the following conditions may be presented:

1. The broad ligaments may be so long and the ovaries so easily raised from the pelvis that the whole can easily be included in the loop.

2. One ovary can be included, while it will be necessary to ligate the other separately.

3. Both ovaries must be ligated separately.

4. The tumor may grow between the folds of either broad ligament, so that it must be partially enucleated.

5. The tumor may be situated so low down in the body of the uterus that it will be necessary to separate it largely from its peritoneal covering before a sufficient pedicle can be formed.

The proper recognition and management of these complications severely test the judgment and coolness of the operator, and can only be learned by experience.

In regard to the after-treatment of the stump, he said that, if it was properly secured at the time of the operation, the less it is interfered with the better. He had sometimes allowed two weeks to elapse before disturbing the dressings. The main object is to keep the stump dry, therefore the dressings should be changed as soon as they become moist. Perchloride of iron should not be applied to the stump, because it is unnecessary and may be injurious. If the wire is properly applied at the time of the operation, it will not be necessary to tighten it again for four or five days, unless there is marked oozing; if the pedicle is small it is not necessary to tighten the loop at all. There is no hurry about getting rid of the stump so long as it remains dry; if pus should begin to ooze from around it after the lapse of a week, it may be treated with iodoform, or the hole may be washed out with a solution of one part of sulphurous acid in nine parts of water, until the sloughing tissue has been removed, the opening being subsequently filled with a mixture consisting of equal parts of glycerine and alcohol, the latter arresting suppuration and promoting healthy granulation.

Appended to the paper was a table showing 45 recoveries out of 57 cases in which the pedicle was treated extraperitoneally, with 4 deaths out of 5 in which it was treated intraperitoneally.

On motion, the discussion of this paper was postponed until the following day.

AFTERNOON SESSION.

DR. JAMES B. HUNTER, of New York, reported

A CASE OF ACUTE DILATATION OF THE STOMACH FOLLOWING LAPAROTOMY.

The operation consisted in the removal of both tubes and ovaries for disease of the latter organs of several years standing, which occasioned severe dysmenorrhœa. The patient vomited at intervals after the operation until her death, which occurred on the eighth day, the vomiting being peculiar, in that large quantities of fluid were regurgitated without much straining. The abdomen became greatly distended and tender, the temperature rose to 101°, and it was supposed that she had succumbed to a low form of peritonitis. The autopsy revealed extreme dilatation of the stomach, the organ filling the abdominal cavity and extending to within three inches of the symphysis, while the intestines and omentum were crowded into the pelvis. There was no evidence of old or recent peritonitis. Death was clearly due to exhaustion. The stomach contained over a gallon of fluid and showed marked atrophy of its coats, especially of the muscular. The natural inference was that there had been a long-standing gastritis, which led to an atonic condition of the organ, and that the latter under the influence of some causes acting after the operation suddenly dilated. The history of the case, and the results of the physical examination, showed that the enlargement had taken place after the operation. There was no pyloric obstruction. What these causes were it is difficult to say. It might have been due to the poor condition of the patient, the vomiting, or (as explained by Morris) to the rapid secretion and accumulation of gastric fluid. The patient had had an omental hernia, a condition which Kussmaul believed favored, or directly caused dilatation, by reason of the direct traction exerted on the fundus of the stomach.

He remarked that two questions suggested themselves in connection with the case, viz.: Could the complication have been foreseen before the operation, and ought it to have been recognized and treated subsequently? While it would have been impossible to foretell the sudden dilatation, the case taught the lesson that every patient who was about to be exposed to the

risks of laparotomy should be thoroughly examined, since only in this way could the integrity of every organ be assured. Gynecologists were too apt to confine their attention exclusively to the pelvis, at the risk of overlooking complications in thoracic or abdominal viscera.

In reply to the second question, it must be urged that the condition of the stomach was so very rare that it was quite excusable to mistake it for the obscure form of peritonitis which is so frequently encountered after laparotomy. Treatment would have been of little avail considering the condition of the patient, still it was possible that if the dilatation had been recognized earlier and the fluid had been removed by the stomach-tube the patient might have been saved.

In conclusion the author referred to the rare occurrence of the complication and cited reports of similar cases by Fagge, Goodrich, Morris, and others, Morris's case being almost identical with the one described in the paper.

DR. A. REEVES JACKSON, of Chicago, read a paper on

THE INTRAUTERINE STEM IN THE TREATMENT OF FLEXURES.

He confined his remarks to a limited class of cases. Many forms of flexion require no treatment, others are not improved, and still others are only made worse. He had not been satisfied with the results of incision and dilatation. He had used the stem for many years without bad results. Dysmenorrhœa is the main indication for treatment, sterility being a secondary consideration. His method of treatment is first to dilate by means of graduated bougies, then after a menstrual period he inserts a soft rubber stem, and keeps it in position by means of glycerine tampons. After six weeks a larger stem is used. As soon as the uterus becomes straightened, a permanent stem of vulcanized rubber is introduced, Chamber's bifurcated stem being especially useful. Recently he had employed one which did not separate at the end. This hard stem is worn for three months, and is then removed. The patient is examined in the course of a few weeks, and if the uterus remains in position it is removed. The success of the treatment lies in its *gradual* character.

The use of the stem had been severely condemned, but clinical experience showed its value. The speaker had seen great benefit, dysmenorrhœa and sterility being both removed. Many hold that pelvic inflammation is the main cause of pain in flexions, but the reader did not believe in the doctrine of such frequent inflammation. The stem when carefully used is no more dangerous than an intrauterine application. He had never seen any inflammation follow the use of the stem in his hands. The great trouble is that men try to straighten the organ too rapidly and forcibly, and without reference to the existence of subacute inflammation. He never uses a stem unless there is dysmenorrhœa; when the flexion is due to a fibroid or to pelvic inflammation, it should not be used. Out of sixty-seven cases treated with the stem, forty-one were cured. The conditions necessary for success are watchfulness, patience, and slow progress.

DR. OGDEN, of Toronto, was in accord with the paper. The uterus must always be straightened gradually, or harm would be done. If the organ is gradually accustomed to a foreign body, the result will be different, than if the stem is introduced at once. The speaker used tampons of dry cotton, dusted over with boracic acid, as it gives a better support than moist cotton.

PROF. LAWRENCE, of Bristol, said that in England stem-pessaries are received with general disfavor. His own plan of treatment is to proceed very slowly, dilating gradually with bougies, and then introducing a stem expanded at its upper end. He cited the case of a married lady who had been sterile for fourteen years, and who became pregnant after straightening the uterus. The main thing was to be sure that the whole trouble was due to the flexion.

DR. JACKSON closed with the remark that it is impossible to introduce pessaries into the canal of a flexed uterus, at least in the case of some American women.

DR. APOSTOLI, of Paris, read, in French, a paper on

SOME NEW USES OF THE CONSTANT CURRENTS IN GYNECOLOGY.

Alluding to the fact that loose and empirical methods of employing electricity in medicine had given place to the use of regular mathematical standards for regulating its strength, he compared the galvanometer to the balance in chemistry. Now, in employing the continuous current, it is always necessary to take into account two factors, the duration of the application and the intensity of the current expressed in milliampères. Thanks to the technique now adopted, it is possible to use a much higher dosage than formerly: when strong currents are employed, there is a caustic action at each pole, while the "trophic action," or nutritive changes will increase in the same proportion. In galvano-caustic applications within the uterus, it is intended that one pole shall cauterize freely, while the other, which is placed upon the skin, must be carefully watched, in order that it shall not cause pain and vesication. This is prevented by giving to the indifferent pole a large surface, so that the current shall be distributed over a large extent of skin, as well as by keeping it moist. By using the reader's pole, constructed of glazed earth, it is possible to apply currents varying from fifty to two hundred and fifty milliampères without causing pain or injury to the skin. This has made galvanism a valuable agent in uterine therapeutics.

Formerly, local applications were confined to the cervix uteri, now we know that it is the mucous lining of the body of that organ that forms the seat of inflammatory processes, dangerous by reason of the readiness with which they are transmitted to the appendages. It is necessary to attack the diseased mucosa directly, which can be done more safely and thoroughly by means of the constant current than by the curette; the former accomplishes the results more slowly, but surely, not only curing the endometritis, but also dispelling inflammations of the parenchyma of the uterus. The reader began, in 1882, to practise electrolysis in cases of uterine fibroid, his treatment being mainly directed to the interior of the uterus, for the following reasons:

1. The endometrium is nearly all diseased in cases of fibroma, and hence the hemorrhage will be checked by cauterizing it.

2. By modifying the nutrition of the mucosa, that of the adjacent neoplasm is also affected.

3. By introducing one pole into the uterus, the ope-

rator would be able to place the organ directly in the current. The reader was invariably accustomed in all forms of metrorrhagia, to place the positive pole within the uterine cavity, using the negative pole in other cases. As the result of his experience in nearly three hundred cases, he was ready to affirm that from ninety to ninety-five per cent. of fibrous tumors would, under this treatment, when continued from three to nine months, decrease in size from one-fifth to one-half, while the hemorrhages would be quickly and permanently arrested and the pressure symptoms would disappear.

The sphere of the constant current in gynecology was not confined to the treatment of endometritis and fibrous tumor of the uterus; its future was a great one, and the reader believed that it would in time constitute the principal curative agent in the medical treatment of pelvic troubles.

Dr. Chadwick said that he had followed the author's method of treatment during the past six months, but had not met with satisfactory results. In one instance the size of the uterus was definitely reduced after a few applications; in another, after eighteen applications, there was no appreciable change. In two instances pain and fever were produced, and two cases terminated fatally.

Dr. Apostoli closed by repeating that he had treated over three hundred patients by electricity for the relief of various pelvic affections, and very rarely seen any serious results follow the applications.

Dr. Chadwick, of Boston, read a paper on

THE OPERATION FOR VENTRAL HERNIA AFTER LAPAROTOMY.

He said that hernia usually appears a year or more after the operation. Supporting bandages do but little good. The symptoms are pain and dragging sensations in the abdomen. Strangulation does not occur, due to the fact that the neck of the hernia is large and yielding. If intestines or omentum are adherent, the hernia cannot be reduced. Hernia is more frequent than is supposed, but the data are imperfect. The incisions are now quite short, the wound heals better, and the pedicle is treated intraperitoneally, so that the abdominal wall is shorter.

The use of the drainage-tube may cause hernia. The prevention of this accident is highly important. Some operators close the peritoneum separately. Dr. Wylie has called attention to the importance of drawing up and uniting the edges of the divided fascia. The union of the fascia is the most important obstacle to hernia. The sutures must be placed near together, and the abdominal tension must be diminished immediately after the operation. Laxatives should be used only to this end.

Simon used to operate on these hernia without opening the abdominal cavity. This method was imperfect, as it did not result in union of the fascia. As regarded the operation for repair, it was merely an explorative incision, with the exception that in hernia the peritoneum might, or might not, be adherent. If intact, should it be opened, or simply pushed back into the cavity?

The muscles and fascia would be found to have retracted, and should the peritoneum be separated from them? Wylie dissected off the peritoneum; Hoffer sutured the peritoneum, fascia, and recti separately; Maydl denuded the edges of the recti muscles and sutured them. The author, in his case, had sewed the peritoneum separately.

[Dr. Chadwick then read the report of a case in which he had operated successfully for ventral hernia after laparotomy, and showed photographs.]

The discussion was adjourned to the following day.

THE BUSINESS MEETING

was held in the evening. The following were elected

OFFICERS FOR THE ENSUING YEAR.

President.—Dr. Robert Battey, of Rome, Ga.

Vice-Presidents.—Drs. James R. Chadwick, of Boston, and A. Reeves Jackson, of Chicago.

Secretary and Treasurer.—Dr. Joseph Taber Johnson, of Washington.

Members of Council.—Drs. F. P. Foster, of New York, C. D. Palmer, of Cincinnati, J. B. Hunter, of New York, and R. S. Sutton, of Pittsburg.

The following were elected

FELLOWS.

Dr. Howard A. Kelly, of Philadelphia; Dr. Horace T. Hanks and Dr. Bache McE. Emmet, of New York; and Dr. R. P. Kinloch, of South Carolina.

It was resolved to hold the next meeting in Boston, on the third Tuesday in September, 1888.

(To be concluded.)

NINTH INTERNATIONAL MEDICAL CONGRESS.

Held at Washington, September 5–10, 1887.

(Specially reported for The Medical News.)

SECTIONS.

Obstetrics.

WEDNESDAY, SEPTEMBER 7TH.

DISCUSSION ON CÆSAREAN SECTION.

Professor Simpson, of Edinburgh, in opening the discussion, expressed himself as very largely in accord with the views so clearly formulated by Professor Lusk in his able paper, further illustrated by Dr. Sänger and Dr. Wathen. He wished to maintain for the obstetrician and the general practitioner the right still in certain cases of difficult labor to break up the head of the child to save the mother's life. Certainly the cases are few, in which the sacrifice of the child's life is demanded, and they are becoming more rare as the sanitary conditions of population improve. In Edinburgh, rickets even is becoming very rare; and as for malacosteon, the only case he has seen for many years occurred not in a pregnant woman, but in one who suffered from dyspareunia in consequence of the narrowing of the pubic arch. The result is that the indication for any form of head reduction is very seldom met with.

But this also narrowed the opportunity for gaining experience in the Cæsarean operation. He had no doubt that the field of application of laparotomy would extend with the appreciation of the conditions under which it can be successfully carried out. It is important in regard to the prognosis to differentiate between two groups of cases. In the first, the practitioner does not get the chance of operating until the woman is exhausted, the child may be dead, and dangerous septic processes are already at work. In such cases, it sometimes gives the patient the best chance of recovery to

open the abdomen and uterus, and without regard to his own reputation the practitioner finds it his duty to give her that one chance. In the other group of cases, the practitioner has the patient under observation before labor sets in, and can choose his time and mode of interference. In such cases a successful result may almost always be expected, and when Sänger and Leopold have diminished the mortality of the method with the sero-serous suture, he (Prof. S.) believed that most obstetricians would feel themselves constrained to adopt the Sänger method in carrying out the operation. The Porro procedure will still have its application in a few instances, as when the uterus is damaged, or the seat of disease; but he thought Professor Lusk had rendered a good service in impressing on the profession the importance of attaining clear impressions as to the conditions of safety in Cæsarean operations.

Dr. A. Martin, of Berlin, summarized his remarks in the following propositions: The abdominal operation is indicated,—1. When it seems impossible to bring a living child through the pelvis in any way. (Take care not to operate too soon!) 2. In cases of neoplasmata; myomata narrowing the canal, or endangering the progress of parturition; carcinomata colli. 3. Other reasons: diseases which show the lives of mother and child endangered by the process of parturition and puerperium.

What operation? Cæsarean section when we can hope that the patient may be able to become pregnant again, even if the operation must be repeated. The Porro operation, or total extirpation, when the character of the tumor, or its seat, or the disease is necessarily fatal.

Dr. Balls-Headley, of Australia, said that the main points in this class of cases are a clear diagnosis that the child cannot be born through the natural passages and a determination to carry out the necessary operation without attempting measures believed to be futile. He limited himself to the two conditions—cancer of the cervix and contraction of the pelvis. Twenty years ago, he assisted Dr. Greenhalgh, of London, in a case of Cæsarean section on account of epithelioma of the vaginal portion. The child and mother survived; the cancer subsequently disappearing. Recently he had seen a case of labor, the cervix the seat of malignant infiltration. He thought craniotomy, with nicking of the cervix, would meet the indication, and the operation was performed. The cervix was rent, and the woman died. In such a case, he would now extirpate the womb.

At a little village, near Bonn, diseases of the bones were frequent, and he remembered one woman who had been the subject of the operation six times. At the beginning of this year, a dwarf, four feet high, came to him. She was in the seventh month of pregnancy. The true conjugate diameter measured one inch. At the ninth month, he performed Porro's operation, mother and child surviving. The membranes were found to be adherent, and in view of the certain inability of escape of discharge by the os, it is quite probable that had the uterus not been removed, the patient would have died. The operation was easy, occupying only twenty-five minutes.

Dr. W. W. Jaggard, of Chicago, said, with reference to the *relative indication* for Cæsarean section—that is, a pelvic contraction in which the conjugata vera measures 2½ to 3⅛ inches—1. Craniotomy does not require any higher degree of operative skill than it is fair to presume every qualified obstetrician possesses, provided good instruments are employed—for example, Carl Braun's curved trepan and cranioclast. 2. The mortality of the operation in pelvic contractions of 2½ to 3⅛ inches, when the woman has not been antecedently infected, and average skill with antiseptic precautions is applied to good instruments, is, as remarked by Barnes, practically *nil*. The statistics of the Vienna school abundantly demonstrate the truth of this statement. 3. An essential condition to the relative indication for Cæsarean section is the consent of the mother, obtained without direct or indirect coercion. He had never seen a woman elect Cæsarean section, when all the facts in the case had been fairly and honestly presented to her. 4. He was under the impression that there is much sentimentalism in the recent extraordinary interest in the child's as compared with the mother's life. The satisfaction of saving the child by Cæsarean section is akin to the delight experienced after the successful performance of a difficult scientific experiment. This interest ceases so soon as the fact of the birth of a living child has been demonstrated to witnesses and the case recorded as successful. As a matter of fact, the expectancy of life in such children is very much less than in those of normal birth. More than seventy-five per cent. perish within a brief period of their entrance into the world.

Dr. W. T. Lusk thought the limit for craniotomy should be placed at a conjugata vera of 2¾ inches; below this limit the indication for Cæsarean section is absolute.

Dr. J. A. Doléris, of Paris, desired to call attention to two facts:

1. It is customary in France to deliver the fœtus per viæ naturales, whenever this is possible, even if the child be sacrificed. Under antiseptic conditions the maternal mortality is *nil*. He had performed craniotomy with perfect success, when the conjugata vera measured considerably less than 2½ inches. 2. It is of grave prognostic moment when the incision in Cæsarean section passes through the placental site. The danger is from secondary internal hemorrhage. The immediate cause of this hemorrhage is uterine inertia; the uterine inertia is frequently produced by the elastic ligature, applied around the lower uterine segment, paralyzing the motor centres of the uterus, and rendering ergot entirely ineffective. He recommended instead of continuous compression by the elastic ligature, temporary compression by the hands.

Dr. J. A. Doléris, of Paris, read a paper entitled

TREATMENT AND RESTORATION OF THE NECK OF THE UTERUS DURING PREGNANCY.

He narrated the histories of four cases of bilateral laceration of the vaginal portion, in which Emmet's operation was successfully performed during pregnancy. Among the symptoms indicating operative procedure, the following were noted, exaggerated nervousness, incoercible vomiting, rebellious pelvic neuralgias, threatened abortion. He drew the following conclusions: 1. The importance of traumatism of the neck of the gravid uterus has been too much exaggerated.

2. When the condition of the neck of the uterus demands surgical reparation, the menace of abortion, instead of being a contraindication, justifies the operation. During and after the operation, anti-abortive medication to be instituted—*i. e.*, chloroform, absolute rest, and opiates. The danger from hemorrhage is not greater than in the non-gravid uterus.

PROFESSOR LEISHMAN, of Scotland, while admitting that preconceived opinion is a serious barrier to the general admission of new truth, desired to express a hope that the Section would receive with great caution any such statements as seemed to be involved in the conclusions assumed by Dr. Doléris in his paper. He did not venture to deny that there might be exceptional instances, in which such an operation was warranted, but what he wished to express emphatically was, that operation on the cervix during pregnancy was (as in the case quoted by Dr. Doléris) very liable to lead to abortion, and that if such an operation is to be admitted at all, it should only be in very exceptional instances and after careful consideration of the special circumstances of a given case. He trusted the Section would not express any opinion in favor of the operation without making this perfectly clear.

DR. THOMAS OPIE, of Baltimore, said that a lady had been sent to him by her physician in January last, for treatment for lacerated cervix. He fully trusted her statement and verified the diagnosis of her attendant. He operated on the bilateral laceration of the cervix with the result of an abortion about the sixth week. The delicate relationship between the embryo and uterus, the fact of many pregnancies going to full term despite lacerations, and his own warning would make him timid about all surgical operations on the gravid uterus.

DR. JOSEPH KUCHER, of New York, read a paper entitled

ON THE RELATION OF THE ATMOSPHERE TO PUERPERAL FEVER.

It has been conclusively demonstrated that we are unable to render a locality absolutely free from germs, and the question then arises, What influence has air impregnated with germs upon the parturient female, particularly can such air cause puerperal fever? The older physicians, though not ascribing the origin of every case of puerperal fever to the surrounding air, were thoroughly convinced that at certain times, epidemics of puerperal fever had been started by atmospheric influence alone. So-called nosocomial malaria was frequently supposed to be the cause of puerperal fever, until Semmelweiss pointed out that this disease always originates from the absorption of septic matter through lesions in the genital tract, and that the instruments and the fingers of the physician and nurse are the chief means of introducing this septic matter to the numerous foci of absorption. Coincidently with this view, fear of the deleterious influence of the atmosphere abated.

When we have once come to the conclusion that the danger from atmospheric influence is insignificant, as contrasted with the dangers of infection from contact, we will not commit such mistakes as narrated by Le Fort, in which an epidemic numbered among its victims the daughter of a colleague. To secure the greatest possible safety from epidemic influence, the patient was delivered at her country seat, and died there of puerperal fever. Careful examination disclosed the fact that the nurse had recently been in attendance upon four women, who had died with similar symptoms; though no case of puerperal fever had occurred in the practice of other midwives, or of the two physicians living in the vicinity. The original infection of the nurse had been through a case of fistulous abscess of the thigh.

DR. T. MORE MADDEN, of Dublin, presented a paper on

THE PREVENTION AND TREATMENT OF PUERPERAL FEVER.

which was then read.

That a disease so many-sided in its genesis and propagation can ever be completely eradicated by any hygienic or antiseptic measures, seems to the author utopian.

The following preventionary measures were recommended:

1. The most scrupulous attention to puerperal hygiene.

2. The preparatory treatment of the patient—suitable nourishment, fresh air, and appropriate tonics—of primary importance.

The author ordered a mixture of potassium chlorate, iron, and quinine, to be taken during the last couple of months of gestation, and he has never seen puerperal septicæmia in a patient who had been thus treated before her confinement.

3. From the first day after delivery until convalescence has taken place, the uterine cavity as well as the vagina should be daily thoroughly washed out with water, as hot as may be well tolerated, to each pint of which may be added an equal quantity of sanital, which, from its absence of color, as well as its aseptic properties and agreeable odor, seems specially suitable for the purpose. Carbolic acid and rectified spirit of turpentine are good, while corrosive sublimate is unreliable and dangerous.

4. He does not use a siphon syringe, but employs More Madden's irrigator.

5. As a general rule, liquor creasotæ (B. P.) should be administered two or three times daily in full doses. This may be advantageously combined with the tincture of the chloride of iron.

6. The prevailing type of puerperal fever is of a distinctly remittent typhoid character, and should be primarily treated by appropriate general stimulants and nutriments, as well as by attention to the removal of all septic matter from the uterus, in the way already pointed out. Turpentine, iron, quinine, ergot, and opium, are the only medicines that deserve consideration. Turpentine, the most important, may be exhibited per os, or per rectum, or by the skin. Turpentine is stimulating, depurating, increasing the elimination by the skin and kidneys, and arrests the development of microörganisms.

General Medicine.

THURSDAY, SEPTEMBER 8TH.

DR. W. F. PAVY, of London, made the following remarks on

DIABETES,

speaking entirely without manuscript, and stating in explanation that he had time only to arrange his

thoughts in a concise form, but not to submit them to writing.

(See page 357.)

DR. HERRICK, of Cleveland, remarked that it had afforded him great pleasure and delight to listen to Dr. Pavy's remarks on this subject. He desired, however, to ask one question with regard to the treatment of the disease. Dr. Pavy had stated that he looked on the urine as the index of the disease—the presence or absence of sugar. Yet in speaking of the disease, he referred to it as an incapacity for the assimilation of saccharine material in the circulation of the liver. Did Dr. Pavy give anything to aid in the assimilation of this principle?

DR. PAVY replied that at the beginning of the disease, when the patient was dieted, the sugar in the urine diminished, and that after the treatment he had described was continued a while, the sugar entirely disappeared. You now make the test of allowing the patient a little bread. When this can be given without producing saccharine urine, he looked on it as an indication that the assimilative power had become greater.

DR. A. B. ARNOLD inquired whether the observations of Dr. Pavy would lead him to agree with the statement that diabetes is more frequent in the Hebrew race than in others.

DR. PAVY replied that his observations coincided with this statement; and not only that, but he had also found that the disease in the Hebrew is more amenable to treatment.

DR. TROAX asked whether death in diabetes is due to acetonæmia, as has been stated.

DR. PAVY replied that he was not a believer in acetonæmia. In response to a question by Dr. Holt, of Vermont, Dr. Pavy stated that although the bromides had been extensively used within the last few years, he had not much faith in them.

DR. R. W. PHILLIP, of Edinburgh, Scotland, forwarded a paper on

THE ETIOLOGY OF PHTHISIS,

which was read by Dr. Stockman, of Edinburgh.

It was not his intention, the author said, to discuss the pathological conditions present in phthisis, nor yet its dependence upon the bacillus tuberculosis. He would start, on the contrary, with the acceptance of the doctrine of the unity of phthisis, as well as that of its dependence upon the presence of the bacillus. The observations of Koch had, in his mind, established these facts. He desired rather to deal with the causes of the principal symptoms—progressive emaciation and asthenia, increasing hæmatosis, and the absorption of waste products. He desired especially to emphasize the absorption of waste products. What, then, is the immediate action of the bacillus tuberculosis in causing death? Their toxic powers are not limited to their presence, but are due in all probability to a product of their action. We know that a distinct variety of fermentation follows the introduction of a certain microbe into a medium, and that the exclusion of the microbe warrants the absence of this fermentation.

The author's investigations of the lesions in organs as well as of the sputum were then narrated at some length, together with a consideration of the methods employed. Most important was that in which he used a carefully prepared alcoholic extract of the sputum. Of this extract a small dose was given to frogs. These animals at once showed indications of having been poisoned. The symptoms in all cases were the same. Depression rapidly ensued without, however, the presence of other phenomena. In mice also it was found possible to produce toxic symptoms with a small dose of the extract. When a large dose was given, the intensity of the depression was proportionately increased. The most interesting point in the experiments was, however, the fact that when small doses were given to animals for a period of several days, progressive emaciation gradually ensued, and at the same time, fever and great thirst were observed.

The experiments were then continued in connection with the administration of certain remedies. It was found that atropia was antagonistic to the action of the toxic principle contained in the extract. Little notice had been made of the treatment of phthisis by atropia, and the author was aware of no author who gives it prominence but Bartholow, in his *Therapeutics*. In conclusion, he said, that it seems probable that the sweating, the fever, and probably to some extent the emaciation of phthisis, are due to the presence of a ptomaine, to which atropine acts to some extent as an antidote.

DR. WM. B. NEFTEL, of New York, then read a paper on

THE ETIOLOGY OF SOME OF THE DISEASES OF WOMEN.

Tight lacing was the chief etiological factor discussed. In accordance with the customs of the times, the author had resorted to experiments on dogs. Bandages were placed around the waists of the animals and drawn so tight as to occasion not a little discomfort, even, in some instances, alarming dyspnœa, compelling the removal of the band. When the animal was killed after having undergone the tortures of tight lacing for a time, there was found an engorgement of the blood-vessels of the abdominal organs. To what degree it differed from the usual post-mortem engorgement was not accurately stated. Tuberculosis was not produced. The evils of the "corset-liver," causing engorgement of the liver and interfering with its chylopoietic functions, were referred to.

General Surgery.

THURSDAY, SEPTEMBER 8TH.

DR. DONALD MACLEAN, of Detroit, said that the mortality in olden times was largely due to the defective measures of controlling bleeding. The method described by Dr. Dennis seems open to the objection that the elastic band might slip, when the operation was delayed. He had amputated the hip a number of times, and has had the utmost satisfaction from the use of Lister's abdominal compressor. He believes that it is superior to any other method for controlling hemorrhage in this region. If the compressor is not at hand the fists of an assistant will answer the purpose, the compression being made on the umbilicus.

DR. WEEKS, of Portland, Me., has employed an elastic compressor consisting of the ordinary black rubber bandage, doubled so as to make four strands two feet in length. This is passed between the thighs, brought

between the tuberosity of the ischium and the rectum, and up in front of the femoral artery. An ordinary roller bandage is placed over the artery. The ends are brought over in front and held by an assistant. This also controls hemorrhage from the gluteal vessels.

DR. REYHER, of St. Petersburg, thought that in emaciated subjects it would not be advisable to make such sudden compression as is caused by Lister's compressor. He had used the rubber tourniquet, but without special satisfaction. He had performed another operation. He made an excision of the head of the bone, and then placed one stick through the wound and another in front, securing them together by rubber bands. The same thing is done with the posterior portion. The flaps can then be cut without hemorrhage. In these operations he had no disagreeable results from this measure.

DR. W. BOONE, of Shanghai, China, said that no one had alluded to the method proposed by Dr. Furneaux Jordan. Where there is sufficient tissue free from disease, this seems to present many advantages. This operation is performed by making a circular cut through the muscles low down, making a flap, and then turning back the flap. The bone is next divided. An excision of the head is next made. In this way you cut the vessels low down and the control of bleeding is absolute.

DR. PALMER, of Jonesville, Wis., had used a method similar to that of Dr. Reyher. Instead of sticks, he passed pieces of sharpened steel wire through the limb in front and behind the bone, and then secures them to other pieces in front of and behind the limb.

DR. CHAVASSE, of Birmingham, Eng., said that in amputations for malignant disease, the less tissue left the better, therefore the operation of Mr. Furneaux Jordan is not a good one for this particular disease. The best method is that known as Brodie's operation, by anterior and posterior skin flaps. In children, the best plan for controlling hemorrhage is by digital compression. This is also applicable in thin subjects. He had also used Davy's rectal staff with satisfaction.

DR. ASSAKY, of Bucharest, Roumania, then read a paper on

IODOL.

He said that wounds unite under iodol by first intention. This union, however, being the result of various and complex conditions attending operation, it is not possible to attribute to iodol alone the absence of suppuration and inflammatory conditions. In wounds which gape and suppurate iodol is an excellent antiseptic. It rapidly retards suppuration, renders it inodorous, reduces the frequency of dressing, and hastens considerably cicatrization. In ulcerating or gangrenous wounds iodol aids to resist the destructive process, and changes the wound, after a variable time, to a healthy granulating condition. This action of iodol extends itself to hard chancres. In case of soft chancres the result is variable. Sometimes it transforms them into a simple wound with brief delay; at others it is insufficient for this purpose, and it becomes necessary to employ in addition, locally, antiseptic lotions. The same is true with reference to open venereal buboes of the groin. The powdered iodol has this advantage over iodoform, that it is free from odor and is not toxic in its effects.

Doses of iodol of from $\frac{1}{10}$ of a grain to 30 grains daily, produce no functional trouble, even if continued a long time. These doses give marvellous results in tertiary syphilis and in scrofulous affections. In the secondary stage of syphilis, taken internally, it rapidly destroys the syphilitic manifestations. Iodol seems to aid the general nutrition and increase strength and flesh. It is indicated in all cases of specific malnutrition. Iodol is an antipyretic. In acute infectious diseases, such as erysipelas, etc., it causes a rapid fall of temperature.

MR. EDMUND OWEN, of London, read a paper on

PARACENTESIS OF THE ARTICULATION IN THE EARLY STAGES OF DISEASE OF THE HIP-JOINT.

It is generally admitted that the sero-synovial effusion, associated with early acute disease of the hip-joint, has an influence on the stiffening and faulty position of the limb. In these cases examination will usually show a deep-seated fulness below the middle of Poupart's ligament, which advances the femoral vessels toward the surface. There is also swelling behind, between the great trochanter and the tuberosity of the ischium. An illustrative case was given. A boy, nine years of age, was admitted to St. Mary's Hospital, London, on account of extreme pain in the right hip and knee. The limb was semiflexed, and the foot slightly inverted. The attempt to bring down the limb caused tilting of the pelvis and arching of the loins. There were all the signs usually regarded as indicating the first stages of hip-joint disease. There was slight fulness in the positions indicated. The pain had come on suddenly two weeks previous in a child apparently healthy. Chloroform was administered, but the leg remained stiff. A trocar and canula were passed through the back of the capsule, and a teaspoonful of sero-purulent fluid containing flakes of lymph was withdrawn. The femur could then be extended, and the joint was loosened. An extension apparatus was applied, and the patient put perfectly at rest. On the fourth day he was free from pain. The convalescence ran a perfect course, terminating in recovery in two weeks.

It may be said that this was not a case of hip-joint disease, but one of simple synovitis. This was admitted, but if the capsule had not been tapped there might have developed suppurative arthritis. If this is admitted, the author claimed that potential hip-joint disease might be cured by paracentesis. We should always be on the lookout for this condition. Where we cannot be absolutely certain that there is distention, we should give the patient the benefit of the doubt, and perform exploratory puncture. This, if done with clean instruments and ordinary care, is devoid of risk.

DR. L. H. SAYRE, of New York, believed that the case related if allowed to go on, would probably have ended in rupture of the capsule and, perhaps, destruction of the head of the bone. In the early stage of the disease, where the limb is flexed, everted, and abducted, as a result of over-distention of the capsular ligament, if the fluid is not absorbed by rest and counter-irritation, it is proper to puncture the joint, thus treating the hip-joint the same as any other joint.

DR. G. W. BOONE, of Shanghai, said that two years ago his attention was called to the injection of joints with glycerine and iodoform. He used it in two cases where there was evidence of the first stage of hip-joint disease. In one case the symptoms disappeared, while

the other case ran the ordinary course of a case of hip-joint disease.

Dr. Lange, of New York, said that in the case reported the child probably had tubercular disease near the hip-joint, which ruptured into the joint, causing effusion. In such cases the painful symptoms can be relieved by tapping the joint. To regard this as an effective treatment for hip-joint disease, which must be regarded in children as essentially a tubercular affection, seems hardly proper. This case is not concluded, and we do not know what the final result will be.

Dr. Owen said this was not a case of tubercular process in the joint. The attack began two weeks before admission; was an acute effusion, and recovered within two weeks after operation. Tuberculosis does not run this course.

Dr. Burnays, of St. Louis, had one case of epilepsy and mania for which he trephined. There was a clear history of injury to the head. The skull had been trephined without good effect. He also trephined, and when the bone was removed the dura mater came up into the opening. This he incised and at once there was an enormous flow of cerebro-spinal fluid. He introduced four catgut sutures to close the opening in the dura mater. The patient recovered, but there was no immediate improvement, although since then there has been some lessening of the number of the seizures.

Dr. T. R. Manly, of New York, reported a case of

GUNSHOT WOUNDS OF THE ABDOMEN

in the left epigastric region. The patient was seen two hours after the injury. The abdomen was greatly distended and evidently contained fluid. The wound was probed with great care, but the point of entrance into the abdomen could not be found. An incision was then made in the linea alba. When the peritoneum was punctured about half a gallon of blood escaped. The hemorrhage was from a branch of the inferior mesenteric artery. This was secured with a ligature. A double perforation was found in the descending colon; this was closed with the Lembert suture, including only the serous and muscular layers. The bullet was not found. The abdominal incision was closed and dressed antiseptically; it, however, failed to unite; in other respects the patient did well. The incision was again closed, the peritoneum being united with a separate row of sutures and the other layers with silver wire. On the third day it was found that the central portion of the wound had opened, but that the peritoneum had united. The patient eventually recovered completely.

Dr. Robert Newman, of New York, read a paper on

THE USE OF THE GALVANO-CAUTERY SOUND, PARTICULARLY IN HYPERTROPHY OF THE PROSTATE.

The instrument consists of a smooth sound with a fenestra at its lower extremity; at this opening is a piece of platinum wire in connection with a galvano-cautery battery. By pressing a key in the handle of the sound, the platinum wire is heated to a bright red color. This does not destroy tissue. The instrument is introduced until the lower extremity reaches the prostate gland, when the current is passed through the platinum wire. These applications are repeated at intervals of three to five days. The author has employed this method of treatment in fifteen cases, seven of these being cases of hypertrophy of the prostate gland. In all these instances there was improvement in the symptoms presented and a decrease in the size of the prostate.

Dr. F. Lemoyne, of Pittsburg, read a paper on

UNUNITED FRACTURE OF THE FEMUR SUCCESSFULLY TREATED BY DOUBLE SPLICE AND WIRED CLAMP.

The method described had been employed in three cases, two of the humerus, and one of the femur. In the femur case the various proceedures employed in cases of ununited fracture were tried, but no union followed. Eight months after the accident the mobility at the seat of fracture was very distinct. The seat of fracture was then exposed by two incisions, one on the anterior and the other on the external aspect of the limb. The fragments were found attached by firm bands of fibrous tissue and the bone tissue was softened; the intervening tissue was cut away. The lower extremity of the upper fragment was then sawed off so as to form a wedge-shaped piece. The upper end of the lower fragment was sawed so as to leave a corresponding V-shaped depression. The extremities were then brought into apposition. A hole was made in each fragment so that the two openings were two and a half inches apart. A steel clamp, its extremities being bent at right angles, was laid upon the anterior surface of the femur, the ends being inserted into the holes already prepared. This was secured to the bone by three bands of wire encircling the limb at the seat of fracture. The limb was placed on a posterior inclined plane, the foot being elevated about eight inches. Sole-leather splints were applied on the external, anterior, and internal surfaces, and the patient was kept as quiet as possible. High inflammatory action with free suppuration occurred. In five weeks there seemed to be some union and the clamp and wire were removed. The limb was still kept in leather splints. One year after the operation, there was good union. The patient could bear his entire weight on the limb. There was, however, shortening to the extent of two and one-half inches.

Dr. T. R. Manly, of New York, said he had had considerable experience in wiring the shafts of bones, particularly in fractures of the thigh. If there is much shortening we should wire the bone at once. We do no harm by making a free incision down to the bone and the silver wire causes no irritation. He leaves them in permanently and the results have been satisfactory.

GYNECOLOGY.

THURSDAY—SEPTEMBER 8TH.

Dr. Joseph Taber Johnson, of Washington, read a paper on the

TREATMENT OF THREATENED OR COMMENCING PERITONITIS AFTER LAPARATOMY BY BRISK PURGATION.

The idea of the propriety of administering purgatives when peritonitis was imminent or present after laparotomy had been performed, occurred to the author about three years ago, while attending a patient under such conditions, together with persistent vomiting. Several small doses (fractions of a grain) of calomel were given in quick succession, the bowels were freely moved, and the patient recovered. The theory of this

method of treatment was that intestinal peristalsis was encouraged and the serous accumulations in the abdominal cavity which accompany peritonitis were absorbed, passed into the intestine, and carried off. Lawson Tait had advocated the same plan, and also Wylie, of New York. Tait's idea was that the free purgation which was excited in this condition, answered the purpose of drainage. The method is more logical, theoretically, than the use of opium, since the latter paralyzes the muscular power of the intestine, and thus favors peritonitis. Three cases were narrated in which life was probably saved by the timely administration of calomel and Rochelle salts, and it is now a customary plan of procedure with the author to keep the bowels open after the third or fourth day following laparotomy, instead of keeping them confined for a week or ten days, as was formerly the custom.

DR. A. MARTIN, of Berlin, then read, in German, a paper on

TOTAL EXTIRPATION OF THE UTERUS PER VAGINAM FOR CARCINOMA.

He thought that sufficient material was now at hand to decide two questions which should be asked concerning every new method of surgical treatment. Those two questions were:

1. Is the success of the operation such that it will promise good results to other than very expert operators?

2. Does the extirpation of the uterus for cancer offer permanent results which are superior to those obtained by any other method of treatment now employed?

It must be admitted that the published reports of operations in English and German literature are still meagre and isolated, though there can be no question that the operation has obtained a decided recognition in Germany. The results of the operations have greatly improved as experience has increased. Thus, in 1881, Olshausen collected 41 cases, with a mortality of 29 per cent.; while, in 1886, Hegar collected 257 cases, with a mortality of 23 per cent. The author has collected a table of 311 cases, extending to the end of 1886, the operators being Fritsch, Leopold, Olshausen, Schröder, Staude, and himself, in which the mortality has been only 15.1 per cent. From the gradual improvement in the results, the belief seems warrantable that this mortality will become still smaller. Even now the results as to immediate mortality are better than obtained in Küster's recently published table (1883) of 778 cases in which amputation of the breast for cancer was performed. The author believes, therefore, that this operation deserves a prominent position among the different methods for treating the cancerous uterus.

As to the question of permanency of result to those who recover from the operation, after tabulating the cases of Leopold, Schröder, and Fritsch, the author gives the result in his 44 cases, in which recovery had taken place, all the operations having been performed previous to 1886. Of these 44 there was recurrence in 13, the remaining 31, or 70.3 per cent., were still in health.

The supravaginal operation of Schröder for that form of cancer of the cervix, which is developed from the pavement epithelium covering its mucous membrane, is recommended by Hofmeier, as the more radical operation. The author's experience in that respect, however, has not coincided with Hofmeier's, since 6 cases out of 28 were fatal and all of the others succumbed within less than three years from recurrence. After the high excision pregnancy is not impossible, and Hofmeier himself considers that such an event would be fraught with great danger to the patient. The author, therefore, prefers the operation for complete extirpation of the uterus in all forms of cancer of the cervix, the operation being indicated only in those cases in which the tissues surrounding the uterus are entirely free from cancerous infiltration. If a radical operation is performed when the tissues are infiltrated a permanent cure should not be expected.

The technique of the operation has little bearing upon the results. It matters little whether the wound remain unclosed, or be closed and drained. The ovaries and tubes should be removed if practicable and all hemorrhage checked. There is no evidence that those who recover experience any loss as to sexual feelings of feminine form. The author, therefore, recommends this operation as the most suitable one for all cases in which the cancerous disease is limited to the uterus itself.

DR. R. JACKSON, of Chicago, read a paper entitled

MODERN TREATMENT OF UTERINE CANCER.

The great difficulties surrounding this subject were stated to be our want of exact information as to its beginnings, and the uncertainty which attends operative procedures as to the complete removal of diseased elements. The diagnosis should not only determine the existence of the disease but also its extent. Since this is practically impossible who can tell when an operation has been radical in its scope?

The best results from operative procedures thus far, with reference to subsequent immunity from the disease, have been obtained by the use of the actual cautery. Supravaginal operations of the various types have also given excellent results. The statistics for the complete extirpation of the organ by abdominal operations are so discouraging that it is not strange that the operation has been practically abandoned. The results from vaginal hysterectomy with a few operators have been much better, but when we compare these and the duration of life of those who survive the operation with the estimated duration of life for those who have uterine cancer but do not submit to operation the balance is largely in favor of non-interference. Recurrence of the disease after vaginal hysterectomy takes place in four and a half months on the average, and this is certainly no better than can be obtained by less radical procedures. If hysterectomy has a field, it is in connection with disease of the body of the uterus, and this occurs with comparative infrequency, and is very difficult of diagnosis. In the author's opinion the attempt to establish hysterectomy as a suitable operation has been unsuccessful. His conclusions are:

1. Any operation for cancer which does not completely remove the disease will be followed by recurrence.

2. During life the limit of cancerous disease originating in any part of the uterus cannot be known; hence, no operative procedure can afford a guarantee of complete removal.

3. In view of this fact no operation is justifiable which greatly endangers life, provided other and safer means are available.

4. Vaginal hysterectomy is more dangerous, in a certain sense, than the disease which it is designed to remedy. Some individuals will live longer without the operation than with it.

5. Other methods less dangerous than hysterectomy are available for ameliorating and retarding the progress of the disease. They also show as good results as regards recurrence, hence, they are to be preferred.

6. Vaginal hysterectomy does not avert or lessen suffering; it is not a useful but an injurious operation, and, therefore, is unjustifiable.

DR. MARTIN, of Berlin, remarked that the statistics which Dr. Jackson had used were old and inapplicable to the present status of hysterectomy. Of his (Martin's) statistics for hysterectomy which gave data to the end of 1886, 66 cases alone could be used as cases of cancer. Of that number, 44 remained cured more than a year and a half after they had been operated upon.

Dr. Cordes then read, for DR. VUILLET, of Geneva, a paper entitled

THE BURIED SUTURE WITH IODOLIZED SILK IN VESICO-VAGINAL FISTULA.

The author has as yet tried this material in the manner specified in the title of the paper in but one case. The result, however, was perfectly satisfactory, the wound being aseptic, and doing well, and he thought the method worthy of further trial.

A second paper by the same author was read entitled

THE DILATATION OF THE UTERUS BY PROGRESSIVE OBTURATIONS.

The method consisted in repeated pluggings of the cavity of the uterus with iodoformed gauze, under perfectly antiseptic conditions. Each plug or tampon was allowed to remain twenty-four to forty-eight hours, and six to eight operations were usually necessary to obtain the required degree of dilatation. By that time the cavity had become so large that its entire surface could be photographed or inspected with the naked eye. The operation was considered especially useful for the investigation of cases of malignant disease and intra-uterine new growths in general. It was asserted that no septic accidents had ever resulted from the operation, the means of dilatation constituting a perfectly antiseptic dressing, and also exerting as great a degree of dilatation as could be desired. It was also observed that this operation had a very favorable effect upon women suffering from neuroses, in the same way that pregnancy does.

DR. TRENHOLME, of Montreal, read a paper entitled

EXTIRPATION OF THE UTERUS FOR BLEEDING MYOMA.

One great difficulty in the treatment of such cases consisted in the treatment of the pedicle, the conditions of the stump being usually very unfavorable for such treatment, especially if the extraperitoneal method be used. The author's plan in such cases was, first to split the tumor through the centre, then enucleate each segment in turn from its peritoneal covering. The two flaps which were thus formed were then brought together and closely united with a cobbler's stitch. A stump being now made, it could readily be brought up to the surface of the body and clamped. Or the pedicle might be dropped, and the author thinks this method superior to that with the clamp. In some cases he had cut out the tumor by means of a wedge-shaped incision, which was then closed with a layer of deep followed by a layer of superficial sutures. Silver sutures were preferred in all cases in which it was possible to use them. Should peritonitis supervene, he had usually been able to control it by using hot fermentations.

DR. CLARKE, of Boston read a paper entitled

URETHRAL CARUNCLE, ITS HISTOLOGY AND PATHOLOGY.

Various opinions were cited with regard to the structure and significance of these bodies. The intense annoyance and pain to which they give rise suggest an abundant supply of sensory-nerve filaments. The author had made a careful histological study of the subject, and the results were seen in a series of microscopical sections, which were photographed and projected upon an illuminated screen. The conclusion of the author was that the caruncle is a papillomatous new growth which may be of indefinite duration, but does not tend to retrograde metamorphosis.

DR. NELSON, of Boston, then read a paper on

THE RELATION OF MICROÖRGANISMS TO UTERINE MYOMATA.

A single case was reported in which a microbe was discovered in and cultivated from an uterine myoma. The author stated his case with the greatest reserve, and did not presume to draw any positive conclusions from such limited experience. The greatest care had been exercised in the cultures, which had been made upon agar-agar at a temperature of 100°, and had reached the fifth generation. Tubes containing the fourth and fifth generations were shown. The microbe resembled that of anthrax, morphologically, being about half the size of the latter. Photographs of it were projected upon an illuminated screen.

THE REMOVAL OF UTERINE MYOMATA BY ABDOMINAL SECTION.

DR. DUNLAP observed that in his early experience the greatest difficulty attending these operations concerned the treatment of the pedicle. He found it a good plan to make flaps of peritoneum, cover the stump with them, and stitch all together with the cobbler's stitch. He believed that in most cases myomata should not be operated upon. In more than forty years' experience he had found that the maximum of development in nineteen cases out of twenty was reached before the tumors became a source of danger to life. If an operation were done he thought the use of the clamp should be avoided, if possible.

LARYNGOLOGY.

THURSDAY, SEPTEMBER 8TH.

DR. W. E. CASSELBERY, of Chicago, Ill., read a paper on

NASAL FIBROMATA.

He gave the history of a case in which he removed the growth with a galvano-cautery écraseur, employing a steel piano wire instead of the usual one of platinum.

The growth was attached to the ethmoid and its base was thoroughly cauterized. There was no return seventeen months later. He closed with the report of seven other cases which he had collected.

DR. COOMES, of Louisville, Ky., related a case of fibro-myxoma of the nose, which recovered after removal of the growth.

DR. E. FLETCHER INGALLS, of Chicago, Ill., reported two cases in which there had been an extension of the growth into the pharynx. He believed that cocaine did not always sufficiently prevent pain and that frequently hemorrhage followed its use.

DR. CHARLES STOCKTON, of Buffalo, N. Y., favored the compound platinum and iridium wire.

DR. CASSELBERY had used a ten per cent., and even stronger solution of cocaine by means of the cotton applicator.

DR. J. O. ROE, of Rochester, N. Y., read a paper on

CHOREA LARYNGEALIS,

in which he described this affection and related four cases. A spasmodic cough in the first could only be relieved by hypodermatic injections, but in the end disappeared suddenly.

Internal medication and pneumogastric nerve galvanization was the treatment in another case. A third had nocturnal coughing spells.

MR. LENNOX BROWNE, of London, England, was not in accord with Dr. Roe in what he called chorea laryngis. He had seen choreic movements of the larynx without cough. He had seen several coughing cases and thought they were fairly common. One woman, he recalled, who always got this laryngeal cough during pregnancy, but which left her with the advent of quickening. In one case the cough was removed by the removal of an enlarged tonsil. A second case was cured by a sojourn at the seaside, but this treatment failed to relieve a second attack, though a sea voyage had the desired effect.

DR. ROE concluded by explaining that hysterical coughs were often enough caused by diseased nostrils, enlarged tonsils, and other causes apt to excite reflex disturbances. Of course, such cases were not choreic. The distinctive difference between a nervous or reflex laryngeal cough and one due to chorea was in the presence of choreiform twitchings of the laryngeal muscles as seen by laryngoscopical examination. The cough is not diagnostic. Chorea laryngis can only be positively diagnosticated with the laryngoscope.

DR. F. M. COOMES, of Louisville, Ky., read a paper on

THE DELETERIOUS EFFECTS OF TOBACCO ON THE THROAT AND NOSE.

For years he had observed the effects of tobacco upon consumers. In his experience smoking caused more harm than chewing. Snuff chewing is almost wholly confined to women, especially those of a certain class. Tobacco has a bad local effect. Chronic pharyngitis is the commonest result, and is due to both chewing and smoking. Many ministers' sore throats are tobacco throats. He related illustrative cases. Smoking causes great injury to the air passages. The nasal mucous membrane of inhalers of tobacco smoke is generally hypertrophic. Smokers have probably worse throats than chewers, because they use an inferior kind of tobacco and keep the heated smoke in contact with the mucous membrane for a time. It has been said that all the irritation from the use of tobacco is not due to nicotine alone, but also to the burning of certain potassium salts formed in the tobacco. Crystals of potassium salts can even be detected upon the stems of the leaf after stripping, and from these many kinds of tobacco are largely manufactured. The noses and throats of fully ninety-five per cent. of tobacco chewers and smokers he ventured to say are more or less in a pathological state. He has seen many smokers with a swollen epiglottis and vocal cords, which he supposed were largely due to persistent coughing in the effort to bring up tenacious mucus.

DR. STOCKTON, of Buffalo, N. Y., considered this a very interesting subject, especially for laryngologists. Holland has the largest proportion of smokers and America of chewers. His experience showed that chewing is worse than smoking. If it is a fact that potassium salts act so badly on mucous membranes, why use them as was customary? He objected to the use of any of the potassium salts, especially upon the mucous membranes. The worst case of atrophic cataract he ever saw was caused by the use of these salts. Its effect is to tan the mucous membrane, and it is used in tanning hides. The nicotine cannot do much harm, as it is driven off by the heat. Cigarette smokers may get nicotine, but cigar and pipe smokers, as a rule, would not, as they do not inhale. He thought that chewers absorb more nicotine than smokers do.

MR. LENNOX BROWNE, of London, Eng., remarked that sailors lead pretty physiological lives because forced to do so, and the use of tobacco is diminishing among them. Tobacco certainly is highly deleterious. He used it himself and did not give it up because it afforded him a great deal of enjoyment. Chewing must certainly be worse than smoking. Sir Henry Thompson had said that cigarette smoking is the least harmful of the modes of using tobacco, especially if a new holder is often obtained. His tobacconist always supplies him with a new holder with each 100 cigarettes. He had noticed that snuff takers are more apt to have nasal polypi than any other class of persons.

CORRESPONDENCE.

THE ADVANTAGES OF THE PLASTER-OF-PARIS JACKET.

To the Editor of THE MEDICAL NEWS,

SIR: In your journal of the 3d instant I notice a quotation from an article by Dr. Bruns, of Jitomir, Russia, which appeared in the *London Medical Record* of July 15, 1887.

The gentleman seems to be under the impression that he has discovered something new in the use of water-glass for making spinal supports, in place of plaster-of-Paris; whereas it was done years ago, and then condemned, because the silicates are not porous, and so imprison the insensible perspiration which is continually taking place, whereas gypsum allows it to evaporate.

To prove the porosity of a plaster-of-Paris jacket, make a small one over a tumbler as a model, and then, after withdrawing the tumbler, cover the ends also with

plaster-of-Paris bandages, and make a hole in one end large enough to admit the stem of a lighted tobacco pipe. Now blow through the bowl of the pipe, and so fill the little box with smoke, which will soon be seen issuing from it in all directions.

This feature of porosity is one of the most important advantages which plaster-of-Paris possesses over the silicate jackets, and varnished leather, and shellac cloth, etc.; while in the manufacture of all of these there is required a solid mould to make which a plaster-of-Paris jacket is first constructed on the patient, and thus a great deal more time and trouble are required than in the original plan of my father, Professor Sayre.

One great advantage of the latter is also that the physician is rendered independent of the instrument-maker, a point of no small importance to a man living in the country, while the other methods above mentioned require usually the services of a skilled mechanic, or else a much greater amount of time than is at the disposal of a busy practitioner.

Dr. Bruns says that his water-glass jackets weigh "for a child of eight or ten about 3½ pounds," a fact much in favor of plaster-of-Paris, as those for a girl of eighteen or nineteen weigh but 2 to 2½ pounds, while for a child of eight I have made them as light as 1½ pounds.

As to the objection that plaster-of-Paris jackets "give rise to pressure sores, as well as (in pauper practice) to the appearance of numerous lice," I would say, that skill in the accurate adjustment of the jacket and attention to complaints of pain, will prevent the former, and as for the lice they will grow under a "water-glass" as well as under plaster-of-Paris if either be applied to a filthy body.

The point, however, which has caused me to write this letter is the fact that Dr. Bruns evidently does not understand the difference in treatment of Pott's disease and lateral curvature of the spine, as he says: "A serious drawback of Sayre's jacket is, it cannot be taken off at will." Now, if it is a case of Pott's disease in the acute stage, the quieter the bones can be kept the better, and the jacket should no more be removed daily than should the splints from a broken leg.

In the later stages of the disease it is well to split the jacket down the front, and fasten it together with hooks and lacings, so that it occasionally may be removed for bathing; while in lateral curvature the jacket is *always* cut open and *removed every night*, and while the patient is practising gymnastic exercises, which are as essential for the cure of this disease as rest is for the other. My father has taught me these principles for years.

Yours respectfully,

Reginald H. Sayre, M.D.

225 Fifth Avenue, N. Y., Sept. 14, 1887.

NEWS ITEMS.

Successful Laparotomy for Gunshot Wound of the Abdomen.—Dr. C. E. Case, of Tocoma, W. T., writes us that he has recently successfully performed laparotomy with antiseptic precautions in the case of a boy who was shot by a 32-calibre pistol, the ball entering two inches above and to the right of the umbilicus and passing out of the body three inches to the right of the spine. Considerable blood was found in the abdominal cavity. The boy is now convalescing.

Programme of the International Congress of Hygiene at Vienna.—This Congress will meet at Vienna, September 26, 1887, under the presidency of Archduke Rudolph and Professor Ludwig.

The addresses will be as follows:

Professor Brouardel on Typhoid Fever and its Propagation.

Professor Pettenkofer on the Relative Position of the Study of Hygiene in Medical Colleges and the Higher Schools of Technology.

Professor Corradi on Longevity from the Standpoints of History, Anthropology, and Hygiene. And

Professor Charles Théodore on the Most Important Changes in the Population of Europe in the Past Thousand Years.

Discussions will also be held on these and kindred topics.

The hospitality of Vienna and its suburbs has been extended to the Congress; and an excursion down the Danube to Buda-Pesth will be made.

The Government coöperates most actively in the work of the profession for the success of the Congress.

Death by Decapitation. — Regnard and Loye presented recently to the French Academy of Sciences the following results of their examination of the body of a decapitated criminal:

Two seconds after decapitation no sign of consciousness could be detected.

Corneal reflexes persisted six seconds after decapitation. Ventricular contractions were observed for twenty-five minutes; auricular contractions for one hour. Aside from ocular reflexes, contraction of the jaws, and spurting from the carotids, the impression was as if a cadaver had been decapitated.

This calm death, without agony, was evidently caused by inhibition, resembling that caused in animals by certain irritants to the nervous system.

The entrance of air beneath the arachnoid was a purely physical phenomenon caused by the escape of blood from the cranium.—*L' Union Médicale*, July 12, 1887.

The Children of the English Poor.—The attention of the House of Commons was recently called to the starved condition of poor children in English schools. The *British Medical Journal* estimates that eighty or ninety per cent. of these children are physically unfit for either study or exercise from starvation.

The House Secretary has announced his intention of issuing a circular prescribing that due precaution be taken to avoid excess in the legal punishment of young children. The occasion for this action was the recent flogging by a policeman of a boy, aged seven years, for theft. When brought to a surgeon he had fifty wounds from the lash, and was in a condition of severe prostration.

The Foods best Digested with Tea and Coffee. —In the *Journal of Anatomy and Physiology*, Dr. J. W. Fraser reports the results of his experiments on the action of tea, coffee, and cocoa, on stomach and intestinal

digestion. He summarizes his views by the following recommendations and deductions: 1. That it is better not to eat much albuminoid food-stuffs at the same time as infused beverages are taken; for it has been shown that their digestion will in most cases be retarded, though there are possibly exceptions. Absorption may be rendered more rapid, but there is a loss of nutritive substance. On the other hand, the digestion of starchy food appears to be assisted by tea and coffee; and gluten, the albuminoid of flour, has been seen to be the principle least retarded in digestion by tea, and it only comes third with cocoa, while coffee has apparently a much greater retarding action on it. From this it appears that bread is the natural accompaniment of tea and cocoa when used as the beverages at a meal. Perhaps the action of coffee is the reason why, in this country, it is usually drank alone or at breakfast—a meal which consists much of meat, and of meats (egg and salt meats) which are not much retarded in digestion by coffee. 2. That eggs are the best form of animal food to be taken along with infused beverages, and that apparently they are best lightly boiled if tea, hard boiled if coffee or cocoa, is the beverage. 3. That the casein of the milk and cream taken with the beverages is, probably, absorbed in a large degree from the stomach, and that the butter used with bread undergoes digestion more slowly in the presence of tea, but more quickly in the presence of coffee or cocoa; that is, if the fats of butter are influenced in a way similar to oleine. 4. That the use of coffee or cocoa as excipients for cod-liver oil, etc., appears not only to depend on their pronounced tastes, but also on their action in assisting the digestion of fats. —*Science*, July 15, 1887.

DISINFECTANT CANDLES.—Perhaps the most elegant method of disinfection hitherto suggested is that which we owe to the ingenuity of Mr. George Browne, F.C.S., who has taken advantage of candle combustion to free, in a vaporous state iodine and phenol, by the decomposition of iodo-salicylic acid. Iodo-salicylic acid is quite as effective in its destructive properties on the lower forms of life as iodoform, while it has not its disagreeable odor. We have tried them in water closets with admirable effect, the air of a rather confined closet being kept quite free from all unpleasant odors by burning one of these candles at intervals during the day in it. Also, it removes the smell of tobacco smoke from a room which has been impregnated with it. The presence of iodine in the air can be demonstrated by a little starch paste, a pretty experiment being to hold a globe rinsed with a weak solution of starch paste over the flame of the candle, when fluorescent particles of the iodide of starch will be deposited.—*Provincial Medical Journal*, August 1, 1887.

THE MODERN PHYSILIAN.—ROBERT LOUIS STEVENSON, in the preface to *Un lorgneds*, pays the following tribute to the medical profession:

"There are men and classes of men that stand above the common herd; the soldier, the sailor, and the shepherd not unfrequently, the artist rarely; rarer still, the clergyman; the physician almost as a rule. He is the flower (such as it is) of our civilization; and when that stage of men is done with, and only remembered to be marvelled at in history, he will be thought to have shared as little as any in the defects of the period, and most notably exhibited the virtues of the race. Generosity he had, such as is possible to those who practise an art, never to those who drive a trade; discretion, tested by a hundred secrets; tact, tried in a thousand embarrassments; and, what is more important, Heraclean cheerfulness and courage. So it is that he brings air and cheer into the sick-room, and often enough, though not so often as he wishes, brings healing."

SOLUBILITY OF PILL COATINGS.—The relative solubility of pill coatings has been experimented on by Dr. Thompson, and by him reported in the *Chemist and Druggist* to be as follows, the most soluble being first named: Gelatine, sugar, talc venet., balsam of tolu.

ORIGINAL ARTICLES.

RECENT ADVANCES IN THE TREATMENT OF PULMONARY CONSUMPTION.[1]

BY SOLOMON SOLIS COHEN, A.M., M.D.,

LATELY CHIEF OF THE MEDICAL CLINIC, JEFFERSON MEDICAL COLLEGE HOSPITAL, PHILADELPHIA.

WHETHER our efforts be directed toward cure—that is, toward putting our patients in a condition that permits them to recover; or whether we aim at the prevention, which is better than cure; excluding from consideration measures purely palliative, the objective therapeutic point may be summed up in one word—Nutrition. Of those methods intended to promote nutrition, first in importance comes the subject of superalimentation; to which the prominent attention it deserves was directed by Debove's communications upon forced feeding, or gavage, in 1881 and 1882.

Debove being convinced that many consumptive patients, despite loss of appetite, maintained comparatively good powers of digestion and assimilation, determined to resort to mechanical feeding. He therefore passed into the stomach, through the mouth, a flexible rubber tube connected with a funnel (such a tube as had been employed for lavage—washing the stomach—and the method of introducing which will be described in the latter connection); and by this means introduced much larger quantities of food than the patients would voluntarily swallow. The taste of the aliment thus administered becomes a matter of no consequence, and we are, therefore, able to select that which will give the most nutriment in the smallest bulk. Meat powders were adopted as the basis of Debove's nutritive mixtures; but milk, eggs, soups, and farinaceous powders may be used, either separately or in conjunction therewith. When necessary, pepsin, pancreatin, hydrochloric acid, etc., may be added, or peptonized aliments be employed. A mixture that was used with advantage by Dr. Stern, of Philadelphia, and myself, in the cases of two patients treated at the Philadelphia Polyclinic, consists of a quart of milk, two tablespoonfuls of beef powder, three eggs, fifteen grains of scale pepsin, and thirty drops of dilute hydrochloric acid, warmed, and administered twice a day; the patient eating what he wished in the interval. In hospital service, forced feeding is practised three times daily, but in private practice, we must be content with what is possible.

Meat powders may be purchased in the shops, or can be prepared at home by cutting boiled meat into little pieces, drying thoroughly by means of a water bath, and grinding in a coffee mill. Powder so prepared is said by Dujardin-Beaumetz to answer its purpose very well. The farinaceous powders used in France are prepared from cooked lentils, malted lentils, and maize. I have no personal experience with them, but they are said to be highly nutritious. About seven ounces of the alimentary powder, whether meat or farina, or both, are mixed with a quart of milk or water, or milk and water; the milk being added slowly to form a paste, which afterward dissolves readily in the additional liquid. When the long tube of Debove cannot be passed, or when patients will not allow it to be passed, it often suffices simply to pass the entrance of the œsophagus with a shorter tube, as recommended by Stoerk; or to make use of the special apparatus of Dujardin-Beaumetz or Bryson Delavan, which consists of a glass jar with two tubes; one of which, above the level of the fluid, communicates with a hand-bulb for supplying compressed air, the other, below the level of the fluid, communicating with a short œsophageal sound of small calibre; an ordinary rubber catheter will answer at a pinch. When the bulb is compressed, the fluid food is driven over. Efforts of swallowing on the part of the patient will facilitate the process.

From the reports made by reliable observers in France and elsewhere, as well as from a few cases under my personal observation, I feel no hesitancy in affirming that remarkable gains in weight may be obtained from forced feeding, and that very often there will be concomitant recession in febrile and other phthisical phenomena. Improvement in physical condition of the lungs has been reported, but I have never succeeded in keeping a patient under the treatment long enough to verify this by personal observation. American patients in private or dispensary practice are not as tractable as foreign ones, in these matters, and I have had no opportunity of conducting the treatment of phthisis in hospital inwards. To secure the benefits of superalimentation with the great run of patients, I have had to employ alimentary mixtures similar to those of the gavage process, by natural methods. The general dietary advised is a largely nitrogenous one, of which beef, raw or rare, broiled or roast, forms the principal item; there being added sufficient milk, eggs, fish, lamb, mutton, poultry, leguminous vegetables, and greens; fruits in season, large quantities of butter, with small quantities of bread, potatoes, and starchy foods in general. Alcohol is employed as a food when it is necessary to obtain force with the least expenditure of digestive energy.

Fried foods of all kinds, pastry and other indigestible matters, are of course prohibited. Patients are advised not to allow more than three hours to pass without taking food, except during sleep; to drink a glassful of cream or milk, or cream punch,

[1] Read before the Medical Society of the State of Pennsylvania, June 30, 1887.

milk [one h, or egg nog, just before going to bed, and to have milk at hand to drink in case of waking during the night or early morning. Not more than three set meals daily are advised, but in the intervals milk, with or without alcohol, chicken soup, bouillon, rich broths, etc., are administered; as a vehicle usually, for the beef-peptonoids of a well-known firm of American manufacturing chemists. Of this preparation it is endeavored to give not less than two ounces daily, and the amount may be increased as circumstances require. Various preparations of meat-juice purchased in the shops, or prepared at home, may be used in the same manner, according to indications. The aim of the treatment is to supply enough nutriment not alone to counterbalance current waste, but to make up previous excess of waste over repair, and the details must be elaborated in each case with regard to individual condition. Cod-liver oil, we well know, is an advantageous addition to the dietary in some cases, but not so many as we have supposed. At least it is not indispensable. Oleaginous inunctions are often of considerable benefit.

When overfeeding by natural methods fails, or when the patient is unwilling or unable to swallow the necessary quantity and quality of food, resort should be had without hesitation to the œsophageal tube and forced feeding.

But having supplied the proper kind and amount of aliment, we must place our patient in a condition to digest and assimilate it. It is true, as already suggested, that we may make use in certain measure of predigested foods, and that we may assist digestion in other instances by the administration of the digestive ferments; but our endeavors must not cease there.

The problem before us naturally divides itself into three parts: First, the preparation of the digestive tract, to elaborate and to absorb the chylous fluids—primary assimilation. Second, the promotion of the complex process of the breaking down and displacement of imperfect tissues and effete products, and replacement by new and vigorous tissues, with evolution of forces required in the economy; *i. e.*, metabolism—secondary assimilation; and third, the promotion of the excretion of waste products.

The first desideratum is endeavored to be secured by methods which cleanse, disinfect, and stimulate the digestive canal; varied in detail according to circumstances. When we have reason to suppose, for example, that a sluggish gastric catarrh interferes with digestion, washing out the stomach may be practised with good effect. The procedure is quite simple. A stomach-tube of similar material to French catheter tubing, about 28 inches long, and from $\frac{1}{2}$ inch to $\frac{7}{8}$ of an inch in diameter, is attached by a short section of glass tubing, to a soft rubber tube about one yard long, in the extremity of which is inserted a hard rubber funnel of about six-ounce capacity. The stomach-tube having been dipped into warm water or warm milk, is introduced into the œsophagus and propelled by successive pushes, or swallowed by the patient; and the funnel being sufficiently elevated, from a pint to a quart or more of warm water (100 F.), in which is dissolved a drachm or two of borax, table salt, or baking soda, is slowly poured into the funnel. As the last of the fluid is passing out of the funnel, the latter is rapidly inverted over a receptacle on the floor, and the contents of the stomach are thus siphoned out. The manœuvre is repeated until the returned water is clear. This process, called lavage, which, as already stated, suggested gavage, and is practised in much the same manner, leaves the gastric mucous membrane in excellent condition for digestion and absorption. It may be immediately followed by gavage, as recommended by Dujardin-Beaumetz. The drinking of half a pint to a pint of hot water, half an hour to an hour before meal time, will sometimes accomplish much the same purpose, and is, of course, less troublesome.

When a condition of septic fermentation is believed to interfere with digestion, a suitable antiseptic agent, such as carbon-disulphide water or solution of hydrogen dioxide, may be introduced into the lavage solution, and a portion allowed to remain a few minutes in the stomach; or creasote, carbolic acid, iodoform, the solutions mentioned, or other agents may be administered in the ordinary way. When the intestinal canal is believed to be the seat of the trouble, we may attempt to wash it, indirectly, by lavage, or by potations of hot water, or to medicate it with creasote, bismuth, sulphocarbolates, mercurials, iodoform, sulphides, naphthalin, or other appropriate drugs. I have reason to believe from the effect produced upon some cases of phthisis attended with diarrhœa, that the injection per rectum, of hydrogen sulphide, directly or indirectly arrests septic fermentations in the small intestine.

To aid digestion, stimulate digestive secretion, and promote absorption, in addition to the measures already referred to, preparations of malt, Hoffmann's anodyne, bitter tonics, nux vomica, arsenic, preferably Fowler's solution, iron, nitro-hydrochloric, nitric, and phosphoric acids, trinitrin, and other appropriate medication may be employed when indicated.

Nutriment being administered, digested, and absorbed into the blood, must be converted into vital forces, and into tissue. Exercise and respiration are the natural means to effect this. "Respiration," said Arbuthnot, "is the second digestion."

When the patient is able to carry out the instructions, and when there is a sufficiency of unimpaired lung tissue, respiratory gymnastics, and voluntary forced respiration may suffice. Ordinarily, however, these measures will not be efficient, and must be replaced or supplemented by a method which affords mechanical assistance to respiration, independent of voluntary exertion. This method offers itself in the inhalation of compressed air, a subject which will always be associated with the name of its great promotor, Waldenburg. The air is inspired under an excess pressure, gradually increased from $\frac{1}{50}$–$\frac{1}{40}$ up to $\frac{1}{10}$ or $\frac{1}{8}$ of an atmosphere. Expiration is ordinarily made into the atmosphere; sometimes into rarefied air. The inhalations are administered once or twice daily. At each period, ten or fifteen, twenty-five or thirty, up to one hundred or more

respiratory acts are completed in five to fifteen minutes, and the process is repeated after an interval of about ten mtinutes.

The value of this procedure as an aid to nutrition, formed the theme of a paper I read before the Pennsylvania State Medical Society last summer, and needs not now to be elaborated. Let me, however, briefly recapitulate the principal points. The inhalation of compressed air dilating the air-cells as it does, by gentle and equable pressure, aids nutrition by securing the proper exposure of venous blood to the atmosphere, facilitating the disengagement of carbon dioxide and the taking up of oxygen to be carried by the hæmoglobin to the tissues, and assist in force-production and tissue-building. The mechanism by which this is accomplished is complex. The air passages are cleansed from decomposing products of secretion and desquamation, and the alveoli are reopened in unused, blocked, and partially consolidated areas of pulmonary tissue, thus securing efficient pulmonary ventilation. Increase of partial pressure, favors dissociation of carbon dioxide and association of oxygen in the pulmonary capillaries. Direct pressure and pressure differentiation tend to promote the relief of congestion in the lungs, the absorption of inflammatory congeries of new cells, and the stimulation of both intra-pulmonary and peripheral circulation. Increase of blood pressure, further, stimulates the production of lymph. Thus is secured not alone the exposure by increased volume and rapidity of pulmonary circulation, of a greater number of corpuscular oxygen carriers to the increased volume and weight of inspired oxygen, under the conditions most favorable to oxidation of hæmoglobin, but also the penetration of the corpuscles with their vitalizing burden in the nutrient lymph-stream, further into the tissues. This latter effect may theoretically be heightened, by a measure advocated by Prof. Bartholow in simple anæmia, with sluggish peripheral circulation; namely dilatation of the terminal vessels by means of trinitrin (nitroglycerin). I have as yet no available experience with nitroglycerin in phthisis.

One circumstance which had long militated against the popularization among the profession of pneumatic treatment, was the cost and cumbersome clumsiness of the necessary apparatus. In 1883, with the assistance of Mr. Charles Richardson, of the house of Queen & Co., Philadelphia, I succeeded in largely obviating these objections by means of an apparatus, which can not only be employed in the physician's office, but may be entrusted to the management of the patient or his friends at home, and is comparatively inexpensive. It is fully as efficient as the apparatus of Waldenburg upon which it is modelled, and like its original, is superior to a certain widely advertised and extravagantly costly patented instrument, devised in 1885. It consists simply of a small gasometer and a foot-bellows. The inner cylinder is weighted at the bottom, in order to throw the centre of gravity as low as possible, and preserve its steadiness without pulley or flanges. Air is pumped in by means of the foot-bellows, the supply valve of the latter being connected with a rubber tube of large aperture, which is placed out of the window, to secure pure, fresh air. Without additional weighting the inner cylinder gives a pressure of $\frac{1}{70}$ of an atmosphere. By placing additional weights on top, the pressure may be increased to any desired amount up to one-fortieth of an atmosphere. The supply of air is continuous, and the patient may inhale directly from the apparatus, or the stream of inspired air may be made to pass through a Wolff bottle containing terebene or other volatile medicament.

The mouth and nose are covered with a mask to exclude atmospheric air, and the ingress and egress of respired air are regulated by a stopcock. For detailed information as to the use of compressed and rarefied air, time requires me to refer to my previous communications, or to the text-books on inhalation.

To the administration of compressed air inhalations, twice a day, is to be added, when possible, due exercise in the open air; and when this is not advisable or possible, passive exercise by massage, frictions, and similar measures. Three hours after meals, during the culmination of digestion and the activity of absorption is the preferable time for open-air exercise. In the presence of active febrile processes, both active and passive exercise are to be moderated or even interdicted. Compressed-air inhalations, however, need not be abandoned. Inhalations of nitrogen have been recommended to abate fever. I have not tried the measure.

Digestion, absorption, assimilation, metabolism being assisted, it remains to promote excretion of waste, in order to rid the system of the now well-recognized danger of auto-intoxication by leucomaines, ptomaines, etc., and to make room for reconstructive materials. Stimulation of the emunctories by diuretics, cholagogues, cathartics, even diaphoretics are here indicated; but drugs should be avoided as far as possible, and when absolutely indicated, only the mildest remedies are to be chosen, these being promptly discontinued when the desired effect has been produced.

Our general tonic medication, exercise, forced respiration, etc., will of course, assist directly, and indirectly, as emunctorial stimulants. The daily sponge bath, which, to the well, is a matter of comfort and cleanliness, becomes to the consumptive a measure of therapeusis. The drinking of water, preferably hot, is again applicable as the best of diuretics and a potent diaphoretic. Lemon juice and sugar may be added to render it more palatable, the former indeed, increasing its value as a diuretic. Nitro-hydrochloric acid is among the best hepatic stimulants in this connection. An enema is ordinarily the best method of emptying the bowels. To overcome intestinal torpor the same measures employed under other circumstances, nux vomica, belladonna, faradism, etc., may be resorted to. Among the preferable cholagogue cathartics, are podophyllin and rhubarb.

The indications thus far considered may be fulfilled in the generality of cases by the following routine:

1. An abundant and proper diet, as already discussed; gavage if necessary.

2. The drinking of hot water, or hot lemonade; lavage, if necessary.

3. Moderate open-air exercise; respiratory gymnastics; daily inhalations of compressed air.

4. The administration of some such pill as this, three or four times a day: Iodoform, 1 to 2 grains, creasote or other, minim to one minim; to which may sometimes be added: reduced iron, 1 grain, or arsenious acid, $\frac{1}{60}$th to $\frac{1}{30}$th grain, the pill being made up with glycerine, crude petroleum, or extract of liquorice, with the addition, if indicated, of some bitter extract, such as gentian, cinchona, or nux vomica, and dispensed in capsule. Among other useful prescriptions may be cited, when iron is indicated: Compound syrup of phosphate of iron (Parrish); tincture of chloride of iron, dilute phosphoric acid, and Churchill's syrup of hypophosphites (J. Solis Cohen); the official syrup of hypophosphites and iron, etc. Iron seems to be better borne by the stomach, and to be more readily appropriated by the red blood-globules when inhalation of compressed air is practised. I have noticed this even in non-phthisical anæmia. Cardiac weakness, excessive febrile action, and other conditions may call for appropriate medication.

Although the ordinary administration of drugs is beyond the limits proposed to be discussed in this paper, it may be interpolated, while upon the subject of internal medication, that great improvement is, in many cases, apparently due to the use of iodoform, both singly and in combination, in doses ranging from one to five grains three times daily. Gains in weight are often very gratifying, when sufficient food is furnished. Thus I recall a patient under my care in the medical clinic of Jefferson College Hospital, who, although far gone in the disease, and, doubtless, beyond the possibility of permanent restoration, gained eleven pounds in one month while taking a pill of iodoform, two grains, three times a day, and drinking from one to two quarts of milk daily, with the addition of beef peptonoids.

Crude petroleum, like creasote and tar products in general, seems to have a favorable influence upon cough and expectorations. The good effects of iron and arsenic in anæmia and malnutrition generally are well known. Their action in phthisis needs no other explanation. It is due primarily, I believe, to direct influence upon digestion; secondarily, to general stimulation of constructive metamorphosis.

Thus far we have considered, in the main, measures directed to the general system. To the inhalation of compressed air, a measure designed in part mechanically to counteract local pathological conditions, and to the administration of iodoform and creasote, drugs devoted in part to the restriction of morbid histological action, we may add some of the newer devices immediately directed against the local morbid processes, in part or in whole.

First, in this division of our theme, is the subject of medicinal inhalations. This might well be made the subject of an elaborate paper. Time permits but a hasty indication of its value. The general profession has been unaccountably slow to realize the advantage of a method which permits of direct medication of the respiratory tract in greater or less extent. This hesitation may have been produced by the extravagant claims of some unbalanced observers. I will try to avoid that error, but I cannot help speaking with enthusiasm. There are certain volatile medicaments long known to exert favorable influence upon pulmonary diseases, although the method by which they operate is a matter of dispute. From a purely empirical standpoint, then, I will enumerate, in the order of merit, those that appear to me to be the most generally useful. These are, creasote, ethyl iodide, terebene, spirits turpentine, tincture benzoin, spirits thymol, and spirits chloroform. Eucalyptol is often useful, but, in the main, has disappointed me. Whatever the reason may be that the atmosphere of pine woods benefits those suffering with chest troubles, is the reason that terebinthinate inhalations at home have sometimes an almost equally good effect; especially so, it seems, if combined with oxygen. Ethyl iodide, besides some specific effect of its own, offers a ready means of local and general iodization without disturbing the stomach; to preserve it, it should be mixed with alcohol, and dispensed in a dark bottle.

In chronic processes, creasote, terebene, and ethyl iodide are employed for general good effect. To control subacute epiphenomena, terebene and ethyl iodide are most frequently resorted to. Benzoin is preferable for acute catarrhal processes. Thymol is sometimes substituted for creasote when the odor is a source of complaint. Chloroform finds indications as a sedative to troublesome cough, and as a mitigant of the sharpness of some specimens of terebene. Burroughs and Welcome's terebene is to be preferred for internal use, but the commercial terebene (Merck's) seems better for inhalation, and very often requires the admixture of chloroform or spirits of chloroform. These agents may be inhaled from a wide-mouthed vial, but preferably from the sponge attached to the little perforated zinc respirator, devised by Dr. Barney Yeo, of London, which may be worn almost continuously, with very little inconvenience, thus keeping up a desirable effect. Many patients wear the respirator during sleep, and are perfectly comfortable. Fifteen or twenty drops of a mixture consisting, for example, of equal parts of creasote, terebene or ethyl iodide, and spirits of chloroform or alcohol, may be dropped on the sponge, and renewed two or three times a day. One of the volatile substances enumerated may be floated on the surface of water in a Wolff bottle, connected with the compressed-air apparatus, or with a reservoir of oxygen. Terebene is the one usually chosen for this purpose. Vaporous sprays of various antiseptic, stimulant, or sedative solutions may be administered by means of the Oliver or globe atomizer, or one of the many contrivances depending upon the same principle—a combination, that is, of the Bergson and Sales-Giron methods of nebulization, giving a very fine mist which apparently penetrates the air passages for some distance. Messrs. Codman and Shurtleff have, at the suggestion of Dr. J. Solis Cohen and myself, arranged a neat combination of the Oliver atomizer with the stopcock of a compressed-air apparatus. Should this device stand the test of experience, I will describe it in a future paper. Hydrogen dioxide

suggests itself as a valuable drug for use in this manner.

Acting upon a recommendation of Prof. Bartholow's, I am making some observations on the inhalation of sulphurous acid gas, an old remedy, by a new method. It has been found that carbon dioxide and sulphur dioxide, both extremely rebellious gases when attempt is made to liquefy them separately, may, by a comparatively slight pressure, be together brought into a liquid form and confined in an ordinary mineral water siphon bottle. On releasing the pressure, they immediately return to the gaseous state, and the air of an apartment may thus be readily charged with any desired quantity. The diffusion and probably the mixture with carbonic acid, robs the sulphurous acid, to some extent, of the suffocating properties it exhibits when inhaled undiluted. The dose is to be regulated in each case by the individual capacity to breathe the sulphurous atmosphere—which varies greatly—and the patient is to pass as much time as may be practicable in the medicated apartment.

Sufficient time has not elapsed since I have been able to obtain the liquid referred to, to venture a positive expression of opinion from my individual experience. I believe that it will prove to be a valuable addition to our resources. This leads, naturally, to the subject of gaseous injections of carbonic acid and hydrogen sulphide. At the time that I had announced the sub-titles of this paper, the Bergeon method of treating phthisis was a novelty in this country; but as the members of this Society are now beyond doubt thoroughly familiar with it, instead of describing the process in full, I shall simply give a few practical points, the result of personal experience: First, as to the method of preparing and using the gases, and, secondly, as to what may and what may not be expected of it.

The intelligent physician will "prove all things and hold fast to that which is good;" even though imperfect experience may decry as utterly useless that for which unbalanced enthusiasm had claimed too much. He will not hold scientific investigators responsible for the vagaries of irresponsible newspaper reporters, nor reject that which palliates, because it does not infallibly cure. In the first place, we must remember that the effect of the Bergeon injections is produced by the elimination of the hydrogen sulphide (or other active agent) through the air tract. Unless we obtain evidence of this elimination by recognition of the odor in the expired air, or the blackening of test paper of plumbic acetate (in case H_2S be employed) by the breath, we are not securing the proper effects, and cannot expect improvement. Failing to secure this evidence in many cases, with most of the natural waters used, I have been well satisfied by the use of the solution recommended by Yeo after Bardet, which is prepared by adding to eight ounces of water three drachms each of the following solutions:

No. 1.—Sodium sulphide (c. p.)	℥ss.
Distilled water	f℥vj.—M.
No. 2.—Tartaric acid	ʒj ʒij
Salicylic acid	ʒss.
Distilled water	f℥vj.—M.

Secondly, to avoid colic and griping pains we must be sure no air remains in bag, bottles, tubes, or any part of the apparatus, and must warm the injected gases.

Thirdly, twenty minutes to half an hour must be consumed in the process. From four to six quarts of carbon dioxide should be used at each injection, after the first few to establish tolerance. The patient should remain recumbent for half an hour after the cessation of the injection.

Fourthly, the best times for injections are just before breakfast, and just before going to bed—*i. e.*, three hours after supper.

Fifthly, patience and perseverance are necessary, both on the part of patient and physician.

Sixthly, tartaric acid is more easily carried and more neatly handled than sulphuric acid, and will disengage carbonic acid from sodium bicarbonate as quickly. About two parts by measure of tartaric acid to three of sodium bicarbonate is a good working rule.

This method of treatment is not designed to destroy the bacillus tuberculosis, but to remedy those local conditions, mainly suppurative, which permit this microbe to find a suitable habitat in the lungs. A significant fact lately reported, and, if verified, of vast scientific importance in correcting current errors as to etiology, is that the sputum of patients thus treated, fails to produce tuberculosis in animals.

The effects of the treatment, as I have seen them in many, but not in all cases, are more or less rapid reduction in temperature, diminution of cough, improvement in the character of expectorated matters, promotion of sleep, increase of appetite, cessation of night-sweats. These palliative results, great in themselves, are still greater in the removal of obstacles to nutrition. The physical signs attributable to collateral catarrh and suppurative processes subside. I have seen no cure, but then there has not been time either to permit recovery or to test its reality. I have not noticed any marked recession in physical signs in the lung due to the tuberculous process itself; but in two cases, patients of Dr. J. Solis-Cohen's, I have seen cicatrization of laryngeal ulcerations apparently tuberculous, with subsidence of pyriform tumefactions. This is a rare occurrence, even with assiduous local treatment, and in these instances local treatment was not instituted. In no case, however, have we abandoned superalimentation, or refrained from medication when it seemed to be indicated. I regard the Bergeon process as a good adjuvant to other treatment, but until I have larger and longer experience therewith, I should hesitate to place sole dependence upon it. To establish its proper value we must employ it in all cases, and find out in what group it seems to be most useful. I should say from my own experience, and from what I learn from my friends in Philadelphia, that the cases in which it appears to be most efficacious are neither those where the lung is hopelessly broken down, and it is powerless; nor those in which softening has not begun, and it is unnecessary; but those in which septicæmic processes, due to pulmonary suppuration, are a source of danger and a cause of depression; yet in which there is still a

hope of prolonging life if the suppurative process can be controlled. When this has been accomplished, I should then feel disposed to resort to inhalations of compressed air. The latter are, indeed, the one great dependence in cases of early phthisis, and were I compelled to choose between compressed-air inhalations and all the drugs of the pharmacopœia, I should unhesitatingly prefer the former. I know that I have seen consumption cured by its means. I have seen cases, in the practice of my brother, that have remained well for ten years, and know of some still living that have survived the predicted time of death even longer; and I am happy to say in conclusion that the patients of my own, whose cases I reported to this Society last year, are still alive, and to all appearances perfectly well. The treatment adopted in these cases and carried out at home—obviating the expensive and often futile quest after a health-restoring climate—was superalimentation, compressed air, ethyl iodide and terebene inhalations, iodoform, creasote, and iron internally; measures directed not against a microbe, which is the evidence of disease, but against the malnutrition, which is its cause.

GLIOMATOUS HYPERTROPHY OF THE PONS.[1]

BY HENRY HUN, M.D.,

PROFESSOR OF DISEASES OF THE NERVOUS SYSTEM AND OF PSYCHOLOGICAL MEDICINE, ALBANY MEDICAL COLLEGE.

Gliomata of the pons are rare, and but few cases of them are to be found in medical literature.[2] Therefore it seems to me to be desirable that the following case, which is a beautiful example of such a tumor, should be published.

Case.—*Steadily increasing incoördination of movements, bulbar paralysis, and general motor paresis. Glio-sarcoma of the pons Varolii.*

April 17, 1886. C. L., female, æt. six. The father of the patient died a little more than a year after she was born, with symptoms of melancholia and dementia. An autopsy was held, of which I can obtain no account except from his widow, who says that there was found "water on the brain and tumor of the brain." There have been many cases of nervous disease in the family of the father, but none in that of the mother. Patient has had a number of attacks of spasmodic croup, and three years ago had measles. For a number of years her left leg has become tired easily, and for some time she wore a rubber strap on her left foot, which showed a tendency to turn in. Otherwise she has been in excellent health till two months ago, when she had an attack of croup followed by a cough. Every time that she coughed she felt a severe pain in the top of her head, and felt a pain in her head at no other time. About three weeks ago she began to walk badly, and seemed to have trouble in balancing herself when standing. Her mind is clear, her memory is good, and she is not in any way nervous. She has an excessive appetite, and has vomited a little at times.

She is a well nourished, intelligent girl, but has a vacant expression. Her speech is drawling. She keeps her mouth open most of the time, drools when eating, and has some difficulty in swallowing. Her head is drawn toward the right shoulder most of the time, especially when she makes any exertion. She stands with her feet wide apart, and is careful not to lose her balance. When she walks her right leg seems more rigid than her left; so that she takes freer and longer steps with her left leg, and consequently in walking she tends to walk in a circle, turning always toward the right. Her walk resembles that of a drunken person; being very unsteady, swaying, and pitching, as if every moment she were about to fall. Her legs and arms are rather weak, and the movements of her arms, especially of the right, are very awkward, but she holds them in no fixed position. There is no disturbance of sensibility in any part of the face, body, or extremities, and she recognizes objects placed in her hand when her eyes are shut. Plantar reflexes normal, no ankle clonus, knee-jerk exaggerated, especially on the right side. On ophthalmoscopic examination well-marked optic neuritis is found in both eyes. Urine contains neither albumen nor sugar.

May 21. She has slowly but steadily failed. Her legs and arms are now not only awkward, but also very weak. Her legs bend under her when she bears any weight on them, and she can neither walk nor stand. In addition to the weakness of the legs, there is a trace of spasm about them, but no ankle clonus can be obtained. Tactile, painful, and thermic sensibility is normal in all parts of the body. She is dull, but her intelligence seems intact, and she shows little if any loss of memory. Her articulation is indistinct, deglutition is difficult, uvula is raised very sluggishly, though equally on both sides, and the movements of the tongue are sluggish, although it is protruded without deviation. She still drools much, especially while eating and at night. Pulse is small, and varies from 120 to 140. At times when she is asleep her respiration is very rapid and panting, but it is rather slow when she is awake. When asleep her eyelids are partly open, and the eyeballs are turned outward, but when she is awake the eyeballs, at times, turn slightly inward, so that she squints, although no paralysis of any of the ocular muscles can be detected. Up to this time she has been taking pot. iodid. grs. 20 and pot. bromid. grs. 15 t. i. d., without any good effect. This was stopped to-day, and a pill containing phosphorus gr. $\frac{1}{64}$, ferri carb. gr. 1, quin. sulph. 1, and ext. nuc. vomic. gr. $\frac{1}{2}$, was given t. i. d.

June 4. She has been decidedly better lately. Her articulation and deglutition have improved slightly. She is brighter and can sit up without assistance, but cannot walk. The day before yesterday a well-marked ankle clonus could be obtained in both feet during the whole day, which has not been present either before or since. She complains of no headache, except the pain in the vertex when she coughs.

June 13. During the past week she has steadily and rapidly failed. On some days the left arm and leg have appeared completely paralyzed, while on other days she would move them a very little. She has been able neither to talk, walk, stand, nor even to hold her head up, which falls backward, forward, or to either side, according to the position in which she is held. Her hearing and cutaneous sensibility have remained unaffected, and her sight is but very slightly impaired. Lately she has given indications of having pain in the occipital region, and there has been a decided increase in the size of her head during the past week or ten days. She has had no convulsions. Her pulse has been small and feeble. This morning her respiration was stertorous for a few hours, and then became normal again. Her intelligence seemed clear until the very moment of her death, which took place quietly and suddenly this evening.

Autopsy, held twenty-four hours after death; head only examined. Bones of skull rather thin. Dura mater only slightly adherent to skull-cap. Increased

[1] Read before the American Neurological Association, July, 1886.

[2] Neurolog. Centralbl., 1883, p. 5.

amount of subarachnoid fluid. Cerebral convolutions flattened, and cerebral substance very œdematous. Corpus callosum is pressed upward and is very soft and thin, and almost broken through. Great and uniform dilatation of both lateral ventricles, which are filled with fluid of normal appearance. No dilatation of the third and fourth ventricles. Cerebellum normal. The pons Varolii, as seen both from the base of the brain and from the fourth ventricle, is greatly enlarged; being three or four times the normal size. On section the whole pons is found to be replaced by a tumor, apparently a glioma, which preserves wonderfully the normal appearance of the part, so that it looks like a greatly hypertrophied pons. A little posterior to the middle of the pons on the right side, is a focus of softening, spherical in shape, and about three-quarters of an inch in diameter. When hardened, a section of the pons at its largest point measured two and a half inches in width and one and three-quarters inches in depth. The tumor seems to be confined pretty accurately to the pons; the crura cerebri, and the medulla oblongata being but slightly enlarged.

On microscopical examination the nervous elements of the pons are found to be encroached upon, infiltrated, and, in some places, destroyed by a great accumulation of small cells. The prevailing character of these cells is spindle, although there is a considerable number of spheroidal cells, both large and small. There is no considerable development of "spider cells." Between the small newly formed cells there seems to be a delicate newly formed basement membrane, independent of the neuroglia. There is also present a very great many newly formed vessels full of blood. The proliferation of cells is not limited to the pons, nor is it circumscribed by any sharp line, but extends throughout the whole extent of the crura cerebri and the medulla oblongata, being less abundant the further the section is removed from the pons. In the anterior part of the crura cerebri the roof of the aqueductus Sylvii is so softened that no section of it can be made, and from the posterior portion of the third ventricle a canal about one twentieth of an inch in diameter, with well-defined walls, runs backward and downward, and terminates in a mass of softened tissue near the centre of the inferior surface of the crura cerebri. Neither the wall of this canal nor the neighborhood of the roof of the aqueductus Sylvii seems to be the especial seat of the glioma. The wall of the canal is remarkably firm and well-defined, except at its extremity where it terminates in the softened tissue on the under surface of the crura cerebri.

In regard to the exact diagnosis as to the nature of the tumor in this case, the diffuse infiltrating, rather than displacing character of the growth, makes it resemble a glioma; while the form of the cells, the presence of a basement membrane, and the absence of any considerable new development of "spider cells," is in favor of its being a sarcoma. Such tumors are sometimes called gliosarcomata; but in consideration of the remarkable way in which the normal (though hypertrophied) appearance of the pons is preserved in these tumors, it seems to me to be better to call them by the name proposed by Kuemmel,[1] "gliomatous hypertrophy of the pons."

The very vascular nature of such growths has been described by Spitzka[2] and others. Gerhardt[3] says that the vascularity of these tumors is so great that temporary congestions may lead to fatal attacks of apoplexy, and that frequent attacks of temporary paralysis and apoplexy are characteristic of gliomata, because of their great vascularity. The little canal which ran through the crura cerebri, connecting the third ventricle with the base of the brain, is of interest. It is evidently analogous to the fissures sometimes found in the posterior horns of the spinal cord, which Schultze[1] has pointed out, are usually due to softening of gliomata. Similar changes have been described by Fuerstner and Stuehlinger[2] as occurring in the cerebral cortex. In this case the softening extended across the crura cerebri in a straight line to the third ventricle. It is possible that this softened tissue was simply absorbed, and that the canal was thus formed; but it seems to me much more probable that the pressure of the fluid in the ventricles, which was great enough to cause a thinning and almost a perforation of the corpus callosum, forced and washed out the softened gliomatous mass, and thus formed the canal. The patch of softened tissue near the centre of the pons, not being subjected to the pressure of any fluid, remained in situ.

Although in this case the tumor was of large size and involved a portion of the nervous system, lesions of which are especially prone to produce paralysis, yet there was no disturbance of sensibility and no absolute paralysis of motion, except that of the left arm and leg, and even this paralysis varied somewhat from day to day. Gerhardt[3] says that even in large gliomata permanent paralyses are often absent, because the nervous elements within the tumor are not destroyed by it. The paralysis of the left arm and leg in this case was probably due to the patch of softening in the right side of the pons, this was the only patch of softening in the tumor. Throughout the rest of the pons, medulla, and crura cerebri, the nervous elements were compressed, but not actually destroyed; and consequently, although there was widespread paresis, there was no paralysis. The nerve cells and fibres composing the gray matter which forms the floor of the fourth ventricle, were compressed by the new-formed cells of the tumor; and in consequence the patient presented the symptoms of bulbar paralysis, *i. e.*, drooling, paresis of lips, tongue, and pharynx, difficulty of articulation, and difficulty of deglutition. Belonging to this same set of symptoms are the disturbances in the centres for respiration, circulation, and the ocular muscles, which, curiously enough, were most marked when the patient was asleep. Besides the gray matter there are two great systems of fibres in the pons; one, the transverse fibres, connects the cortex of the cerebellum with that of the cerebrum, and probably transmit impulses relating to the coördination of movements; the other, the fibres of the pyramidal tract, connects the cerebral cortex with the subcortical centres and through them with the muscles, and transmits impulses for voluntary movements. Both of these sets of fibres were pressed upon by the rapidly increasing cells of the tumor and their function impaired, and consequently the earliest symptoms of the tumor

were incoordination of movement and weakness, which steadily increased in intensity up to the time of death. The absence of disturbances of sensibility in this case does not prove that the sensory fibres escaped the pressure, for it is well known that in cases of a general lesion of the spinal cord the motility is more easily impaired than the sensibility.

This tumor in its growth produced no symptoms of irritation, there were no convulsions, and but little headache. There was simply a steadily increasing loss of function of those nervous elements, which were subjected to the pressure of the growing tumor. It is remarkable that, notwithstanding the great amount of œdema of the brain present in this case, and an internal hydrocephalus, so extensive as to cause a perceptible enlargement of the head, consciousness and even intelligence were preserved up to the end of life.

AN INTERESTING CASE OF SPURIOUS ANEURISM OF THE INNOMINATE ARTERY.

BY H. A. HARE, M.D. (UNIV. OF PA.),
DEMONSTRATOR OF EXPERIMENTAL THERAPEUTICS AND INSTRUCTOR IN PHYSICAL DIAGNOSIS IN THE UNIVERSITY OF PENNSYLVANIA.

I DESIRE to place on record the history of this interesting case, chiefly because it is a very good example of the fact that even the most definite signs of true aneurism may be present, and yet the post-mortem examination prove the entire absence of any lesion of the bloodvessel.

The symptoms and physical signs of this lesion were so evident that I reported the case as one of innominate aneurism with aortic dilatation, in the *Medical Record* of May 16, 1886, but not until several other physicians had also reached the same opinion as to the character of the case. The reasons for my so doing become evident when the following history is read:

Annie D., æt. seventeen years, came under my care in March, 1886, complaining of cardiac palpitation and severe pain in the chest and left arm when laying down. This pain was then of about three months' duration, and was steadily growing worse. There was no history of syphilis, but there was one of frequent attacks of acute articular rheumatism, recurring every winter for the last six or seven years. Her father and a brother are also subject to the same disease, but the two remaining children are free from it. She was fairly well developed, but pale and anæmic; menstruated first at the age of fourteen years. There was no history of traumatism, or of scarlet fever.

On inspection, there was to be seen an egg-shaped protrusion in the supra-sternal notch, very expansile, and bulging at each systole of the heart. The dilatation extended well up into the innominate artery for over an inch from its point of origin. Pulsation was strongly marked in all the vessels of the neck. The apex beat of the heart was in the sixth intercostal space, about an inch to the left of the nipple. There was no distinct thrill over the precordial space, but it was well marked in the supra-sternal notch and over the dilated portion of the innominate artery. On auscultation over the swelling there was heard a rough and a soft murmur, accompanied by a *thrill*. Over the aortic orifice was heard a double murmur—a short, sharp, and rough systolic, and a long, softer, and more blowing diastolic. These murmurs were very distinct over the sternal notch, the diastolic murmur becoming intensified as the ear was carried down the sternum, reaching its maximum at the ensiform cartilage. Over the pulmonary orifice both murmurs were heard, but were somewhat muffled. Both were transmitted posteriorly to the left, but did not depend on mitral disease, as they were heard more loudly over the right scapular region than the left. Both murmurs could be heard in the vessels of the neck, the diastolic feebly. There was the typical "water-hammer" pulse, 2- to the quarter minute, with marked difference in volume of the pulse in the radial arteries, both to the finger and as registered by the sphygmograph, the right falling behind the left. Abdominal pulsation could be seen, but it was not marked. Percussion revealed cardiac dilatation, with great hypertrophy. There was no dysphagia, dyspnœa, or loss of voice.

The patient was now lost sight of till September 13, 1886, when she came under the care of Dr. Griffith, to whom I am indebted for several additional points of interest. During the time she had been away the pain had become paroxysmal in character, and was sometimes preceded by unpleasant, undefined sensations. There was also, at this time, marked dyspnœa during the pain, which did not exist when she was first seen by me. The pain decreased under the use of small doses of nitro-glycerine, but no marked improvement took place. The case again passed out of sight till the middle of March, 1887, when she returned to the writer, complaining of great pain in the abdomen, half way between the umbilicus and the ensiform cartilage.

On examination, there was found a very marked localized pulsation noticeable to the eye and touch. Auscultation also discerned a bruit of a not very positive character, but fairly well marked. The pain in the chest was worse, and the whole condition of the patient far worse than when last seen.

Nothing more was heard of her till the 28th of May, when her mother came to me, stating that at 4 A.M. they had heard her coughing, and at 5 A.M. found her dead in bed. The post-mortem, made the next day by Drs. Osler and Griffith, and myself, showed very marked disease of the aortic valves, with the entire escape of the mitral leaflets, and also total absence of any structural lesion of the aorta or of the innominate artery, the coats of both of which being found smooth, devoid of calcareous deposits, and perfectly normal, except for a slight increase in elasticity when stretched; and not only was this the case, but there was no increase in the calibre of either bloodvessel after death, proving that all the symptoms seen during life had arisen from an over-elasticity, and not a rupture of any one of the coats of the bloodvessel wall. The abdominal aorta was also found to be of a normal calibre, and devoid of any pathological condition.

It will be seen that in this instance we were confronted by a case in which all the ordinary and well recognized symptoms of aneurism of these vessels were present to a well marked degree, and there was nothing to stand against the diagnosis of aneurism during life, save the age of the patient, who was, of course, unusually youthful for this affection.

It is proper to state that such cases have been previously recoided, and that, as a general rule, they occur in young females of a hysterical temperament, although they may also appear in males with the same tendencies. There is no reason, apparently, why such a condition of the bloodvessels, occurring in a person not suffering from any cardiac lesion, should provoke anything but a favorable prognosis;

and, since an unfavorable opinion may in such cases do great harm, it is well for the physician to be on his guard.

OPERATION FOR DEFLECTION OF THE NASAL SEPTUM.

By W. PEYRE PORCHER, M.D.,
OF CHARLESTON, S. C.

I REPORT the following case on account of the simplicity and successful termination of the operation performed for its relief.

M. S., white, aged forty-five, had suffered from what he thought to be an unusually severe case of catarrh for five or six years, attended with exfoliation of bone.

His cartilaginous septum had become deflected to the right and depressed, causing an unsightly deformity and great difficulty in breathing.

On examination the lumen of the right nostril was found to have contracted to about the size of a small pea, as a result of adhesive inflammation, and the left nostril was greatly diminished on account of the deflection. There were also evident signs of exfoliation of bone on the right wall of the septum.

A pledget of cotton, saturated with a 10 per cent. solution of hydrochlorate of cocaine, was first introduced into each nostril, and under a continuous spray of rhigolene vapor the adhesions in the right nostril were divided, and the normal calibre restored.

A curved bistoury was then passed high up into the left nostril and through the septum, and an incision was made obliquely from above downward, and from left to right, along the line of the deflection, and extending to within one-quarter of an inch of the external end of the septum. A steel pin, upon which a small disk of rubber had been previously threaded, was then introduced into the right nostril and through the septum above and in front of the incision, its point being in the left nostril, was brought close up against the septum, across the incision and buried in the mucous membrane lining the floor of the nostril.

This, besides bringing the septum into a perpendicular position, widely distended the left nostril, and separated the walls of the right, which had been previously adherent, and he was enabled to breathe freely. A second pin was introduced, parallel to and a little above the first. On reporting at my office at 9 A.M. the following morning, the second pin was removed, as I found its point had not been carefully imbedded, and at 2 P.M. he again reported to me, stating that he had accidently withdrawn the remaining pin, and I anticipated a prompt return of the disfigurement. This, however, did not occur. He was ordered a posterior nasal douche to keep the passages cleansed.

With a piece of cotton mounted on a small cotton carrier, I carefully prevented any return of the adhesions in the right nostril, and on the sixth day he was discharged with perfectly free respiration and scarcely a trace of his previous deformity.

This operation is recommended by Dr. J. B. Roberts, of Philadelphia, my only departure from his instructions being the obliquity of the incision from left to right through the septum, so that in correcting the deflection the cartilage was at the same time raised, thus correcting the depression which previously existed.

HOSPITAL NOTES.

JEFFERSON COLLEGE HOSPITAL, PHILADELPHIA.

OPERATION FOR PROCIDENTIA UTERI.

DR. A. MARTIN, of Berlin, was introduced to the Class by Prof. Parvin on September 22d, and gave a demonstration of his operation for the treatment of procidentia uteri.

Procidentia uteri, he stated, is not to be satisfactorily treated by any operation which closes a large portion of the vagina only; the cicatricial tissue so formed will not endure: the operative treatment of this affection to be successful must include the uterus, the vagina, and the perineum. The patient presented for operation, a multipara, was suffering from retroflexion, subinvolution, and unilateral cervical laceration of the uterus with procidentia.

Dr. Martin described his plan of operation (as given in his book and that of Hegar and Kaltenbach) by diagrams upon a blackboard. He stated that he preferred catgut prepared in oil of juniper for suture material, and that he employed the continuous suture on the vagina and perineum, and the interrupted suture on the cervix uteri.

Proceeding to the operation Dr. Martin employed continuous irrigation with weak bichloride solution, stating that he was thus enabled to dispense with sponges; that the hemorrhage was insignificant, and that a cleanly and antiseptic operation was thus performed.

He first drew down the uterus, and amputated its cervix by wedge-shaped excision of the anterior and posterior lips, with subsequent interrupted suture. He then proceeded to operate upon the anterior vaginal wall, stating that for denudation in such operations he preferred a knife which he had devised whose edge was so arranged as to cut in many directions. After denudation he introduced the continuous catgut suture from above downward, meeting no difficulty in coaptation until the lower portion of the denuded surface was reached, where it was necessary to introduce étage sutures. The suture was brought back to the point of origin, and the uterus replaced with a sound.

The posterior vaginal wall was then denuded, the operation being so performed as to utilize the firm tissues of this portion of the vagina as a support for the uterus. Beginning at the vaginal column, the left side of the denuded surface was first closed, and then the right by the continuous suture. The cicatricial tissue in the perineum was then exsected; a single strong suture placed at its upper extremity and the remainder closed by the continuous suture, étage stitches being employed wherever needed; the continuous suture was brought back to the point of commencement, completing the operation.

The result was a firm perineum, a vagina restored throughout its entire extent, and a uterus replaced and

stimulated to involution by the excision of diseased cervical tissues.

The after-treatment advised was three weeks' rest in bed, the avoidance of movement of the bowels for four days, freedom from exercise for three months, and abstinence from sexual relations for eight or ten months. Ordinary precautions to secure cleanliness were to be observed. In the event of pyrexia, antipyretics were to be given. No local treatment or manipulation was desired.

MEDICAL PROGRESS.

Total Extirpation of the Uterus.—Schauta, of Prague, in the *Wiener medizinische Presse* of July 3, 1887, discusses the choice between partial and total extirpation of the uterus for cancer. He quotes the statistics of those operators who favor early extirpation, as compared with partial resection, as follows:

After total extirpation 70 per cent. of patients operated upon were in good health one year after operation; 50 per cent. of those on whom the partial operation only was made. After two years 100 per cent. of recoveries from the radical operation were in good health, 40 per cent. of recoveries from the partial operation; after three years the proportion was 100 to 40 per cent.; after four years 55 to 38 per cent.; after five years 43 to 35 per cent. Schauta reports a typical case in his own practice where an excellent result followed operation for the disease in its incipiency. He strongly advises early and radical operative treatment.

Sulphur in Chlorosis.—In some cases treatment stimulates the secretory activity of the gastric mucous membrane; in others, ferruginous drugs are successful; in others, both proceedings are useless. In these latter cases there is a deficiency, not of iron, but of sulphur, without which living albumen and active cellular substance cannot exist. Basing on these theoretical considerations, Schulz and Strübing have given sulphur in chlorosis. From the six cases thus treated they draw the following conclusions:

1. In cases of simple chlorosis, in which iron has no effect, the general condition is markedly improved by sulphur.

2. After sulphur has been given for some time, treatment with iron could be started and continued successfully.

3. Sulphur is not borne in cases of chlorosis complicated with catarrhal, inflammatory conditions of the digestive tract.

℞.—Sulph. depur. . . . . 150 grains.
Sacch. lact. . . . . 300 grains.
M. F. pulv. Half a teaspoonful three times daily.
—*Medical Chronicle*, August, 1887.

Metrorrhagia at Puberty.—Dr. Henry C. Coe, of New York, reports the following interesting case of this in the *New York Medical Journal* of August 27, 1887:

A perfectly healthy girl, aged thirteen, well developed for her age, of a full habit, and has never shown any evidence of sexual precocity, or nervous excitability, began over a year ago to menstruate at long intervals, and since spring the flow has reappeared more regularly, and on one or two occasions has been profuse, but not excessive. There has never been any dysmenorrhœa. She has now been at the seashore nearly five weeks, and has during that time been exposed to the usual excitement, late hours, improper diet, etc., incident to life at a fashionable watering-place. She has, however, neither danced nor indulged in seabathing. She had been at Long Branch two weeks, and was awakened during the night (July 13th) by cramps in the stomach, accompanied by a sudden gush of blood from the vagina. The flow continued steadily, and when Dr. Coe saw her the next morning she presented the appearance of a woman after a smart postpartum hemorrhage, her night-dress, the sheets, and the mattress being literally soaked with blood, while there was a large mass of blood-clot in the bed. He estimated the loss of blood at about twelve ounces. The child was kept for three days in the recumbent posture, on low diet, and had twenty-five drops of the fluid extract of hydrastis canadensis every six hours.

On the fifth day she was allowed to walk down stairs to breakfast; there had been no show for two days. While eating she felt a peculiar sensation in her stomach and at once returned to her room and lay on her bed. Suddenly there came a gush of blood, as on the first occasion, although the amount was somewhat smaller than before. The use of hydrastis, which had been discontinued, was resumed in doses of twenty five drops every two hours without result. Several napkins were saturated in rapid succession, and the child's mother became greatly alarmed. Ergotin, in full doses, was administered every two hours, and an ice-bag was applied over the hypogastrium, but was removed at intervals of half an hour. A pint of hot water, containing two drachms of alum, was carefully injected into the vagina with great difficulty. The little patient had no pain, except an occasional cramp, which preceded the expulsion of a clot. Her pulse and temperature were not affected. The flow diminished during the afternoon, but was still excessive, even for an adult. The blood was brightred in color, and was certainly not menstrual in character.

During the next forty-eight hours two alum injections and two drachms of the fluid extract were given daily. The hemorrhage gradually diminished until by the fourth day only two ounces of blood were lost. On the sixth day there was no show, and the patient was allowed to sit up and walk across the room, as her appetite was impaired by the close confinement. She felt a little weak, but was not otherwise affected by the loss of blood. She was not allowed to leave her room. Four days after the complete cessation of the last hemorrhage the regular menstrual flow began at exactly the proper time. There was no pain, but the flow was unusually profuse. She was kept absolutely quiet in bed during the first five days, and received twenty-five drops of aromatic sulphuric acid every six hours, with alum injections, night and morning, during the first two or three days, neither of which seemed to have the slightest influence upon the menorrhagia. Dr. Coe is convinced that the excessive loss was directly due to residence at the sea-shore.

The patient subsequently went to the White Mountains, and has had no return of the metrorrhagia.

Treatment of Acne.—Lassar recommends a treatment of acne which, he says, is easy of application, and nearly always successful. He uses a modification of the old ointment of Wilkinson in the following form:

R.—β Naphthol	150 grains.
Sulph. præcip. . . .	750 grains.
Vasal. flav., or Landol. puriss.,	
Sapon. viridis	āā 375 grains.
M. leniter torendo fiat pasta.	

The paste is spread in a thin layer on the affected skin, and left on for fifteen to thirty minutes. A burning sensation is felt, but this soon disappears; the ointment is then rubbed off, and powdered talc is dusted over. This is followed by a slight inflammatory reaction, which soon gives way to browning of the skin, and finally desquamation. The whole process is compared to the browning, etc., of sunburn. The desquamation may be shortened by the nightly application of a two per cent. salicyl-zinc-amylum-vaselin paste.

Lassar has employed this treatment in more than 100 cases, and relates some very successful cures of very bad cases. This paste is of service, too, in other superficial inflammatory skin diseases, as sycosis of the beard, and in lupous granulations.—*Medical Chronicle*, August, 1887.

Liver Abscess in Children.—Unger, of Vienna, after reviewing the recent literature of this disease, concludes that children are less liable to hepatic suppuration than adults.

With the exception of abscesses from impacted gallstones the same causes obtain in children as in adults. The symptoms are peculiar to the individual case. The most important symptom is chills and pyæmic fever in a previous disease of the area connected with portal or mesenteric veins. Percussion and aspiration will complete a diagnosis.—*Wiener medizinische Presse*, July 31, 1887.

Sulphurous Acid and Liquid Vaseline, for Phthisis.—Villi exhibited at a recent meeting of the Therapeutic Society of Paris a solution which he had made for Dujardin-Beaumetz, of sulphurous acid in vaseline; the strength of the solution varied with the temperature from 1 in 100 to 2 in 100 parts. It was given hypodermatically in the gluteal region, as deeply as possible, in doses of 75 minims daily. General improvement in the symptoms and general condition of the patient was the result.—*Revue Générale de Clinique et de Thérapeutique*, August 4, 1887.

Convallarin and Convallamarin, Glucosides of May-lily.—Nathanson, a Russian physician, has investigated these substances, with the following results: The first step made by Dr. Nathanson was to have the commercial glucosides analyzed; a second, to undertake a series of therapeutic experiments at Professor Koshlakoff's clinic. The first preparation of convallamarin obtained by him from Merck (in 1885) proved to be a mixture of that glucoside with convallarin and some products of decomposition of both, as an analysis by Professor A. A. Loesch had established. The explanation of discrepancies between different observers was then pretty near. Of course, no experiments were made with that preparation, and the purest glucosides were obtained from Merck to be given in four cases of disturbed compensation (in a patient, aged fifteen, with aortic regurgitation and relative mitral insufficiency; in two patients, aged fifty-seven and forty, with aortic regurgitation alone; and in a patient, aged forty-eight, with mitral regurgitation and stenosis). The results were these.

1. Convallarin (given in the dose of from $\frac{5}{10}$th to $1\frac{1}{2}$th grains three or four times daily for three to eight successive days) produced only nausea, diarrhœa, and gastric pain. The pulse, breathing, daily amount of urine, and dropsy either remained unchanged or showed unfavorable alterations.

2. Convallamarin was administered in the daily (gradually increasing) dose varying from one-half to five grains for eleven to seventeen successive days. In one of the patients, to whom digitalis, scilla, caffeine, and adonis had been previously given and failed, convallamarin also remained, on the whole, inactive, the improvement consisting only in a slight decrease of dyspnœa and palpitation after exercise. But in the remaining three patients a rapid and striking improvement ensued; the pulse became slower and more regular, the amount of urine augmented, dropsy decreased, and all other signs of disturbed cardiac compensation gradually and steadily disappeared.

3. Of accessory effects, only slight nausea, salivation, and giddiness were observed in one of the patients when the daily dose had been increased to 4½ grains; in another, slight nausea and vomiting made their appearance when the daily dose had been raised to 3¼ and 6 grains.

4. No cumulative action was ever observed. The general conclusion of Dr. Nathanson is to the effect that convallarin possesses but a purgative action, while convallamarin represents a useful cardiac drug endowed with the power of reëstablishing disturbed compensation, and free from any unpleasant accessory effects. Selection of an absolutely pure preparation is a matter of paramount importance.—*London Medical Record*, July 15, 1887.

An Incompatible Prescription.—Powell found the following incompatible, from the formation of a heavy double chloride of quinia and mercury, which was precipitated.

Tinc. ferri perchlor	℥vj.
Quin. disulph.	gr. xlviij.
Acid. hydrochlor. dil. . . .	q. s.
Liq. hydrarg. perchlor. . . .	℥iv.
Aq. dest.	ad ℥xij.

—*American Journal of Pharmacy*, August, 1887.

The Microbe of Wolf Rabies.—In a preliminary note in the *Vratch*, No. 21, 1887, p. 415, Drs. Julius Motte and N. Protopopoff, of Professor S. D. Kostiürin's laboratory, in Kharkov, state that while studying wolf rabies they have met with a microörganism which seems to be closely connected with the rabic virus in wolves. The following is an outline of the experiments. A young wolf was inoculated by hypodermatic injection of an emulsion of the brain of a dog which had died from spontaneous rabies of the furious

type. Twelve days and four hours later the wolf developed symptoms of paralytic rabies, which ended fatally in about forty hours. Half an hour after the animal's death, an emulsion of the wolf's brain was introduced beneath the dura mater of a rabbit by trephining. The rabbit died in three days; an emulsion of its brain was inoculated in a second rabbit, from that to a third, and so on. A fifth rabbit, and a sixth inoculated from the fifth, died about twelve hours after the operation, with all the symptoms of paralytic rabies. On the *post-mortem* examination of the sixth rabbit, a considerable quantity of opaque fluid was found between the dura and the pia, and in the subarachnoid spaces. This fluid contained, besides a few leucocytes, an enormous number of extremely minute, short, and very motile bacilli, of a very special kind; in fact, the fluid represented a natural "pure culture" of the microorganism. An inoculation with brain and spinal cord from that rabbit invariably produced paralytic rabies in other rabbits, death always ensuing in about twelve hours. On *post-mortem* examination, the same microbes were found in all cases. The animals' blood also contained similar bacilli, but in far smaller numbers. A rabbit inoculated by trephining with the blood died in twenty nine hours. Having prepared a pure culture in meat broth, Drs. Motte and Protopopoff inoculated it either by trephining or by hypodermatic injection. In the former case, all the animals (four rabbits) died from paralytic rabies in twelve hours; in the latter, in from two to six days. The same microorganisms were detected in a young rabbit which had been inoculated by trephining with an emulsion of the brain of another wolf, which had died of spontaneous rabies. The authors promise to publish at an early date the results of their inquiry into the morphological and biological features of the microbe which they have discovered.—*British Medical Journal*, July 23, 1887.

TERPINE IN PILL FORM.—RABOW gives the following formula:

R—Terpini hydrat.	. . . .	gr. 45.
Sacc. alb.		
Mucilag. gum. Arab.	. . .	āā q. s.

ut f. pil. 30 in num.

Sig.—One pill three times daily.—*Therapeutische Monatshefte*, August, 1887.

WOUNDS INFLICTED BY LIONS.—At a recent meeting of the Paris Surgical Society a report from M. JEANNEL, of Toulouse, was read, narrating an interesting case of an animal tamer, aged thirty, whose arm was severely bitten to the shoulder by a lion. The wounds were lacero-contused; the humerus was laid bare; the limb had been amputated at the elbow-joint by the lion. The accident occurred at 9 P.M.; there was no excessive shock or prostration, and the surgeon postponed active interference until morning. On the following day well-marked emphysema and gangrene were present; temperature 105°; the general condition of the patient bad. Amputation at the shoulder-joint, after preliminary ligation of the subclavian and scapular vessels, was made at once. There was slight hemorrhage; patient died of profound septicæmia in a few hours.

M. POLAILLON had a similar case, two years previous, of lacero-contused wound, with multiple comminuted fracture of the forearm from a lion's bite. He amputated immediately at the shoulder-joint, but the patient died of acute sepsis. The origin of septic infection in these cases was thought to be not only the contusion of the tissues, but contagion from partly decomposed meat which the lion was eating. Amputation should be made promptly.—*Revue Générale de Clinique et de Thérapeutique*, August 4, 1887.

PEAT MOSS AS A DEODORIZER.—DR. D. M. USPENSKI, in a preliminary note in the *Vrach*, describes a number of bacteriological and other observations he has made on a kind of peat moss belonging to the sphagni, which is indigenous in many parts of Russia and Siberia, and which is used with considerable success in the form of coarse powder for disinfecting cesspools and privies in Warsaw, Riga, and other towns. It is found that about four ounces sprinkled over an ordinary stool are sufficient to deodorize and dry it, so that the receptacle can be emptied and cleaned at proper intervals without any unpleasantness arising. This substance seems to have a wonderful power of absorbing moisture, for it was found by experiment that a pound of it which already contained 25 per cent. of water was capable of absorbing no less than seven pounds and a half more water. When added to fecal matter in the proportion of 10 per cent. by weight, it changes it into an almost dry mass of an earthly appearance, devoid of smell and easy to remove. A hundred pounds of the powdered moss will absorb 1438 litres of ammonia. The dry mass obtained by the action of the moss on feces, on being analyzed by Mr. Miltser, was found to contain from 2.38 to 2.66 per cent. of nitrogen, and from 0.96 to 1.15 per cent. of phosphoric acid, and, of course, formed a very valuable manure. The powder as received contained 23.9 per cent. of water and 5.38 per cent. of ash, and without any preliminary drying they absorbed fourteen times their own weight of water. Bacteriological experiments proved that the moss has a great capacity for diminishing microorganisms of various kinds. If this substance can be easily and cheaply obtained, it would appear to offer advantages over the dry earth we are accustomed to use, and in large towns would doubtless prove very valuable.—*Lancet*, September 10, 1887.

RESORCINE, EXTERNALLY.—WYSS recommends the following for *eczema*:

Resorcin	. . . . .	3i.
Glycerine	. . . . .	3ss.

And also,

Resorcin,	. . . . .	gr. 15 to 30.
Vaseline	. . . . .	3ss.

UNNA advises a five per cent. pomade for *eczema*, *variola*, and *scarlatina*.

For *pityriasis versicolor* IHLE has found useful:

Resorcin	. . . . .	3ij½.
Vaseline	. . . . .	3ij½.
Rice powder,		
Oxide of zinc	. . .	āā 3vi¼.

In *erysipelas* resorcin may be given hypodermatically in five per cent. solution, or externally in seventy per cent. ointment.—*Revue Générale de Clinique et de Thérapeutique*, September 1, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance. . . . . $5.00.

Single Copies. . . . . 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, OCTOBER 1, 1887.

CHOLERA AT THE NEW YORK QUARANTINE.

The arrival at the Port of New York of the steamship "Alesia" of the Fabre line, from Naples *via* Marseilles, with cases of cholera on board, is a warning which is not likely to be overlooked or neglected. The danger from this particular importation of the disease is probably extremely small, but it has been recognized in time, and the quarantine establishment of New York is probably better fitted than any other to deal with the emergency. The passengers have been transferred to the buildings on Hoffman and Swinburne Islands, the well being separated from the sick, and they will there be kept under observation for a reasonable time. Several cases have occurred among those who were apparently well when landed, showing that the infection was pretty thoroughly disseminated among them, and so long as fresh cases continue to occur, so long it will be necessary to keep up the isolation.

The ship itself and the baggage are probably more dangerous than the passengers as sources of infection, but they are easier to deal with, and it may be considered as certain that they will be completely and effectually disinfected. Taking all these circumstances into consideration in connection with the lateness of the season it is very improbable that there will be any spread from this particular importation.

The significance of the presence of these cases in New York harbor is, and upon this too much stress can hardly be laid, that the specific cause of cholera exists in some of the Mediterranean ports, and probably also in the interior in their vicinity, although there may be few or no signs of its presence, in a form which is capable of becoming virulently active under favorable circumstances, and that therefore all ships and immigrants from these ports are more or less dangerous. This danger with regard to any particular ship on which the disease has not appeared when it arrives on our coast is very small, so small that, in view of the many other channels through which cholera might now come to us, it would not be worth while to enforce special precautions, but taking into consideration all the sources of importation of cholera to which we are now exposed, the persistence of the disease in Europe and its appearance in South America, the danger of its introduction into this country within the next nine months is very considerable.

We have had a long forewarning, and during the past three years much has been done to put our cities, towns, and villages into good sanitary condition, but much remains yet to be done, and it is to be hoped that the infected "Alesia" will prove to be a powerful stimulus to municipal authorities, water boards, and health officials to carry out the well-known measures for securing cleanliness and pure water, which are the only certain safeguards against this form of epidemic disease.

HYPERSECRETION OF GASTRIC JUICE.

The functional value of a glandular organ and that of its secretion may be considered identical. An apparent exception is furnished by the stomach, an organ to which muscular movement is of decided importance in the performance of its function. There are numerous facts, however, which prove that a normal gastric fluid is not secreted by a stomach of which the walls are atonic from any cause. A digestive secretion, to be normal, must not fall below or exceed a certain amount; it must have a definite composition; and, finally, it must be discharged through its ducts or follicles, intermittingly or remittingly. Being intended to act upon the food, its presence in the stomach when food is absent is out of place, uncalled for, and constitutes a morbid condition.

Nearly all functional disorders of the stomach are classed under the head of dyspepsia, and their treatment is based upon the theory of a deficient or altered gastric secretion. Hence, the constant administration of pepsin, pancreatin, acids, and alkalies. It is only quite recently that certain well-marked stomach disorders have been proved to be due to an excessive and unintermittent secretion of gastric juice. This condition is by no means a pathological curiosity. First described by Reichmann, in 1882, cases have since been reported by Sahli, Schütz, van den Velden, and especially by Riegel, who, in the course of the last eighteen months, has seen twenty nine cases.

The symptoms of hypersecretion of gastric juice,

or, to be more accurate, of unintermittent secretion, depend upon the duration of the morbid state, and on the hygienic environment of the patient. Sometimes the emaciation, feebleness, and anæmia are so extreme as to excite the suspicion of carcinoma, and with these symptoms there is apt to be epigastric tenderness and dilatation of the stomach. On the other hand, cases of old standing may present little evidence of impaired nutrition. Increased thirst, heart-burn, nocturnal attacks of pain in the epigastrium, acid eructations and vomiting, and dilatation of the stomach, constitute a set of highly diagnostic symptoms. The only certain means of diagnosis, however, is afforded by an examination of the contents of the stomach. If these be removed from five to six hours after a frugal meal, the following indications will be obtained: 1. The amount of material in the stomach is much greater than is usually found at such a late period of digestion. 2. The albuminoids are completely digested. 3. The amylaceous substances are undigested. 4. The fluid is more than usually acid. Riegel (*Deutsche med. Wochenschrift*, July 21, 1887) has found the percentage of hydrochloric acid three times greater than normal.

As above stated, these are *indications*. Absolute proof of the condition is furnished by the withdrawal of the stomach contents when the viscus is empty of food. The stomach is thoroughly washed out in the evening, and the patient fasts until the following morning, when the sound is again introduced. If the condition under consideration is present, from 8 ounces to a pint of a colorless or greenish, turbid, slightly viscid fluid will be withdrawn. It is strongly acid, gives all the reactions of hydrochloric acid, contains no organic acids, and digests albumin rapidly. In short, it is gastric juice.

Hypersecretion must not be confounded with hyperacidity. The latter consists in a too liberal response to a physiological summons, while the former is gratuitous. There are, however, transitional forms between the conditions, for the secretion which is excessive in response to a physiological, will, in time, be produced in the absence of any stimulus.

There is an undoubted relation between hyperacidity and hypersecretion and gastric ulcer. In more than one-third of Riegel's cases decided symptoms of ulcer, including hæmatemesis, had been present at one time or another. This observer holds that the excessive secretion of hydrochloric acid is not, as Jaworski believes, a direct, but merely a predisposing cause of ulcer. The ordinary dangers of a trauma of the gastric mucosa are greatly increased under such circumstances. A simple erosion in a stomach that is never empty of gastric juice will probably proceed to the formation of an extensive ulcer.

The causes of hyperacidity and hypersecretion are not, as yet, understood; but that the condition is of neurotic origin is proved by its ephemeral occurrence in neuropathic individuals in general, and particularly during the *crises gastriques* of those affected with tabes.

The chief features of the treatment are the methodical washing out of the stomach, preferably just before the principal meal, and the employment of alkalies and alkaline mineral waters. In no other affection is lavage of the stomach more beneficial. The diet should consist almost entirely of albuminoids, and the thirst, often excessive, may be assuaged by bits of ice, for it is an important point that the dilatation of the stomach, so frequently present, should not be maintained by a too free ingestion of fluid. So important is this considered by Riegel that he advises the use of small doses of opium to obtund an overpowering sense of thirst.

THE LIBRARY OF THE SURGEON-GENERAL'S OFFICE.

THE new fire-proof building for the Army Medical Museum is now approaching completion, and a large part of the Library has been transferred to it, and is thus safe from fire, although the books are not accessible, being piled on the floor of the Library Hall, awaiting the completion of the iron book stacks in which they are to be placed. The original contract called for the completion of this building in April last, but the builders have not complied with their agreement, and it will probably not be completed until November next.

In July last the Secretary of War ordered that the rented buildings occupied by about 150 clerks in the pension division of the Surgeon-General's Office should be vacated by September 1st, as Congress had made no provision for rent for these buildings for another year, and that room must be made for these clerks in the old Museum building, which belongs to the Government. This necessitated the vacating a large part of the Library hall and of the rooms connected with it, and the packing into the smallest possible floor-space of the books, which could not be moved. The result of the peremptory order of the Secretary of War is that the Library has been practically almost inaccessible for about six weeks, and it will remain so until the middle of October. We have heard some complaints about this, and especially that it should have occurred during the meeting of the International Congress, but, as the result of careful investigation, we are satisfied that it was practically unavoidable, and that the Medical Department has been in no way to blame for the delay and confusion.

The insinuations which have been made that the

closure of the Library during the Congress was unnecessary, and that it was intended as a slight to that body, are wholly without foundation, for we know that Dr. Billings used every effort to hasten the work, and that no one regrets more than he does the fact that the Library could not be accessible to visitors at that time. Fortunately it was found possible to leave the Museum practically undisturbed, and it received a large number of interested visitors during the week of the meeting of the Congress.

It is very satisfactory to know that the treasures of the Library and Museum will soon be not only out of the dangerous position in which they have heretofore been placed, but also in light and airy rooms, where they can be properly displayed and classified, and thus be most interesting and useful.

THE ETIOLOGY OF ACUTE ENDOCARDITIS.

We have already referred to the observations of Orth, Philipowicz, Prudden, and others, which demonstrate the constant association of microörganisms with the lesions of ulcerative endocarditis, and the possibility of the artificial production of the disease in animals with or without previous laceration of the valves. A number of forms have been cultivated, chiefly cocci, but in one or two cases small bacilli, and in two instances in which the endocarditis complicated pneumonia, the same kind of organisms were found in the lung and on the heart-valves.

Weichselbaum has recently studied the question with great care, and has given his results in the *Centralblatt für Bacteriologie und Parasitenkunde*, Bd. ii. No. 8. Cultures were made from fourteen cases of ulcerative endocarditis, as soon as possible after death, in some instances within an hour or two. In twelve, microbes were present; in six cases the streptococcus pyogenes; in three, the pneumonia diplococcus; and in three, less common, but equally distinctive, forms. In the two negative cases the vegetations were old and calcified. The experimental work confirms the results of previous observers regarding the feasibility of inducing artificial endocarditis.

A much debated point, upon which we need further observations, is whether in the ordinary verrucose endocarditis microörganisms are present in the vegetations. Klebs, Koster, and Ziegler regard this form as also bacteritic, but Osler, Orth, and others have failed to demonstrate their presence. Recently, E. Fränkel and Sänger, in *Virchow's Archiv*, Bd. 108, have found organisms in nine out of fourteen cases, and have shown that the colonies may be so scanty that the culture method gives much more definite results than can be obtained by section and staining. In two instances, however, Weichselbaum could not find them, and suggests, in explanation, that the vegetation may have been old and the organisms dead. More extended observations are required before we can attribute every case of warty endocarditis to the irritation of microbes on the valves; meanwhile the studies which have been made bring us nearer to the solution of the important problem of the origin of these secondary cardiac inflammations, so often disastrous in themselves, and more frequently injurious in initiating a progressive and damaging lesion.

The eighth volume of the *Index Catalogue* of the Library of the Surgeon-General's Office, U. S. Army, has just been issued, and extends from *Ligier* to *Medicine* (*Naval*). It covers 1078 pages, and includes 13,405 author titles and 36,816 subject titles. As examples of its richness in bibliography, we find that the references to "lithotomy" and "lithotrity" cover 85 columns, to the "liver" 142 columns, to "malaria" 15 columns, and to "measles" 26 columns. This volume, like its predecessors, has been compiled under the supervision of Surgeon John S. Billings, and, as has been well said by a contemporary, "if Dr. Billings had done nothing else for his profession, the talent and energy expended in this work would alone entitle him to the earnest gratitude of every lover of medical science and literature."

SOCIETY PROCEEDINGS.

NINTH INTERNATIONAL MEDICAL CONGRESS.

Held at Washington, September 5–10, 1887.

(Specially reported for The Medical News.)

SECTIONS.

Obstetrics.

Thursday, September 8th.

Dr. Emile Poussié, of Paris, read a paper on

TYPHOID FEVER OCCURRING DURING THE PUERPERAL STATE, AND TERMINATING IN RECOVERY.

The points of interest were: The development of the typhoid fever during the puerperal state; the anomalous début of the disease, resembling a commencing peritonitis; the form of the disease,—the ordinary one, of slight gravity although developed during the puerperium; and the fact that the sick woman not only recovered, but no sequelæ appeared.

Professor Simpson, of Edinburgh, thought it fortunate that Dr. Poussié had brought forward his case in connection with the subject of puerperal fever. It was important to observe that there might be many varieties of fever occurring in puerperal women. Dr. Poussié's case illustrated the possibility of the occurrence of typhoid fever during the puerperium, and such cases might be met with in all ranks of the community, wherever pregnant and lying-in women occupied bedrooms open to the invasion of sewer-gases. But sometimes

women recently confined have been said to die of puerperal fever, who have been the subjects of one of the other zymotic fevers. The danger of scarlatina in puerperæ was well known, and he had seen a parturient woman die three days after labor of measles.

The paper read, dealt, however, more directly with the febrile condition of the puerpera, resulting from the introduction of septic matter into the system, and resembling more or less the febrile condition set up in surgical patients after wounds and injuries. What might be the nature of the poison? How was it introduced into the system—whether only through the genital tract at the hands of the attendants, or also through the atmosphere? How were its ravages to be met? These were the questions now open for discussion in this Section.

DR. GRAILY HEWITT, of London, believed that defective contractions of the uterus are largely responsible for the occurrence of puerperal fever in private practice. This defective contraction is due largely to weakness. Therefore, he urged attention to hygiene and good feeding during pregnancy, and extreme care in securing firm retraction of the uterus after labor and during the early hours of the puerperium.

With reference to antiseptic precautions, he regarded the cavum uteri as the starting point of general infection in the majority of cases. For purposes of intrauterine irrigation, he recommended Berdin's celluloid, double catheter, exhibited at the Copenhagen Congress.

As regards treatment, he relied upon food and stimulation, relating the history of a case of the worst kind—a woman in a lying-in hospital hourly expected to die—patient recovering after the exhibition of a bottle and one-half of brandy within twenty-four hours.

DR. W. W. JAGGARD, of Chicago, expressed his belief in the Semmelweiss doctrine of puerperal fever. He desired to enter as vigorous a protest as possible against the irrational and pernicious use of intrauterine irrigation proposed by Dr. More Madden. When the indication for intrauterine irrigation after labor was perfectly clear and distinct—as after the introduction of the hand into the cavum uteri in version—the uterine cavity should be washed out with a two per cent. solution of carbolic acid in sterilized warm or hot water, by means of Carl Braun's hard rubber tube or Chrobak's modification of Bozemann's double catheter. This secured relative disinfection of the endometrium.

Then to secure continuous disinfection it was necessary to introduce a bacillus containing sixty to seventy-five grains of powdered iodoform, Mosetig-Moorhof's formula. The cavity of the uterus was now disinfected and permanently sterilized, and ought to be *let severely alone*. It was seldom necessary to repeat this process.

To secure retraction of the uterus it was good practice to apply gentle massage to the fundus uteri twice daily during the first forty-eight hours of the puerperium, as was customary in Carl Braun's wards in Vienna. There was little danger of interfering with puerperal thrombosis by this means if not continued longer than forty-eight hours. He agreed with Dr. Graily Hewitt, Kucher, and others that a well-contracted uterus was well nigh proof against infection. He had seen used and had himself used iodoform on a colossal scale since attention was called to the drug by Mosetig-Moorhof in 1881, and had never seen a case of iodoform toxæmia arise when the drug was employed as here described.

DR. JAMES C. CAMERON, of Montreal, said a satisfactory treatment for puerperal fever will never be reached until the profession learns to recognize that, in the immense majority of cases, puerperal fever is puerperal septicæmia. Robert Barnes, in a recent review of Parvin's *Obstetrics* in the *British Gynecological Journal*, says that this view is narrrow, because it does not take into account the peculiar condition of the puerperal woman's blood. He then reiterates his threefold theory of endosepsis, autosepsis, and exosepsis. Such teaching does great harm. Endosepsis is a myth, and if general practitioners are taught that puerperal fever can arise of itself, their practice can never be satisfactory. According to the germ theorists, septicæmia postulates the existence of two factors, the soil and the germ; hence rational antiseptic treatment should run on two lines, the sterilizing of the soil and the exclusion or destruction of the germs. The exclusion of germs after labor is best obtained by the dry method of dressing—the insufflation of iodoform into the vaginal outlet and the constant closure of the vulva with a dry antiseptic pad, sterilizing the air entering the genital canal. The pathologist sterilizes his culture tube, plugs it with cotton-wool, and thus keeps his culture free from the contact of atmospheric putrefaction germs; so the obstetrician plugs his obstetrical culture tube and keeps it free from atmospheric contamination.

With regard to the use of the uterine douche and curette, he had obtained brilliant results in suitable cases, but he strongly emphasized the warning uttered by Dr. Jaggard, that great harm is done by continued and injudicious douching. The object of local treatment is to remove local sources of infection; when this is once thoroughly done, a bacillus of iodoform is introduced and the dry dressing applied, the parturient canal is practically aseptic, and only harm will result from further local treatment.

When general systemic infection has occurred, a struggle between the white corpuscles and the microbes ensues; the issue depends upon the relative strength of the opposing forces, the army of the defender and that of the invader. The rational treatment of this general condition seems to be that applicable to all rapidly prostrating general diseases, such as diphtheria—large quantities of nutriment and stimulants, with iron and quinine, when required, will give more satisfactory results than any other. Success in the treatment of puerperal septicæmia will depend upon the skill of the physician in recognizing when to use local, and when to use general treatment. The patient must be treated and not the disease; there is no such thing as a specific treatment for puerperal septicæmia.

DR. J. A. DOLÉRIS, of Paris, after referring in flattering terms to the papers just read, said that he wished to emphasize the precepts of Dr. Earle's paper. He had practised curettement of the puerperal uterus as late as the fourteenth day, with excellent results.

PROF. RODNEY GLISAN, of Portland, Oregon, read a paper on

CONSERVATIVE OBSTETRICS; WITH SPECIAL REFERENCE TO THE REMOVAL OF THE SECUNDINES AFTER ABORTION, AND TO THE TREATMENT OF THE THIRD STAGE OF LABOR.

He thinks that the expectant method of treating re-

tained secundines after abortion, and of the placenta in labor, is unsafe in private practice, especially when the doctor resides at a distance from his patient; yet it may succeed fairly well in hospitals under the constant vigilance of experienced practitioners. He believes that the heroic method of always removing the secundines in abortion immediately after the expulsion of the embryo, and of the placenta immediately after the birth of the child, is in private practice safer than the do-nothing mode because there is less danger of hemorrhage and septicæmia, yet he prefers a conservative method to either of the others.

In an active practice of thirty-nine years Prof. Glisan has never found any instrument for the removal of the secundines after abortion so safe, useful, and trustworthy, as the finger. He adopts the bimanual method of abdominal depression of the uterus with one hand to within easy reach of the index finger of the other; and then inserting the latter finger far enough into the womb to seize the secundines and remove them. In cases of excessive sensibility, or great abdominal rigidity, or of undilatability of the cervix, he administers an anæsthetic—either chloroform, or a combination of it and ether—except when the patient is anæmic from hemorrhage, when ether alone is used,

In the removal of the placenta during labor he adopts a modified or conservative Credé method. That is, he advises pressure to be made on the fundus of the womb in somewhat the manner recommended by Credé, and with his precaution of using force only during the acme of uterine contractions, but he would use less pressure than is advised by Credé, and aid it by moderate traction on the cord, to which Credé is strongly opposed.

Dr. Glisan does not believe that moderate traction on the cord, when the womb is in a state of good contraction, and is properly grasped by one hand externally, is attended by the least risk of inversion of the uterus, or of increasing the hemorrhage by a suction-like process of the placenta on the cavity of the womb.

Dr. Graily Hewitt, of London, said that he believed it was most important in the treatment of abortion to remove the secundines, but that he had observed that early in the abortion the internal os was often very narrow. In such cases a little time should be allowed before attempting manual extraction. For removal, the finger was best, coupled with depression of the uterus from the outside.

Dr. John Bartlett, of Chicago, presented

A STUDY OF DEVENTER'S METHOD OF DELIVERING THE AFTER-COMING HEAD.

He pointed out evidences in the writings of Deventer that he practised a method of delivering the after-coming head, which he regarded as easier, and safer for mother and child, than other methods. This method, as described and practised by Smellie, shows it to consist of a reversal of the so-called Prague method, in that the body of the child is carried backward toward the perineum, with a view of turning the occiput out from under the pubes; the anterior surface of the neck resting on the perineum.

Professor Simpson, of Edinburgh, said he regarded the great Dutch obstetrician as one of the most reliable obstetric writers, whose statements as to his success in practice he accepted without reserve. It is an interesting illustration of the importance of the relative study of the works of contemporary writers that it was from the works of Smellie that Dr. Bartlett has been able to unearth Deventer's secret.

Dr. A. F. A. King, of Washington, D. C., said that the method of Deventer had been overlooked by modern writers. The method of traction downward and backward toward the perineum is generally recommended when the occiput has rotated posteriorly and the chin pole is below the pubes, but it is generally advised to deliver the arms first. He would take pleasure in trying Deventer's method, and would recommend it as a legitimate procedure.

Diseases of Children.

THURSDAY SEPTEMBER 8TH.

Dr. Albert R. Leeds, of Hoboken, N. J., read a paper on

THE SCIENTIFIC BASIS OF THE NUTRITION OF INFANTS.

He said that he desired to engage the attention of the Congress upon this subject, both on account of its intrinsic vital importance, and because he believed that the existence of a scientific basis for the nutrition of infants has been satisfactorily established. This paramount importance is shown by the fate of infants under present conditions of nutrition: out of every 100 infants fed on mother's milk, statistics show that about 8 die at the end of the first year; out of 100 wet-nursed, 18 die; and out of 100 fed on "infant foods," 51, or more than one-half, die by the end of the first year.

In an investigation made in 1883 upon all infant foods then in use (*Transactions of the College of Physicians of Philadelphia*, 1883), he found that all these foods, whatever might be their name or pretensions, belonged to one or the other of two great classes; they were either flour, plain, baked, or cooked, or they were sugar admixed with cereals in some form, the so-called Liebig's foods. The cause of the great mortality among infants using these foods is obvious—they are physiologically as unsuited to the nutrition of a human infant as grass and hay are to the nutrition of a calf deprived of cow's milk.

All the varieties of "infant foods" are intended to prevent the formation of hard clots by keeping asunder the particles of caseine by means of starch, dextrine, sugar, etc.

Four years ago he proposed that we should abandon artificial foods altogether. He prepared for infants deprived of mother's milk, milk to which he gave the name of "humanized," since it was, as far as could be ascertained, the same in composition and properties as mother's milk. As a foundation for this work he made analyses of eighty samples of mother's milk. They varied greatly in composition with the age, temperament, physical health, etc. of the mother. But when their average composition came to be compared with that of cow's milk, certain facts stood out very prominently. They were: first, that the amounts of sugar and fat in mother's were much greater than in cow's milk; second, that the caseine was much less; third, that the nature and proportions of the ash were not the same. But the most important difference was in the

different digestibility of the caseine of the cow's milk. At the time that he was engaged upon this research, the treatment of cow's milk with artificially prepared pancreatic extract in order to convert the caseine into a soluble peptone, was being largely resorted to. He was aware of this fact, and of the experiments of Dr. Roberts, of England, upon this subject. But at that time, no one, so far as he is aware, had studied the relative character of such peptonized caseine and the caseine of mother's milk. On making such an investigation, he found that in properties and tests the two bodies behaved in precisely the same manner. Finding that the distinguished pharmaceutical chemist, Mr. B. T. Fairchild, could prepare a tryptic ferment which could be relied upon with certainty to effect the desired change in cow's milk, he made this tryptic ferment the basis of the so called peptogenic powder. By diluting cow's milk with the requisite quantity of water, its percentage of caseine is lowered to the same amount as in mother's milk. By the addition of cream, the percentage of fat is adjusted, and the heating of the milk for five minutes with the peptogenic mixture does the remainder. The "humanized milk" thus prepared has already been the sole nutrition of many thousand infants, especially children of weak and disordered digestion, and he believes it to be a successful solution of the problem of infant nutrition.

General Medicine.

FRIDAY, SEPTEMBER 9TH.

SIR JAMES GRANT, of Canada, then made some remarks on

THE TREATMENT AND ETIOLOGY OF DIPHTHERIA.

He regards it as a blood disease, and therefore always directs that the patient be given each day a warm bath with mustard in it. The irritation of the skin draws away the blood from the throat where it would enter, and thus relief is obtained. He has noticed in Canada that in the winters in which a heavy fall of snow occurs the disease is rare, as it is also in the following summer; but if the snow-fall is light and the winter damp, then the disease is rife both in the winter and summer.

He has also noticed the fact that convalescents from diphtheria do better in hilly regions than at the seashore, and in sending such persons away to recuperate he always insists on the high lands.

The Section passed a vote of thanks to Sir James Grant for his interesting remarks.

DR. A. B. PALMER, of Michigan, had used pilocarpine for the same purpose for which Dr. Grant had used baths.

DR. JOHN A. OCTERLONY, of Louisville, read the report of the Committee which was appointed to investigate the statements made by Dr. Joseph Kaposi, with reference to the

ANTI-VACCINATION STATISTICS

of Keller in Austria. The most astonishing statement in the report of Keller was that in children, under one year of age, vaccination produced no result at all, as the mortality of unvaccinated was 13.25 per cent., while that of the vaccinated was 13.50 per cent. When Kaposi undertook the review of Keller's statistics, he had no idea that they had been falsified; but before he had finished, he encountered some very surprising results. Summoning Dr. Keller to Vienna to testify in regard to his statistics, he found that Keller had died shortly before, and that no statistical tables had been found among his effects. The correctness of this statement has been verified. Kaposi then addressed himself to the railroad surgeons and asked them for duplicates of their reports to Keller. Of the nineteen surgeons of the company who were living, nine responded by furnishing the desired duplicates. 549 cases were thus found. The duty of the surgeons of the road was to report, during an epidemic of smallpox, whether the patients had been vaccinated and whether they had been revaccinated. This was to be done with the greatest care, as to age, etc.; in children under one year, for instance, the exact age in months was to be given. Notwithstanding the care with which these reports had been prepared and transmitted to Keller, his report contains no reference to the number of patients who had been revaccinated.

As a result of their investigations, the Committee arrived at the conclusion that Keller had altered the statistics of his physicians, which he should have carefully compiled. He had in all instances changed the figures in such a way as to raise the number of deaths of vaccinated and lower the number of deaths of the unvaccinated.

DR. A. B. ARNOLD, Chairman of the Section, then made some remarks on

DILATED AND FATTY HEART.

The etiology, pathology, symptomatology, diagnosis, and treatment were considered in their order. Some cases are congenital, where young persons have been found to have a fatty degenerated heart, much dilated. Insufficiency of one or other of the valvular orifices of the organ is a much more frequent cause, being most frequent in persons past the middle period of life. Fatty degeneration may follow insufficiency of either of the orifices. Digitalis is the remedy most relied upon in the treatment of this condition. Strychnia, too, is a most excellent remedy; but in order to obtain its full effects, it must be given in much larger doses than are usually administered. Beginning with the usual dose, one-sixtieth of a grain, it should be gradually increased until probably a one-sixth grain dose is reached—almost until physiological effects can be noticed.

DR. LYNCH, of Baltimore, cautioned against permitting too free exercise by those afflicted with fatty degeneration of the heart. With regard to the use of digitalis, he said that we can with it keep off the fatal termination of the disease for a time, but, finally, a time comes when it loses its effect and nothing will longer sustain the heart. It is also advisable in these cases to diminish to the minimum the quantity of fluids taken, in order to render the proportion of red blood-corpuscles relatively greater than otherwise.

DR. GEORGE E. FELL, of Buffalo, N. Y., then read a paper on

FORCED RESPIRATION IN OPIUM POISONING.

Artificial respiration has a wider range of application than might at first be supposed. It has been used in drowning, strangulation, occlusion of the air-passages, poisoning by carbonic acid gas, chloroform, opium, or

its alkaloids, strychnia, woorara, snake bite, in hemorrhage, and even in nervous shock from a blow or fall. Of the methods, a few may be mentioned, as those of Marshall Hall, Sylvester, Howard, and others, which depend for their success upon the movements of the limbs of the body of the patient, supplemented usually by pressure on the part of the physician.

We have further the methods in which tubes and mouth-pieces are used, and the air supplied by means of bellows of various forms.

Then, again, we have the methods used in physiological laboratories, in which the trachea is opened, to supply the air for respiration. The first of this series of methods is that generally used, and may be useful so long as the muscles of respiration maintain their tonicity and the heart has not ceased to beat. The second series, in which mouth-pieces are used, may prove uncertain in action, owing to the difficulty of passing air into the paralyzed larynx with the œsophagus presenting a more direct route to the stomach. The third series presents a positive method, by opening into the trachea.

To the latter method he applied the name of forced respiration, to distinguish it from the ordinary "artificial" respiration. After a considerable review of the best medical works and consultation with the most prominent members of the profession of Buffalo, the essayist had not been able to find a case in which forced respiration had been applied to the human subject under opium poisoning. The value of the method, the essayist thought, would be apparent after the recital of a case.

On Saturday, July 23, 1887, at 12.30 A.M., he was called to attend a patient whom he found in a semi-comatose condition. The patient, as he was informed by his wife, had been drinking heavily for a week or more, and in order to secure sleep had taken chloral. Finding this inefficient as taken, he had resorted to a dose of morphine. The quantity he had taken was equal to twenty grains. The symptoms produced were those ordinarily following a large dose of the drug. Dr. Fell at once administered an emetic, followed it by a cathartic, and commenced giving him drop-doses of the fluid extract of belladonna at frequent intervals, until a solution of atropia could be obtained. This he then administered hypodermatically in doses of one-sixtieth of a grain. In order to keep him awake, the patient was walked around. This was continued until finally his strength failed, and he sank to the floor exhausted. His breathing now become more stertorous than before, and signs of immediate dissolution were present. Thinking he could do no more the essayist abandoned his efforts at about 4 A.M. Four hours later, he was called by a physician who had been subsequently summoned to the case. He found the patient breathing with little more ease than when he left, but exceedingly weak. Sylvester's method of artificial respiration was resorted to, and continued at frequent intervals for an hour. The patient's strength continued to fail. Finding it impossible longer to keep up the patient's respiration, tracheotomy was performed. The steps of the operation were described by the essayist. A heavy tube was inserted, one which had done service upon dogs in the physiological laboratory. The apparatus used in experiments was also employed to produce artificial respiration. In a short time, natural efforts at respiration commenced. It was soon observed, however, that after the forced respiration had been continued for awhile, the natural efforts were suspended for a time—in other words, that the supply of oxygen provided to the patient in this manner was greater than that required by nature, and the blood became overcharged with oxygen. The large laboratory tube was then removed and an ordinary tracheotomy tube inserted.

He then described a smaller apparatus which he had had prepared for the purpose of producing forced respiration in the human subject, and closed with the statement that the method was not only easy of execution, but one suited to a large number of cases, the only restriction to it being the danger of over-inflation of the lungs.

Dr. Brainard, of Los Angeles, California, stated that he had used the method of producing artificial respiration by strongly elevating the shoulders, by raising the arms and compressing the chest in order to secure expiration. He had found it efficient in every case, and had not felt the need of any such method as that just described. In some cases the tongue must be held forward in order to prevent its closing the entrance into the trachea.

Dr. Fell stated that he had not proposed forced respiration as a method applicable to every case, or as a substitute for artificial respiration. He had used Sylvester's method with success in some cases, and, as stated in the paper, had employed it in the commencement of the case reported, but in cases of opium poisoning, as in this case, a time comes when Sylvester's method will no longer be effective. He did not advocate opening the trachea, itself a serious operation, when the patient can be saved in any other way; but when all other means have failed is the time to resort to forced respiration.

Dr. Entrikin stated that he did not wish to belittle the operation just reported, but that he had succeeded in several cases in producing artificial respiration by introducing an ordinary rubber tube into the trachea and forcing air through it by means of a bellows.

The Chairman then expressed in a few words his gratification with the success of the Section, thanking the members who had so kindly contributed to the scientific work done, and declared the assemblage adjourned.

Obstetrics.

Friday, September 9th.

Dr. Ira E. Oatman, of Sacramento, Cal., read a paper on

the treatment of puerperal eclampsia.

He recommended the use of veratrum viride after the convulsions are under control by anæsthetics. Eight drops per os or fifteen per anum should be exhibited until the frequency of the pulse beat is reduced to forty, and nervous and vascular tension is relieved. He believes this drug to have a specific effect. Whiskey must be kept near in case of extreme cardiac depression.

Dr. Duncan C. MacCallum, of Montreal, said that eclampsia should not be treated as an entity, in which the conditions are always the same, but as a disease occurring under widely varying conditions, which confer an individuality on each case. He relied on chloro-

form, morphine, chloral, and the bromides. He had seen sixteen cases; all recovered.

DR. A. F. A. KING, of Washington, said that the normal presentation and position of the fœtus *in utero* during pregnancy, before labor begins, is the dorso-anterior position of an oblique presentation. Pressure of the gravid womb upon the aorta, vena cava, and their branches produced renal trouble. He recommended, in the treatment of eclampsia, postural treatment. Place the woman in the knee-elbow position, or the latero-prone position of Sims, and then by manipulation lift the womb out of the pelvic cavity and place it upon an iliac fossa, where it ought to be naturally.

DR. AUST. LAWRENCE, of Bristol, England, expressed suprise that in America all cases of eclampsia apparently recovered. In England, the affection was extremely fatal.

DR. W. W. JAGGARD, of Chicago, said: 1st. Puerperal eclampsia was caused by renal inadequacy, to use an expression of Sir Andrew Clarke's, dependent upon functional or organic disease. 2d. The immediate cause of the convulsion was, probably, vasomotor spasm of the cerebral bloodvessels. 3d. The indication for treatment, *par excellence*, was profound anæsthesia, to relax the spasm. Therefore, chloroform, morphine, chloral, and the bromides were indicated. Joseph Berens and H. C. Wood, of Philadelphia, had demonstrated that veratrum viride produced general vasomotor paralysis and diminution of the general blood pressure. There were, therefore, *à priori*, considerations, in favor of the use of the drug. Niemeyer says, "You bleed the patient into her own veins when you exhibit veratrum viride." 4th. He had read Dr. King's remarkable paper, of which mention had been made. He thought his arguments fallacious, and utterly inconclusive. Certainly, in the present state of our knowledge, it would be supreme folly—worse than folly—to lift up the head out of the pelvic cavity and place it on an iliac fossa, if that were possible. He was of the opinion that the observations, upon which Dr. King based his hypothesis, did not correspond with the objective findings of the immense majority of observers.

DR. E. PAUL SALE, of Aberdeen, Miss., read a paper on

THE MANAGEMENT OF PREGNANCY, WITH REFERENCE TO THE PREVENTION OF POST-PARTUM HEMORRHAGE,

in which he recommended viscum flavescens, stylosanthis elatior, aletris farinosa, cimicifuga racemosa, salix nigra, as uterine tonics, in cases predisposed to hemorrhage, the result of atony or the hemorrhagic diathesis.

Gynecology.

FRIDAY, SEPTEMBER 6TH.

The session was opened by a discussion of some of the papers of the preceding day.

TREATMENT OF THREATENED OR COMMENCING PERITONITIS AFTER LAPAROTOMY BY BRISK PURGATION.

DR. GORDON, of Maine, fully endorsed Dr. Johnson's plan of purging in peritonitis, following laparotomy, having been strongly influenced in his opinion by the recommendation of Tait. He had also used this plan successfully in the treatment of puerperal fever, salines being the agents used to produce the purgation. He considered that the day for the opium treatment of peritonitis had passed.

THE BURIED SUTURE WITH IODOLIZED SILK IN VESICO-VAGINAL FISTULA.

DR. CUSHING, of Boston, remarked that he had no experience with that form of suture material, but frequently found occasion to use the buried suture. In many instances, they served an excellent purpose, especially when some soluble material, such as catgut, was used.

THE TREATMENT OF UTERINE CANCER.

DR. A. MARTIN, of Berlin, said that his method of operation, in brief, is as follows: The patient is placed upon the back, the vagina thoroughly disinfected, and the sides of the vagina and the perineum are retracted. The cervix is grasped with a volsella and dragged to the vaginal entrance, at the same time carrying it as high as possible toward the symphysis pubis. The posterior vaginal fornix and peritoneal pouch are then cut through, the peritoneum is drawn down and stitched to the vagina; a ligature is then passed which includes the lower third of the left broad ligament, after this another which includes the upper and middle thirds. The same procedure is next adopted with the right broad ligament. The anterior vaginal fornix is then opened, the bladder carefully separated, and the edges of the peritoneal and vaginal wounds stitched together as they were, posterior to the uterus. The organ is then retroverted, the body of it being brought into the vagina. The lateral attachments are next divided and the peritoneum stitched to the vagina as in the previous cases. A catheter is then passed into the bladder to draw off its contents. During the entire operation the wound is irrigated, no sponges being used. He considers that this operation has now passed its stage of trial in Germany. The best operators insist upon limiting the operation to those cases in which the uterus alone is involved by the disease. The operation is also indicated in certain cases of prolapsus uteri, and occasionally for myomata. It is also called for in sarcomata and adenomata. The prognosis from the operation is favorable if the surrounding tissues are healthy, but if infection has taken place the result will probably be unfavorable.

DR. DIARNY, of Buda Pesth, had had some experience with this operation as Prof. Tauffer's assistant, the latter having had a large series of successful operations. He thought Dr. Jackson's argument in regard to loss of life in years by those who had submitted to hysterectomy and had subsequently succumbed from recurrence of the disease, death having come more quickly, in all probability, than would have been the case had they submitted to no operation whatever, but allowed the disease to take its own course, was a kind of argument which was unwarrantable and quite insusceptible of substantiation. On the other hand, he might also mention the great gain to the patients in relief from pain, exhausting discharges, and offensive presence even if this respite were to last only a few months. He believed

that the operation was fully warranted whenever here was a reasonable possibility of removing all th diseased tissue.

Dr. Dudley, of Chicago, thought that the status of American operators with respect to the operation would improve with increased experience.

Dr. Graily Hewitt, of London, considered that humanity owed a debt of gratitude to Martin and his colleagues for their pioneer work in this field.

Dr. Reeves Jackson, in closing, still believed that the facts were against vaginal hysterectomy as a justifiable operation. While according all merit to Dr. Martin and his colleagues for their great skill in operating, and admitting the possibility of even better results in their hands, the operation was not one, however, which could be done with satisfactory results by the average gynecologist.

Dr. Trenholme, of Montreal, offered a resolution moving the thanks of the foreign delegates to this Congress, to the officers thereof, and the citizens of Washington for their hospitality, and to the Chairmen and Secretaries of the Sections for their untiring labors which had done so much toward accomplishing the success which had attended the sessions of the Sections.

This motion was seconded and carried unanimously.

Dr. Caleb R. Reed, of Ohio, read a paper on

the intrauterine stem pessary as an emmenagogue.

This method of treatment had been condemned by Emmet and others, while Thomas, Goodell, Mundé, Reeves Jackson, Winckel, and others approved of it. The plan of the author in dysmenorrhœa or amenorrhœa was to use a tent of slippery elm, and the irritation and dilatation thus produced were often effective in bringing on a flow which answered all the purposes of the menstrual flow, whether occurring at the time which was appropriate in the given case or not. The method had never been accompanied by bad results in the author's experience.

The work of the Section was closed with the reading by title of a number of papers.

AMERICAN GYNECOLOGICAL SOCIETY.

Twelfth Annual Meeting, held at New York, September 13, 14, and 15, 1887.

(Specially reported for The Medical News.)

(Concluded from page 370)

Thursday, September 15th.

Morning Session.

The adjourned discussion of Dr. Bantock's paper on

the treatment of the pedicle in supravaginal hysterectomy

was next in order.

Dr. Martin, of Berlin, said that the chief danger from the intraperitoneal treatment of the pedicle was hemorrhage. Hegar and Kaltenbach, in Germany, practised the extraperitoneal method. The reader learned the details of the operation from Péan, but it was thought that hemorrhage should be controlled during, as well as after, removal of the tumor. This was effected by means of the India-rubber tube, which he was the first to introduce. After excising the tumor, his practice was to excise a wedge-shaped mass from the centre of the stump, and to bring the opposite surfaces together by means of superficial and deep catgut sutures. In this way bleeding was perfectly controlled. The statistics of supravaginal excision presented by Hegar and Kaltenbach were always referred to in support of the extraperitoneal method. A certain number of patients died of sepsis; this might occur whether the pedicle was within or without the abdomen. Many patients died from circulatory disturbances, as thrombosis and embolism; others from excessive hemorrhage. Undoubtedly the bad results from intraperitoneal treatment of the pedicle were frequently observed in the most severe cases, which were hopeless anyhow. By dropping back the pedicle, the parts were restored to their normal position. Statistics were not yet sufficiently extensive to warrant positive deductions. The great advance in ovariotomy had been made by Sir Spencer Wells, who originally fixed the pedicle outside, but the still greater advances of recent times were made since the pedicle was dropped back. Dr. Bantock had admitted that the ideal method was to drop back the pedicle; we should try to improve this method, and to perfect it until it was free from its present imperfections. The author stated that up to 1887 he had operated eighty-four times; eleven per cent. died of sepsis, and seventeen per cent. from hemorrhage and embolism. Among the last thirty, ten per cent. died.

Among the author's cases one was mentioned in which the pregnant fibroid uterus was removed. The speaker enucleated subperitoneal tumors in such cases, but did not perform amputation, and had in two or three instances saved both the mother and child.

Prof. Simpson, of Edinburgh, had seldom found it necessary to resort to the surgical treatment of fibroid tumors. It was impossible to say that there was any fixed plan of treating the pedicle suitable to all cases; each must be treated according to the necessities of the case. The clamping of the pedicle occupied less time than the preparation of the stump as described by the last speaker. Time was an important consideration in these operations. In one instance he was obliged to drop the stump back, as he had no clamp large enough to encircle it. The patient died on the fifth day, of septicæmia. He did not agree with Dr. Bantock as to not applying iron to the stump, since he had used the dried persulphate with satisfactory results.

Dr. Gardner, of Montreal, had operated five or six times, using the serre-nœud in every instance. He had seen no reason to adopt any other method. The extraperitoneal treatment had certainly furnished the best results thus far.

Dr. H. Marion Sims had always treated the stump extraperitoneally. His father had invariably met with bad results in the intraperitoneal method. The speaker had lost only two out of eight cases.

Dr. Mann, of Buffalo, had tried the intraperitoneal method in one out of six cases, and was obliged to re-open the abdomen on account of hemorrhage; after that he had left the pedicle outside. All the patients recovered. He treated the stump with iodoform, and found that it remained dry for a week or ten days.

Dr. Van de Warker, of Syracuse had had four

cases; in two the stumps were treated intraperitoneally, in the other two they were clamped. One of the former patients died. In one instance, where the pedicle was included in the wound, a raw surface remained for a long time, necessitating a secondary plastic operation.

Dr. Bantock, in closing, expressed great satisfaction at the fact that Dr. Martin was present to discuss his paper, and said that he was gratified to find that while his own mortality was 12 per cent., Dr. Martin's was nearly 25 per cent. Statistics alone were not enough; the main point was that among the speaker's fatal cases, there were much fewer deaths from septicæmia. The intraperitoneal method was much more attractive but was none the less dangerous. The ideal method had not yet been found. He believed that it was a mistake to apply any astringent to the stump; if the serre-nœud was properly tightened, it would remain dry. The septic trouble began *below* the loop, hence the peritoneum must be accurately attached around the pedicle.

Dr. R. Battey, of Georgia, read a paper entitled

BATTEY'S OPERATION: ITS MATURED RESULTS.

Alluding to the fact that he had ten years before presented a paper on the proper field for the operation, the reader said that when he first determined to perform it in 1872 he felt that it was a bold step, which must result either in the establishment of new principles in surgery, or in his own disgrace and professional ruin. The account of the first operation was published in 1872 and was widely read. The first recognition of the operation in Great Britain was by Prof. A. R. Simpson, of Edinburgh, who published, in 1879, the report of a case of double oöphorectomy. Mr. Tait had claimed some connection with Battey's operation soon after in an alleged conversation with Dr. Chadwick, in 1873, which conversation the latter was unable to recall. Hegar published, in 1878, the report of an unsuccessful operation which he had performed in 1872. Now numerous operations were reported from all parts of the country, but these reports were defective, in that the patients were not kept under observation sufficiently long after the operation. Since his work had been purely private, he had been able to keep the cases under observation for many years. He had preferred to retain the term "Battey's operation," since it expressed the object of the procedure (the production of the menopause) better than the terms "oöphorectomy," "spaying," "castration," etc.

He here presented a table showing the results in 54 cases of Battey's operation; 33 were cured and 8 much improved, 5 little improved, and 8 were not at all improved. The menopause was produced in 50 cases, while in 4 pseudo-menstruation persisted. Several of the cases were read in detail.

The following were his conclusions:

1. The change of life was a most important factor in securing the complete results of the operation.

2. In a few cases a cure occurred at once, but in the majority the patient passed through various climacteric disturbances.

3. The time which elapsed between the operation and the disappearance of these disturbances varies from one to three, or even five, years.

4. Some of the cases reported were badly selected and should not have been operated upon.

5. Patients addicted to morphine and other narcotics must abandon the habit in order to be perfectly cured.

6. Cases proper for operation, if allowed to suffer for years unrelieved would reach a stage when they would become incurable.

7. In a few cases intractable neuralgia in the stump developed after operation, and resisted all treatment.

8. A careful analysis of the cases showed that the removal of the Fallopian tubes did not appear to influence the production of the menopause or the final cure.

9. The operation was not infallible, the percentage of failures was large, but not more so than in many other operations in surgery, notably those for the cure of cancer of the uterus.

Dr. Sutton asked Dr. Battey if we were to understand that his operation was confined to the removal of the ovaries *alone*, and that the menopause was produced by the extirpation of the ovaries alone.

Dr. Jackson commended the modesty of Dr. Battey, and called attention to the uselessness of oöphorectomy statistics issued a week after the operation.

Dr. Parvin wished to know how frequently the tubes and ovaries had been removed in his operation.

Dr. Howard alluded to the necessity of having some clear rules to guide in the performance of Battey's operation.

Dr. Lloyd Roberts asked Dr. Battey to tell what the condition of the uterus was in his cases.

Dr. Howard Kelly, of Philadelphia, said that his results in Battey's operation had been invariably satisfactory after the lapse of two or more years.

Dr. Polk said that it was highly important to have an exact definition from Dr. Battey. Surgeons wished to know where they stood in this matter. What was the condition of ovarian disease that demanded removal of those organs? As regarded tubal disease, the indications were becoming clearer. We know no more regarding the exact amount of ovarian disease that demanded removal than we did fifteen years ago.

Dr. Bantock said that he had always been under the impression that "Battey's operation" was synonymous with "normal ovariotomy."

Dr. Simpson said that the patient on whom he had operated in 1879 had been much improved as regarded menstrual pain, but that she was not yet a healthy woman. Some of Dr. Battey's patients had been entirely restored.

Dr. Battey said, in conclusion, that the removal of the ovaries was not a necessary element in Battey's operation; the change of life was the thing aimed at, not removal of the ovaries. The same result might be accomplished by simply ligating the ovarian vessels as proposed by Prof. Simpson. Removal of the ovaries, tubes and ovaries, or even of the entire uterus and its appendages, did not always bring on the menopause. The ovaries were invariably diseased in his experience. He removed the tubes whenever they were diseased; the ratio of tubal disease (pyo- and hydrosalpinx) was small. If the tubes were not diseased he removed the ovaries alone.

In reply to Dr. Polk, he said that he *did not operate for disease of the ovary*, that was a secondary matter. In many cases if we could stop ovulation, the patient would get well. He had never insisted on the necessity

of the existence of visible disease in the ovaries in order to justify their removal.

In reply to Dr. Bantock he said, that he was glad that the question had been asked, for he had tried for fifteen years to make foreign surgeons understand the scope of the operation. In 1881 he had read a paper before the International Medical Congress, repudiating the term "normal ovariotomy," yet only last year Sir Spencer Wells had thrown the expression in his face.

Dr. A. W. Johnstone, of Danville, Ky., read a paper on

THE INFANTILE UTERUS.

He said that the relation of the cervix uteri to the body was similar to that of the pylorus to the stomach; this idea was borne out physiologically by the anatomical difference in the blood supply, the direction of the muscular fibres, and the mucous membrane. The mucous lining of the cervix resembled that of the air-passages, its function being simply to secrete defensive fluids, especially the mucous plug of pregnancy, wherein it differed widely from the mucous lining of the body of the uterus. Clinical observations served to corroborate the theory that the cervix and body were practically two distinct organs; thus, the latter might be perfectly normal while the former was diminished in size. The reader believed that a large proportion of the cases of so-called congenital flexure were due to the non-development of the cervix, which caused that form of dysmenorrhœa which was cured by instrumental dilatation. Moreover, it would be found that this infantile condition of the cervix was especially favorable to the production of laceration. The endometrium was, in his opinion, not a mucous membrane, but it belonged to adenoid tissues. It had entirely separate nerve plexuses which entered it at the cornea, coming from centres in the broad ligaments. If development of this tissue was arrested at any point, the result was an infantile uterus. Traumatism was especially liable to bring about this result.

The reader referred to his studies on the innervation of the uterus. He had found that on each side of the uterus there was a large nerve which entered the cornu just below the insertion of the Fallopian tube. He believed that this nerve presided over the functions of the endometrium. Unless these nerves were divided close to the uterus during the removal of the appendages, the menopause would not be induced also, though both tubes and ovaries were removed. The reader summarized as follows:

1. The uterus was not only an independent organ, but consisted of two parts whose functions were entirely separate, and the growth of either one of which might be arrested.

2. From its exposed position the growth of the cervix was more apt to be interfered with than that of the body.

3. Congenital flexions were largely due to this arrest.

4. If the growth of the body was arrested, the development of the endometrium was interfered with, and sterility resulted; there was probably some lesion of the pelvic sympathetic in these cases.

5. If the body was markedly undeveloped, nothing was accomplished by dilating the cervix.

6. If life had become a burden the premature menopause should be produced by dividing the trophic nerves, as before mentioned.

Prof. Simpson took exception to the author's inference that the ovary alone was supposed to dominate the uterus; it should not be forgotten that the tube also shared in this. It was important to distinguish clearly the difference between the cervix and corpus uteri, but it should not be forgotten that it was only after puberty that the true difference appeared.

Dr. Johnstone, in closing, said that ovulation might occur after the menopause, but the mucosa was not then under the dominant influence of the ovaries. The tubes did not dominate the uterus. He did not know where the nerve-centre of the uterus was, he only claimed that one of its largest trunks was situated just below the Fallopian tube.

Dr. T. Parvin, of Philadelphia, read a paper on

THE IMPORTANCE OF ANTISEPTICS IN PRIVATE OBSTETRIC PRACTICE.

He said that, while no one could question the utility of antiseptics, in private practice there was carelessness about using them. This was due to the incredulity of many with regard to the septic origin of puerperal fever. Women who were delivered at home should be just as carefully attended to as in maternities. Many septic affections were overlooked, because the patients did not die. An entire absence of sepsis in 500 cases of confinement did not prove that a practitioner enjoyed perfect immunity. Health returns were not always accurate. Even if one man was successful without using antiseptics, another might be misled into following the other's example with disastrous results. The puerperal practitioner was always liable to carry infection from surgical and infectious cases, and especially from autopsies. The day was coming when a physician, who lost patients from the neglect of antiseptic precautions, could escape neither the reproach of his own conscience, nor public censure. He showed a pocket-case which he had devised for carrying in a small space, various antiseptic instruments and sutures for repairing lacerations, etc.

Dr. Lawrence, of Manchester, was disappointed that the author had not described his method of using antiseptics. He always had a warm carbolized injection given during the course of the labor, and introduced afterward an iodoform pessary night and morning. The mortality in private practice must be less than in the best hospitals.

Prof. Simpson recommended turpentine as an antiseptic wash for the hands. It removed all the noxious fatty acids. Then the hands were washed with soap and water.

Dr. Reed, of Glasgow, said that during the past seven years he had always used antiseptics before examining women. He made use of glycerine soap and carbolic acid (five per cent.) as a lubricant after cleansing the hands.

Dr. Kelly said that in his own practice he had carried bichloride in gelatine capsules, seven grains in each. In order to avoid contamination from the bed he used a large inflated rubber or pad of a crescentic shape, having a piece of rubber cloth beneath it, which was prolonged below the ends of the crescent so as to fall over the side of the bed. It was very convenient in obstetric operations.

EXTRAUTERINE PREGNANCY AND ITS TREATMENT BY ELECTRICITY.

DR. ELY VAN DE WARKER, of Syracuse, reported a case of extrauterine pregnancy in which growth of the fœtus was arrested by means of the faradic current. The diagnosis was rendered certain by the history of suspended menstruation, the presence of irregular discharges of blood from the uterus, and the passage of a characteristic decidual membrane, while the patient suffered with attacks of agonizing pain in the abdomen. On examination a characteristic tumor was felt on one side of the uterus. Electrical treatment was entirely successful. Referring to the comparative certainty with which extrauterine gestation could be diagnosticated at the present day, the reader urged the use of electricity as affording less risk to the patient than laparotomy, while it almost invariably arrested the progress of pregnancy.

DR. REEVE, of Dayton, referred to a case of extrauterine pregnancy which he had formerly presented to the Society. The expulsion of the decidual membrane added to attacks of violent pain and gushes of blood formed a picture which was hardly mistakable. But, the decidua could not always be found, since it was discharged a little at a time. The fact of a probable pregnancy should first be established. The tumor was a growing one, hence time would always clear up the diagnosis.

We did not know as yet just how long electricity should be used. There was only one reasonable way and that was to keep on until it was pretty certain that the vitality of the cyst was destroyed.

DR. SIMS said that he had treated a case of extrauterine pregnancy four years before, and had recently seen the patient, so that he was sure of her present condition. Dr. Rockwell had passed the interrupted galvanic current from fifteen cells, the patient being under ether. Fifteen severe shocks were given and eight or ten séances were held. After this the tension of the sac was clearly diminished, and the tumor gradually decreased in size. Now, nothing could be felt but slight induration at the site of the tumor.

DR. CHADWICK said that it was important to lay down clear rules as to the recognition of these cases. In all the reported cases up to a year ago, there was not a single one in which there was *certum* evidence of the existence of a fœtus. The reader had used electricity every day for three weeks in a recent case. Five weeks after he had dismissed the patient she passed a portion of a fœtus by the vagina, thus establishing the diagnosis positively. We could not depend on any one symptom in making a diagnosis. The examination of the decidua surely showed that it was the decidua of pregnancy. The reader in his case passed a sound to the depth of four inches into the uterus and thus proved that the organ was larger than it would have been if the case had been one of early abortion, as was first supposed.

DR. MARTIN, of Berlin, had operated on sixteen cases of extrauterine pregnancy. In Germany it was customary to operate at once. The attempt to kill the fœtus was a very old idea. Morphine had been injected into the sac with successful results. Electricity had also been used in Germany with success. What became of the ovum? It was often mummified and did not harm. Was it safe to allow the fœtus to go on growing? There had been difference of opinion in Germany, but now it was conceded that it should not be permitted to go on. Electricity was not popular.

Tubal pregnancy was the most common form, and could be easily diagnosticated and operated upon in the early stages. He had removed a living child; he found no difficulty in dealing with the placenta, since he readily extracted it at the time. He did not believe in leaving it behind to become a large sloughing sac.

DR. APOSTOLI, of Paris, had been greatly interested in the paper. He thought that the electrical treatment of this condition had met with great success. Both currents had been used in France; he had met with better results in using the constant current, since the latter had succeeded where the faradic had failed. It might be applied to the interior of the uterus, or galvano-caustic puncture of the sac might be made through the vagina and a current of fifty milliampères might be passed. The fœtus would be killed in a few seconds.

DR. MANN said that he had long been interested in the subject. Could we make a diagnosis in the early stage of pregnancy? Undoubtedly, at least in this country. Dr. Martin had testified to the fact that the diagnosis was frequently made in Germany. The electrical treatment was better than laparotomy, because it was not so dangerous in the hands of the general practitioner. Very few cases had proved fatal, except where the sac had been punctured. Then if electricity failed laparotomy could be performed without added risk.

DR. JANVRIN referred to a case of tubal pregnancy in which the patient died from hemorrhage after three applications of electricity. Dr. Rockwell had placed the positive pole over the surface of the abdomen, the negative within the vagina. The current varied from twelve to sixteen cells (eighteen to twenty milliampères). He thought that the fœtus was killed at the first application. He was convinced that the colicky pains and symptoms of shock were due to the rupture of vessels in the peritoneal covering of the sac. Hence, he believed in performing laparotomy as soon as these symptoms appeared.

DR. VAN DE WARKER said, in closing, that there was no well authenticated case of death due directly to the use of electricity, hence the woman ought to have the benefit of the chance. If Dr. Janvrin was right, there ought to be a hæmatocele after the rupture of the vessels, but there was none. Cases of death had been reported where the sac was punctured.

AFTERNOON SESSION.

DR. FRANK P. FOSTER, of New York, read a paper on

VAGINAL INJECTIONS IN SIMS'S POSITION.

He referred to the general extent to which hot-water injections were now employed in the treatment of pelvic affections, although the essential features of the treatment—the recumbent posture, and the amount and high temperature of the water used—were often omitted. Dr. Chadwick had called attention to the value of the hot rectal douche as a means of applying heat to the deeper parts of the pelvis, but the plan was defective in that the heat was only applied to the left side of the pelvis, and the water was used in the form of a large enema, the

initial temperature of which was soon lowered; moreover there was doubt if the water retained its situation after being injected. In order to fulfil the indications—*i. e.*, to apply the water as closely as possible to the seat of disease, and to employ a sufficient quantity to secure the greatest effect of the heat, the reader had been using vaginal injections with the patient in Sims's position, since in this way the vagina would retain more water, while from the gravitation of the abdominal and pelvic viscera toward the diaphragm, the water in the vaginal vault comes into closer relation to the affected parts than when the patient is placed upon the back. By means of the injection apparatus devised by the reader several years before, it was possible to give the injection without annoyance to the patient from the overflow of water.

Dr. Barker said that he had been accustomed to use Cleveland's bed-pan in giving vaginal injections. He thought that in private practice Dr. Foster's method would be objectionable to most patients in the higher walks of life, because of the extra trouble entailed, the wetting of the bed, etc.

Dr. Charles Jewett, of Brooklyn, read a paper on

THE TREATMENT OF PUERPERAL ECLAMPSIA.

He desired to call attention to the value of veratrum viride. The drug had been unpopular because of its poisonous qualities. But when a pure preparation was given hypodermatically, it was of great value. It acted by depressing the heart's action and relieving arterial tension. In eclampsia it acted on the vasomotors, paralyzing them. It was also a motor-spinal depressant. Alarming results might follow excessive doses; still there were no fatal cases on record in which it was used in convulsions. It was important for the patient to be recumbent during the course of the treatment. The fluid extract, made from the rhizome of the plant, was recommended by Dr. Squibb. It should be given hypodermatically, in doses of from ten to twenty minims. The guide was furnished by the frequency of the pulse. If the latter was reduced to sixty, no convulsions would occur. If no result was obtained in half an hour, the dose should be repeated. The reader had used the drug in twenty-three cases, sixteen patients being primiparæ, there being only three deaths (13.6 per cent.) due directly to the convulsions; three other deaths occurred from other complications. Other measures were employed at the same time, as chloroform and hydragogues. Veratrum never failed to arrest the convulsions when given early. The pulse fell in from forty-five to sixty minutes after the drug had been given. As regarded its safety, in no instance was any dangerous symptom observed. In one case the patient took six drops three times daily for three weeks. To recapitulate, the advantages of the drug were these: it was harmless and manageable, easily administered, and rapid in its action. Chloroform should be given until the effect of the veratrum was manifest. The labor should be induced as rapidly as possible, if it was not proceeding satisfactorily.

Dr. King, of Washington, approved of the remedy, which he had suggested twenty years before, in a paper in which he sought to explain eclampsia as due to arterial hyperæmia of the brain. In a recent paper the reader had stated that during pregnancy the normal position of the child was transverse. In primiparæ it was usual for the head to descend below the brim during the later months of pregnancy. This premature descent caused pressure on the vessels, and produced hyperæmia of the brain. In three or four hundred thousand cases of pregnancy in primiparæ which he collected, in only a small number was the presentation transverse. Transverse presentations did not lead to eclampsia.

Veratrum certainly lessened the tension in the arteries. By feeling the arteries *above* the uterus in cases of eclampsia this increased tension would be noted.

In a discussion on this subject before the Obstetrical Section of the recent International Congress, one gentleman said that he gave only eight drops at a dose. He believed that a thin, undilatable os uteri in primiparæ was itself due to the premature descent of the head. Why did it occur? From the wearing of corsets, the weight of skirts, and from frequent coition during pregnancy. If these patients were placed in the knee-elbow position, the pressure would be relieved.

Dr. Barker called attention to the fact that he was the first one to use veratrum in this city forty years before, and that he published his results thirty years ago. He was rather disappointed to find that his words had apparently been forgotten. Veratrum was superior to all other arterial sedatives. He first used the drug prepared from the plant as it grew in Connecticut. He early tried Norwood's tincture, but found that it was twice as strong as the preparation which he had been accustomed to use. He had used veratrum for forty years without an accident.

Dr. Jewett closed the discussion with the remark that his original paper contained ample references to Dr. Barker's work. With regard to Dr. King's theory, it had occurred to him that, by external manipulation, the presentation could be changed to a transverse. He thought that convulsions were due to acute anæmia from arterial spasm of the cerebral vessels, and that veratrum relieved this spasm, by paralyzing the vasomotors.

The discussion of Dr. Chadwick's paper on the operation for

VENTRAL HERNIA AFTER LAPAROTOMY

was next in order.

Dr. Lloyd Roberts thought that prevention is the most important matter. Hernia has much increased in frequency of late, since drainage tubes have been so extensively used. He had seen hernia result from the use of catgut sutures, which dissolved before firm union of the wound had occurred. He invariably uses silk sutures, which are not removed until the eighth day; the longer they are left *in situ*, the firmer is the union. He removes the drainage-tube as soon as possible.

Dr. Johnstone said that Tait operates on umbilical hernia by splitting the tissues, turning one flap into the abdominal cavity and the other outside, uniting the denuded edges of the conjoined tendon between these two layers.

The scientific business having been completed, on motion of Dr. Reynolds,

THE THANKS

of the Society were unanimously given to the President for the masterly way in which he had presided over the most successful meeting which the Society has ever held.

DR. GRAILY HEWITT, in reply to Dr. Reynolds's

FAREWELL REMARKS

to the foreign guests, said that in the name of the foreign guests he offered an expression of their cordial appreciation of the courtesy which they have met with. It is a great privilege to meet the Fellows, and they will carry away the most flattering views of the work of the Society.

PROF. SIMPSON seconded Dr. Hewitt's remarks, and said that it has been a great gratification to him to recognize in the President a fellow-countryman. He would carry home useful hints.

DR. LLOYD ROBERTS reëchoed the remarks of the two speakers, and only regretted that he must part so soon from his new friends. He only hoped that he would be invited to the next meeting.

DR. LAWRENCE, of Bristol, said that if he got an easy passage back he would come again.

DR. BALLS-HEADLEY, of Melbourne, thanked the Society for the kind welcome which had been extended to him, and for learned papers which he had heard. He had passed one of the most agreeable weeks of his life at this meeting.

DR. CORDES, of Geneva, offered his thanks for the great kindness which he had received. He had enjoyed the hospitality of other nations, but none is equal to the American.

THE PRESIDENT said that he had been passing as an American citizen, but Prof. Simpson had "given him away." It takes a Scotchman to catch a Scotchman. He extended a cordial invitation to the foreign friends to attend their annual meeting another year.

Adjourned.

NEWS ITEMS.

THE PENNSYLVANIA HOSPITAL has recently purchased about 520 acres about twelve miles from Philadelphia upon which it is proposed to place the Insane department of the institution. The report presented to the contributors at their annual meeting held last week, foreshadows the character of structure intended to be erected. It says:

"For the accommodation of those of the private class who are able and willing to pay for liberal accommodations, to apply in the best manner the results of medical administration for the advantages of all classes, the hospital of the future presents an interesting problem. Some of its features may be expected to differ from structures now in existence. A hospital edifice will still be required, but limited, perhaps, in extent to the probable demands for care of acute cases and those requiring, for any cause, special observation. The plans will probably provide for the close surveillance of suicidal cases at night and for the complete separation and isolation of noisy and turbulent cases from quiet patients. There should be large, well-lighted day rooms for disturbed and untidy persons, apart from their dormitories, so that the latter may be vacated during the day, and that the day rooms may be ventilated when unoccupied. Greater concessions will be made to patients of refined sensibilities, that in the early or in the convalescent stages they may be properly shielded from some scenes and associations that might prove objectionable. Greater attention will be given to the needs and requirements of classes. Buildings with the attractive exterior of a country villa, free from some of the characteristics of a public institution or hospital, and an interior not unlike the arrangements of a private dwelling, will disarm the prejudices of friends, render the change from home less marked by contrasts of surroundings, and admit of an administration more nearly approaching that of a private family. While the degree of restriction may be greater in the hospital structure, in the detached villa it will be reduced to a minimum amount or entirely abolished. An intermediate class composed of harmless demients, paralytics, cases of mild forms of mental disorders, will remain to be provided for in wards that may be adapted to their requirements."

THE WASHINGTON CONGRESS.—*The British Medical Journal* of September 17th, devotes its leading editorial to the Congress and concludes as follows:

The President (Dr. Davis), we think, took a narrow standpoint in claiming for the Congress two principal uses—those of collective investigation, and of enlargement of views and increase of knowledge by mutual comparison and communication. Such means could almost be attained in these days of cheap and universal information and travel without any such machinery. Unless there be added to its undoubtedly excellent but limited programme an attempt at least to direct and draw together the profession throughout the world into one harmonious and comprehensive whole, the danger will arise that the more practical and farseeing of the supporters of the Congress will begin to say "*cui bono?*" and that it may follow an unfortunate younger sister, the Social Science Congress of England, into an unmerited obscurity. We trust that there is no foreshadowing of any such undesirable event in the absence from Washington not only of several of the leaders of medical thought in Europe, but of some of those men who have made the American School of Medicine what it is.

A new departure to greater power and influence would have fitly marked the meeting in the titular capital of the United States. If Washington is a city of fine distances, it is one of few memories. No traditional policy need mar advance in a country whose independent history is barely one hundred years old, and whose School of Medicine has barely had an appreciable existence of two-thirds of that period. But the opportunity has been missed, and though many of the discussions and papers will no doubt be remembered and valued, we fear that the abiding impression with regard to the meeting at Washington will be one of disappointment.

A FRENCH VIEW OF BERLIN AS THE MEETING PLACE FOR THE CONGRESS OF 1890.—A writer in *L'Union Médicale* of September 17, 1887, thus expresses his feelings in regard to visiting Berlin in 1890: "Before adjournment the International Congress decided to hold its next meeting in Berlin. Although possibly the German delegates to the Congress did not outnumber the French, yet they found in America a number of partisans in their favor in Americans of German origin. At Copenhagen the protestations of French delegates, especially of MM. Trélat and Verneuil, were opposed to

Berlin as the place for the next meeting; this obstacle did not exist this year; as but a small number of Frenchmen were at Washington the capital of Germany was chosen by necessity. Will we go to Berlin in three years? I admit that I should prefer to go there in such a peaceful manner rather than be obliged to traverse a route strewn with the bodies of German and French soldiers. But do not ask me my real desire."

A Medical Congress at the International Exposition of 1889.—The Minister of Commerce proposes a series of Congresses of scientific men during the Paris Exposition of 1889. Among these will be a Medical Congress, and also a Congress of Hygiene and Public Assistance.

The Third Congress of Russian Physicians will meet in St. Petersburg in April, 1888.

Professor Billroth.—This distinguished surgeon has steadily regained health and strength during the summer, and, it is believed, will resume his lectures in the autumn.

Professor Virchow's Rejection.—Professor Virchow, as a candidate for Rector of the Berlin University, was recently rejected because, it is stated, of his liberal political opinions.

A Prize Bequest to the Academy of Sciences of France.—The French Academy of Sciences has recently been given a legacy of 40,000 francs ($8000), the income of which will be given as a prize for the best essay on any subject proposed by the Academy relating to the healing art.

Von Nussbaum, of Munich.—This well-known surgeon has recently performed his five hundredth ovariotomy. The occasion was celebrated by a banquet, tendered him by the students of the university.

Over-pressure in Schools.—An earnest discussion is occupying French medical men over the question of over-pressure in schools. It is claimed that in nearly all schools by far too much is exacted of the pupils, and measures are under discussion for lengthening periods of exercise; preventing work at evening; and improving the sanitary condition of school-houses.

The Austrian Minister of Public Instruction has recently issued a report based upon the studies of medical men which advises a better division of school terms, increased holidays, and the lessening of memorizing home work, and severe examinations. The Minister was aided in his investigations by four physicians, and the welfare of the scholar is considered from every standpoint.

A Prize Essay on School Hygiene.—The Medical Society of the Canton Bern, in Switzerland, has offered a prize of 300 francs for the essay which replies best to the question, "How far can the physician remedy the over-pressure existing in Swiss schools, and what are the results of such over-pressure?"

A New Edition of Schroeder's Diseases of Women.—The eighth edition of this standard work has recently appeared, edited by Veit, and containing Schroeder's picture and a short account of his life by the editor.

Night Medical Service in Vienna and Paris.—In imitation of the Paris system of medical night service the Superintendent of Police has decided to establish stations for such service in Vienna, where a physician shall be constantly in attendance, and to which messages for attendance at night may be sent.

The report of the Prefect of Police for the three months ending June 30, 1887, shows in the night medical service of Paris a total of 1712 visits, an increase of 112 over the same period of the last year.

Pasteur's Treatment in Turkey.—No better field for the study of disease in dogs could be found than the Orient, where they are abundant in towns and cities. There will be no lack of canine material for a new institute of bacteriology to be established in Constantinople, to which all persons bitten by rabid animals are to be sent for preventive inoculation.

Poisonous Coloring Materials in Toys.—The Minister of Commerce of France has recently forbidden the employment in the manufacture of toys of the colored salts of arsenic, copper, and lead which are soluble in water. White lead may be used in making India-rubber balloons and stamped tin toys if it be combined with an oil varnish. The reds and yellows produced by the chromates and other salts of lead, may be used if applied with either oil or alcohol varnish. Prosecution for neglect of these laws will be against the manufacturer and not against the retailer, who will be guaranteed by the former that the goods are properly manufactured.

Profitable Practice in Russia.—Dr. Potain, of Paris, was recently summoned to attend an eminent Russian journalist with whom he remained two days. He received 20,000 francs (4000 dollars) for his services.

Pranzini's Brain.—The brain of Pranzini, a murderer recently guillotined in Paris, weighed 1280 grammes (between three and four pounds). An interesting phenomenon was the presence of air bubbles in the arachnoidean spaces, and between the convolutions, which is seen in the bodies of those guillotined. It is caused by the vacuum produced by the sudden withdrawal of a large quantity of blood from the vessels.

Ambulances for the Transportation of Infectious Cases.—A force of ten ambulances is to be stationed in Paris, each of which will have its separate staff, whose lodging will be at the ambulance station. They will be fully equipped to act with the police and hospitals in transferring cases of infectious diseases without risk to the public.

Proprietary Medicines in Russia.—The Russian government has just passed some stringent laws against proprietary medicines. The customs officers have been instructed that the entry and sale of medicines are only permitted under the closest conditions. The articles must not contain any ingredient injurious to health, and

the preparation must be one requiring for its manufacture expensive and complicated machinery, as well as long experience. It must not be liable to deterioration from age or transportation. The price at which the preparation may be sold in Russia is subject to the judgment of the Russian authorities, and its formula can only be kept secret for three years. All other preparations are to be excluded, nor can they be advertised in Russia.—*American Analyst*, September 15, 1887.

LIGHT AND DARK CLOTHING.—The *Epoch* of August 5th contains three papers on "How to Keep Cool and Well in Summer," by Drs. Cyrus Edson and Willard Parker, and Mr. David Jardine, which are in the main full of sensible advice. But Dr. Edson says it is best to wear dark clothing in summer, because black radiates heat more freely than white, and says that animals living in the Arctic regions are white, because that color holds the bodily heat. Dr. Parker, on the other hand, gives the usual opinion that light-colored clothing is best in hot weather. Dr. Parker is right and Dr. Edson is wrong.

The experiments of Coulier ("Expériences sur les étoffes qui servent à confectionner les vêtements Militaires, *Journ. de la Physiologie*, 1858,") show that the difference of absorption and radiation between different colors of the same stuff are not perceptible in the shade at temperatures between 70° and 100° F., while the white is much less absorbent than the black when exposed to the rays of the sun.

Dr. Edson's theory of the cause of the white color of animals in the Arctic regions, which we suppose he would extend to explain why the black races are found in the tropics, is one that is not in the least tenable.

The great point to be kept in view in selecting clothing for the hot weather is, not so much to provide for the hottest part of the day as for the evening when the temperature falls, and when cotton gauze underclothing is likely to lead to chilling the surface and to lay the foundation for rheumatic neuralgias of various kinds.

Thin woollen underclothing and light colored cotton stuffs for outer wear during the middle of the day are the best. The cloth ng should be loose to allow free circulation of air and evaporation from the skin. Tights are hot, though they may look cool on the stage. —*Sanitary Engineer*, August 20, 1887.

PERMANENT BATHS.—In the course of a paper (*Berl. klin. Woch.*, 1887, No. 20) upon the use of permanent baths (at a temperature of about 95° F.), L. RIESS, after giving instances of their value in cases of spinal disease and injury, adduces some rather remarkable facts of their efficacy in the treatment of dropsy, whether cardiac or renal. These cases are often complicated with bedsores, erysipelas, and gangrene, for which such treatment would be suitable, but he says that he long withheld it because of the idea that cardiac or pulmonary disease would be a contraindication to its employment. However, in 1879, in a case of extreme cardiac dropsy (mitral and aortic disease) with considerable erysipelas and cutaneous grangrene of the legs, he determined to try the effect of the permanent bath as a last resort, not without some misgiving lest the immersion should increase the dyspnœa and dropsy. The result proved quite the reverse, for a rapid improvement took place, and when, after having been in the bath for a fortnight, the patient returned to bed, the dropsy and other severe symptoms had disappeared. Since then Riess has adopted the procedure in a large number of dropsical cases, and invariably with benefit, the dropsy in most cases (whether renal or cardiac) diminishing within the first forty-eight hours in a striking degree. The quantity of urine is not increased *pari passu*, so that it is suggested that the effect of the permanent bath is to increase the functional activity of the skin, which is contrary to the prevalent notion. The good results obtained in cases of chronic rheumatism so treated are also mentioned, and it is held that the application of the method is practically very simple, it being necessary, of course, to allow the patient to lie comfortably suspended in a hammock, and to place a thick woollen covering over the bath to retain heat as much as possible. At first it is well to allow the patient to leave the bath at night, but as he gets more used to it he may spend days and nights in it with much comfort to both himself and his attendants.

THE METHODS IN MEDICINE IN THE NEAR PRESENT.

Extracts from an Introductory Lecture to the 63d course at the Jefferson Medical College—Session of 1887.

BY J. M. DACOSTA, M.D., LL.D.

PROFESSOR OF THE PRINCIPLES AND PRACTICE OF MEDICINE.

IN selecting a subject to lay before you to-night, I thought it might not be without advantage to bring together a few observations such as any one who watches the times can make and accept, on the methods in medicine likely to be the prevalent and fruitful ones in the near present. We live in a period of alertness and upheaval. Powerful forces are at work clearing new pathways, crushing obstacles, hewing in to rock here, building galleries there. Restless activity is undermining much of what is old, and asking if it be not better to sweep it all away, and to construct everything anew on different lines. Amidst all this bustle and din, it is well to stand for a moment aside to examine whither we are tending, and in how far the new results can be shaped into means of permanent use. If, in trying to group together some thoughts on the methods in medicine likely to prevail, I appear too sanguine of immediate effect from present work and thought, I beg you to reflect on the gigantic strides medicine has made since the beginning of this century, and how fair it is to presume that, with more workers and improving ways, we shall soon get even quicker and more decided results. Medicine, as we now see it, is almost a new science; scientific medicine, indeed, had scarcely an existence a hundred years ago. It was born with Harvey; but it slumbered until it awoke with Morgagni, with Auenbrugger, with Jenner, with Laennec, with Bichat, with Bright, with Charles Bell, cradling it and guiding its childhood.

The methods in medicine in the near present are certain to be based on the growth of knowledge in the fundamental branches, in anatomy, in physiology, in chemistry, in hygiene, in general pathology and morbid anatomy, as well as on its self-development by improved means of observation and by experiment.

Let us first take anatomy. Is it progressing, and what may scientific medicine further expect from it? The limitation of gross anatomy was, with few exceptions, reached long ago, and this has been fully recognized by anatomical teachers.

Yet, though it be true that gross anatomy is complete, we must ask for further service from the anatomist. We want him to teach with more precision and with a full recognition of its importante, regional medical anatomy, the anatomy of internal organs in their relation to parts around them likely to become implicated in disease and to the external coverings of the body. We also need accurate information as to nerve terminations and anastomoses, both in viscera and on the skin, and as to the courses of nerve fibres in parts of brain and of spinal cord. The great attention now given to nervous pathology and to the application of electricity calls for this; and while much of the anatomical work is done, it still requires definiteness and clearness to serve the purposes of the clinician.

The great advance in anatomy in this century has come through Bichat's work in general anatomy, and the study of microscopical anatomy which it ushered in. An insight has thus been gained not only into the character of tissues and their association, but a philosopical anatomy has been created, which, elaborated by great naturalists, by Agassiz, by Owen, by Leidy, has taught us to study the entire animal kingdom as a whole; to appreciate the relations of the same textures in the highest as well as in the lowest forms; and to view with ever-increasing wonder the admirable adaptation and design in Nature. It has done more. It invites us to extend our studies into one form, in the certainty that, the fuller we do so, the better we shall understand all. It has done yet more. It has aided us physicians greatly by letting us appreciate the kindred diseases of identical textures, no matter in what part of the body situated; and by explaining to us the similarity with which remedies affect these textures, whether they be in one or another organ. General with minute anatomy is thus acting on medicine by making it broader, more scientific.

How is physiology influencing medicine? (It is not for me to review here its general advances.) The study of functions is doing something to tell us how secretion, nutrition, and growth are brought about. But not enough of this knowledge has been gained to become a basis of scientific therapeutics. It may be ours some day; and with it may dawn an era in which disease will be modified or strangled at its birth. What physiology is now working out efficiently for us is the elucidation of the nervous system. The great problem of the functions of special centres in brain and spinal cord is being settled; and with this advance we have gained not only in disease recognition, but in disease cure. It seems marvellous to read in journal after journal of the day of more and more instances in which deft hands, acting in the light of correct appreciation of symptoms, made only possible by the physiological labors of Broca, of Ferrier and their followers, have removed tumors of the brain successfully, and saved lives. The knowledge which influences these actions will grow, and in the near present lead to the most brilliant results.

Chemistry is doing much for medicine. She is constantly adding valuable compounds; such as the bromides, the ethers, chloral, nitroglycerine have been found to be. She is extracting from well tried agents the active principles; such as atropine, hyoscine, aconitine. She is busying herself, as new plants are proved to possess healing properties, with isolating the valuable

and most available parts. She has already taught us so much of the character of the secretions, that we condemn one who does not avail himself of his testimony as criminally ignorant or neglectful. But we still want from her simpler means for the ascertaining of the quantities of the ingredients in the secretions. We want ready methods for the sake of practical utility. And we ask that her work be brought into closer connection with bedside work; that we may understand not only the character of the secretions in a given disease, but the variations in them in the different phases of the same disease—knowledge which would be very valuable in foretelling issues.

Chemistry has entered upon a most hopeful search in the study of the poisons developed by decomposition. It is not only that these "ptomaines," which have been found in diseased or putrid meat and fish as well as in stale eggs and in cheese, explain the poisonous symptoms which we know these articles to occasion; but the alkaloids of decomposition occur also in the human body, there due to cadaveric change, or formed prior to death. The system through their presence may poison itself; and it is likely that by their study we shall get a solution more certain than we now have of the features of uræmia, of the brain disturbances of bad forms of jaundice, of venom poisoning, of the disorder in low and putrid fevers, and in many a state which we vaguely call blood poisoning. Who knows, too, but what we shall understand—what now we appreciate, but do not understand—how strong emotions, how love, fright, anger, or how excessive fatigue produce illness, doing so, perhaps, by developing in the altered secretions a poison disturbing the nervous system or corrupting the blood.

The physician in the times near at hand will be a very decided sanitarian. As it is, we are all sensible of the growing importance of hygiene. We know the value of sunshine, of fresh air, of open spaces, of pure water, of wholesome food, of appropriate dress, of cleanliness, of effective drainage, of thorough disinfection. We appreciate the use of innocent recreation. We feel the necessity of saving young lives from premature exhaustion by the drain on their unformed powers from overwork, especially from the senseless cramming into jaded brains of useless knowledge. We take heed of the exercise that soothes and refreshes, that fits mind as well as body for better purpose, and of the excessive devotion to it which injures both.

But we have still the task before us of making people generally understand all this; and at the task we must go with the aggressiveness of decided conviction. No faint words; no half-measures. Ignorance, cupidity, the obstructive, terrible force of inertia, must be made to feel that they have a deadly enemy at work in every member of our profession. Do you think it unnecessary to be so active? Listen to the report of a Committee to the American Public Health Association a few years since.[1] Of the whole number of deaths in the United States as ascertained by the census of 1880, not less than 200,000, or considerably more than one-fourth of them, were due to epidemic diseases. Measured by the known results in places exempted, by energetic means for their prevention, from the prevalence of epidemic diseases, if these means had been made general throughout the United States, 100,000 of the sacrificed host would probably have been saved. Listen also to these ghastly statistics taken from the recent writings of an eminent sanitarian.[1] They are more particularly concerned with childhood. "Children under five years of age," we are told, "are expected to die in what may almost be a definite proportion." Examining different countries, we find that of ten children born in Norway, only a little over seven attain their twentieth year; in England and in the United States of America somewhat less than seven; in France, only five reach it; and in Ireland, less than five. What a record when we take into account that most of the diseases of childhood are preventable diseases, and that with a just hygiene they would be reduced to insignificant proportions.

But we need not despair of effecting much by sanitary means properly used. Let us look at results already accomplished by means as yet far from perfect. I will quote, as concerning us all most closely, some of the results obtained in our own country. In Michigan the saving of life from scarlet fever alone has amounted in the last eleven years to 3718. In Memphis, the drainage of which was some years ago in the worst possible condition, the death-rate has been reduced in six years from 35 in a thousand to 23.80 in a thousand; in Chicago, in the last five years, from 25 69 in a thousand to 19.46, a saving of 17,214 lives in that city during this period.[2] If then already something is done, how much more can be done by persistent and united effort. The medicine in the near present will be as largely a medicine of prevention as a medicine of cure. Let us trust that it will be even more so. Let us go on in our noble endeavors to be efficient preventers as well as efficient curers of disease. Let us go on with courage and devotion in the self-imposed task of teaching how to lengthen life and to add blessings to it. Let us go on with increased power presenting the splendid spectacle of a profession, earnestly and in its loftiness, striking at its own existence, and, for the common good, endeavoring with all its might to immolate itself.

Much of the advance in medicine of late years has been brought about by the study of general pathology and pathological anatomy. Neither receives in this country the attention it deserves. Yet it is the pathologist who develops into the best clinician. Morbid anatomy is certainly the very foundation of the recognition of disease; it is to the physician what anatomy is to the surgeon. But it is invaluable, too, to the surgeon. A great teacher recently gone from us, one whose sagacious words were so often almost reverently listened to in this very hall, the late Professor Gross, records, in his autobiography, the immense benefit morbid anatomy was to him as teacher, writer, practitioner, and bewails as one of the crying sins of the day its being taught in so few of our schools. But pathological science is cultivated with assiduity by some here and by many in Europe; in the medicine of the near present its full appreciation is certain, and its methods will be the approved methods of great progress.

[2] Rohé: Address in State Medicine before the American Medical Association, Chicago, 1887.

In general pathology there is just now the greatest activity, due to the discovery of minute living organisms in the body; many, indeed, are the speculations as to what these germs, these infinitely small bodies discernible only by the microscope, have to do with the production of disease. The speculations are not new; and standing in this place it is a pleasure to point to it, that one of my predecessors in the Chair of Medicine, Prof. John K. Mitchell, with rare sagacity and keen analysis, was among the very first to lead the way on this fruitful path of research. In relapsing fever, in tuberculosis, the influence of bacteria has been established; in many other, especially infectious maladies, we may fairly infer microbes to be the cause, or to play at least an important part. The whole medical world, dissatisfied with its knowledge of the causes of disease, particularly of communicable disease, is restlessly seeking out these little bodies of specific power. It feels that if it can be made a demonstrated truth that they are causative agents, not only will the mist of conjecture vanish and science henceforth walk in broad daylight, but that there will be hope of overthrowing disease at its very beginning, through means which vanquish its parasitic source. Indeed, already now "Death to Bacteria" is the rallying cry of many of the eager workers in curative as well as in preventive medicine.

Thus far, it must be confessed we have had, as regards internal medicine, no success in the search after agents which destroy the germs. The articles proposed are as apt to poison the patient as the microbe; some would be even more destructive; and none can be as directly and as completely brought into contact with parasitic life in the organs or in the blood, as surgeons bring them in contact in their antiseptic treatment of wounds and injuries. But must we despair of conquering these germs? It is not too sanguine to anticipate that if their paramount importance be fully established, the means for their destruction will be found. When has any discovery stood still? Look at the wonderful uses of steam, and remember what it was in the time of Watt. Recall the simple experiments of Volta, of Galvani, and of Franklin, and think what the great agency they found has become in these days of electric telegraphs, and electric lights, and electric railways, and of applications more dazzling than the imaginative creations of all the Eastern fairy tales. Reflect that life means progressive development, means the present and the future, not the past; and then venture to say that progress stops, and that it will be impossible to bring under control or to stamp out hosts of diseases by crushing their ascertained minute cause.

The whole science of bacteriology is still very young. The greatest practical gain has been to the surgeon, and in the better knowledge of disinfectants for the destruction of the noxious organisms outside of the body. In medicine we are still for the most part groping after the truth, hoping with it to find new lights, new means. And it is not certain that, in the glimpse we have caught of this bewildering microscopic world, we have reasoned clearly about its members. Are the particular microörganisms seen in special diseases necessarily the specific source? May they not be in some instances causative; in others simply the recipients and carriers of disease; in others again merely the followers or attendants on the unknown something that eludes our search? Further, is not their number as well as their presence important in producing morbid action? What we already feel the need of is not the mere accumulation of observations, but better appreciation of the relative value of the facts. We greatly want here what I may venture to call "scientific prospective;" and scientific prospective must be a method in bacteriology, if this promising science is to become the help we all hope it will be.

Thus far we have been regarding the tendencies in medicine, and the ways that will develop out of them in the near present, in connection with the general foundations of the science. But after all everything comes at last to the bedside for judgment on its worth; and the methods of observation by which clinical medicine has grown in the past will continue to be its chief sources of growth. The keen eye, the trained ear, the cultured touch, the collation of symptoms, the correct reasoning, the skilful adaptation of means of cure, will be the same in method; though new ways of obtaining more complete knowledge by the so-called instruments of precision, by the thermometer, by the sphygmograph, by the spectroscope, and, perhaps, by other instruments embodying physical discoveries of the day which have not been as yet adequately used in medicine, such as the telephone, the microphone, and the phonograph, will be more and more fully tested.

The great advance of our times is in therapeutics, partly through the results of suggestive experiment, partly by the more accurate appreciation of the action of drugs on the economy. Still, as in the past, clinical experience must be the final test of the value of remedies. Yet it is certain that the scientific methods now employed, will result in therapeutics simpler, and more effective in their simplicity. In the near present treatment will discard hap-hazard combinations, and aim at producing results with single remedies, or with remedies so adjusted that their combination brings out the full strength of the one most depended on, and reduces power in directions we do not wish it exerted, as witnessed, for instance, in combining belladonna or the bromides with opium. Again, local treatment is likely to be more and more resorted to. Will this make of medicine a mathematical science? Will it make the successful physician simply an accomplished physicist? Vain thought. Indeed, the methods, even those the outcome of the most conclusive experimental science and of the most perfect mechanical treatment, must ever take cognizance that in treating the sick we are dealing with the man in disease, quite as much as with the disease in the man. However more exact our means, however larger our resources, the personal something in the sick, the personal something in the physician will never cease to have their power. And the greatest success will always be with the greatest measure of tact, with the quickest appreciation of vital strength, with the magnetic influence which instills confidence and trust, with the fullest inspiration of hope, as well as with the courage that knows when to take risks and with the wisdom that knows when to rest.

A great deal of the improvement in Medicine, especially in therapeutics, is due to the knowledge that many diseases are self-limited, and to the appreciation of the course they run uninfluenced by medical means. This study of the natural history of disease is invaluable; and

giving us, as it does, a standard, it enables us to correct the claimed importance of special agencies, and to estimate at their true worth the vaunted cures of exclusive systems. It was through it that the protest of Young Physic against excessive and violent medication became effective. It was through it we began to comprehend the power of Nature. But it has done its work largely; and we must not stand still in that work. Young Physic has become middle-aged, and with its years has thrown off some of its youthful eccentricities. To go on now insisting on the supreme powers of unaided Nature, is to be as much behind the times as to continue in the constant use of disturbing, potential remedies, which the phase of medical inquiry alluded to did so much to discredit. Medicine has advanced, and has given us proved agents, alike for cure and for relief. In the near present the pandering to the belief many of the public still hold so dear, that Nature is all-powerful, that Nature must not be interfered with, will be looked upon as a sign of a weak, not of a sagacious mind. Those who seek counsel will rightly turn to him who knows the limits, while he believes in the resources of his art, and uses that art boldly; and not to him who sits down simply to see what Nature will do, and tries to throw the cloak of a philosopher over the shortcomings of a sluggard. New medicine condemns these posers as much as the old medicine they condemn.

We hear much of what Nature will do without assistance. Will she enable a man to walk with a broken leg? How often does she remove pus from the cavity of the chest? Will she arrest a peritonitis, or keep a perforated intestine quiet as efficiently as opium? Will she check the fierce onset of malaria like quinine; rally a faint heart like digitalis; or quiet the sleeplessness about to end in fatal exhaustion like chloral? Let us stop the prating about the unlimited power of Nature, and of not interfering with her processes. The same Providence that gave the power is daily letting us find more and more means to help it, when weakened; to repair it, when stricken. It may be in individual maladies still the best course not to attempt radical interference, since the measures to overcome them have not been as yet discovered. It is often impossible with our present knowledge to do otherwise than to husband strength and to allay disturbing symptoms. Each generation will re-examine and determine for itself, in the light of new helps, its influence over particular affections. A generation that has witnessed the introduction of the hypodermatic syringe, of the bromides, of chloral, of nitroglycerine, of cocaine, of antiseptics, need not despair of gaining more agents potent for control.

We are in an era in which Surgery is becoming the adjunct of medical therapeutics, or acting where Medicine cannot act. How far this is to go, time alone can determine. Before many years what can be safely attempted, and what cannot, will be fully known. But from the mode of procedure good has come. The history of intestinal obstructions and of peritoneal abscesses is the history of advancing success. Extirpation of brain tumors shows alike the increased skill in the recognition of disease and in its treatment. The indications for tapping the chest and the pericardium are becoming better and better defined. The removal of growths in the larynx cures cases beyond the reach of Medicine. The extirpation of enormous diseased spleens has been in some instances successful. There is, of course, risk that the daring efforts and glowing anticipations of surgeons may lead to attempts which cannot possibly succeed. But the method is a method of advance; a method to be used when medical art fails. As internal therapeutics grow in resources, let us hope that the instances of employing surgical means will become fewer. Yet in the near present they will be used, and, assisted by the new and growing surgery of antiseptics, with probably increased ease and surer results.

The practice of the times we are approaching will then be simple, accurate, decided. The leading men of the day show these traits strongly. It will still require on the part of all much labor to attain this simplicity, this accuracy, this decision. It will require continuous work to sustain it; and, with these methods predominant, many a type, many a familiar figure will be seen no more.

In justice, I cannot leave my subject without taking some notice of what the position of Medical Instruction is to be, to keep pace with the improved methods to which we are attaining. It would lead me far beyond my limits to examine this question in detail; but it is evident that Medical Teaching must conform to the spirit and aims of the developing science. It will lay more and more stress on laboratory work, on bedside instruction, on clinical exercises, on personal training. It will do more and more, what I believe this College was the first, certainly in this country, to do, aim at breaking up the class into small sections for special instruction, so that everyone may have the opportunity to learn for himself under skilled supervision. It will, as studies advance, encourage to thoughtful, independent work with scalpel and in the laboratory; that kind of work which caused Soemmering, while a medical student, to earn from famed anatomists like Camper and Monro enthusiastic praises for his researches on the nerves at the base of the brain; the kind of work which Black, at the age of twenty-four, announced in his graduation thesis, revolutionizing Chemistry and paving the way for the great contributions of Lavoisier; the kind of work which led Koller but a year or two years since to discover the properties of cocaine; the kind of work which—I say it with feelings of just pride—is about to bear fruit in the publication of a volume of original essays on remedies of indigenous growth, containing a number of the investigations of our students in the laboratory of the Professor of Therapeutics. Progress in Medical Instruction will lop off many unnecessary studies, followed more particularly in some of the schools of Continental Europe, and having only a remote connection with medicine. It will require of all who engage in professional study mental training; but it will not too narrowly specify the kind of training, allowing the broadest limits in proof of mental aptitude. It will aim quite as much at educating in the methods of work as at mere supply of knowledge. It will lead to freedom of study; stop the wearying system of constant, so-called progressive examinations, which are regarded as tests of fitness to pass from one branch to the other; and will make one examination—the final one—sufficient, no matter when or how the knowledge has been acquired.

Will advancing methods in teaching dispense with lectures? "Lectures, sir!" said Dr. Johnson, "what

man would go to hear that imperfectly at a lecture which he can read at leisure in a book?" Lectures of the kind referred to—mere recitals without demonstration—enlightened instruction will forego. It will insist upon lectures which are not simply what can be read, upon those which address the eye as well as the ear, upon teachers that are not mere talkers, and if one of this class be found in position, public opinion will call for his removal.

THE PROGNOSIS OF CÆSAREAN OPERATIONS.[1]

By W. T. LUSK, M.D.,

PROFESSOR OF OBSTETRICS IN BELLEVUE HOSPITAL MEDICAL COLLEGE, NEW YORK.

If it were proposed to a physician to beat out the brains of a newborn living infant with the view to diminish the perils of the puerperal period, the proposition would certainly be rejected as too horrible for consideration, even though the physician was convinced that the theoretical grounds for the recommendation were correct. Yet there is a disposition to treat any hesitation to destroy the unborn child in the maternal interest as pure sentimentality.

I must confess that I have never felt satisfied with this bit of curiosity, and I am sure that for the bulk of the medical profession nothing can be more welcome than to learn that there is statistical evidence sufficient to warrant us in a very considerable proportion of cases to decline, equally in the interest of the mother and the child, to lend our aid or countenance to the sacrificial operations of midwifery. By statistical evidence I do not mean bare records of deaths and recoveries, but a careful study of recorded cases, deductions from which are rational, and furnish the safest guide to scientific practice. It has been objected to the old statistics that they contained an undue proportion of favorable cases, and it may be a fact that a large number which ended fatally were never recorded; but on the other hand, some years ago I took occasion to analyze the histories of cases upon the death list, contained in the collection published in 1832 by Michaelis. They all belonged to the nineteenth century, and have been included in all the statistical tables that have since been published. In thirty-four the histories given were tolerably explicit. In one of the instances the operation was performed upon a corpse, and in the others upon dying women, or under circumstances which reduced the chances of success to a slender possibility. No wonder, under such conditions, Mauriceau, speaking of the Cæsarean section, declared, "If it is true that any women have escaped, it was the work of a miracle, or the express wish of God, who, if he wills it, is able to raise the dead, as he did Lazarus."

But the operation is not of necessity a fatal one. As regards the Cæsarean section in this country, it is presumable that few, if any cases have escaped Harris's vigilant inquiries. In a personal communication from him, I learn that up to date there have been 153 cases with 56 recoveries. This is undoubtedly a most discouraging report, but the percentage of recoveries should certainly teach us that the operation is capable of betterment by human ingenuity. It was until lately too much the fashion to quote the statement of Baudon, made in 1873, that there had not been a successful case in Paris in eighty years, and to ignore the results of individual operators. Thus Winckel, Sr., practising in a poor community where osteomalacia prevailed, in 15 operations saved 7 mothers and 8 children; Hœbicke operated 16 times with 11 recoveries; Maslieurat Lagemard, operated six times, and all his patients recovered. Déconène, of Courtrae, operated six times, and saved five women and four children, and Harris has been able to report 19 cases in Louisiana with 14 recoveries. In all these instances the operations were performed not in infected hospitals, but in the pure air of the country. Again, Dufeilthay's statistics showed 81 per cent. of recoveries, where the operation was performed before the mother became exhausted, and Harris has shown that under similar conditions in America, 21 out of 28 patients recovered.

These facts have, indeed, become sufficiently familiar, but they have been so persistently ignored by the anti-Cæsarean school in its polemic, that it becomes necessary to reiterate them in the rebuttal evidence offered by Cæsarean defenders. They show that the old operation when performed under fitting conditions, in a healthy locality, and with sufficient skill, has had a fair measure of success. Barnes claims for the alternative operation of craniotomy in extreme degrees of pelvic deformity precisely the same pre-requisites. "Obviously," he says, "we cannot recognize fatal cases of craniotomy in extreme deformity, unless the operation was begun under selected circumstances—that is, before exhaustion had set in, and conducted with due skill and after approved methods."

But in spite of the testimony favorable to prompt action, Harris has recently reported that during the last seven years in this country, in 27 operations only 5 women and 10 children have been saved, and the enemies of the Cæsarean section have pointed to these results as showing that it alone of all the departments of abdominal surgery has profited nothing by modern science. Without question it is, however, the preaching of those, who go around crying woe, woe! that is responsible for this melancholy decline. The operation ought never to be regarded as one of last resort. If the patient is dying, it is the duty of the physician to secure euthanasia, and not to make the death-bed the field for surgical display.

In marked contrast with the poor success attained in late years by operators in this country, Harris[1] has recently reported with gentle irony the histories of nine women in advanced pregnancy, whose wombs were ripped by the horns of infuriated cattle, with the survival of five women and four children, and of six cases of self-inflicted Cæsarean section, in five of which the women recovered.

[1] Read in the Section of Obstetrics, International Medical Congress, September 6, 1887.

[1] Harris: Cattle Horn Lacerations of the Abdomen and Uterus in Pregnant Women. Am. Journ. Obst., July, 1887.

I have spoken so far of the old operation, meaning thereby cases in which nothing was done, or inadequate measures were employed to prevent the subsequent gaping of the uterine incision. Under such circumstances as favorable cases closure was effected usually by an adhesive inflammation, which united the uterine to the abdominal walls. To this were due the favorable results when the Cæsarean section was repeated upon the same subject (8 deaths in 119 operations, Lundgren), as the operation then became virtually an extraperitoneal one. According to Sänger, only one instance is known where complete union took place throughout the entire length and thickness of the wound. Sometimes the cicatricial tissue extended the entire length, but not through the thickness of the incision, and was of a callous consistency; in others, the line of union was at points of extreme tenuity, disposing to hernial protrusions, and in subsequent pregnancies to the production of rupture; while in others again, union took place at intervals only with the formation of fistulous openings, communicating either with the abdominal walls, or with circumscribed cavities within the abdominal enclosure.

Strangely enough, even after these facts had become familiar, it was not immediately obvious that better union could be secured, and the dangers of the operation lessened by the employment of a proper suture. The belief prevailed that sutures were a source of irritation, and that the alternating contractions and relaxations of the uterus during the early days of the puerperal period practically destroyed their utility. So strong, indeed, are old prejudices that Porro's proposition to avoid the risks arising from gaping of the uterine wound by the removal of the entire uterus has very recently been regarded not as a clumsy device, but as a surgical necessity. Indeed, it has been in this country chiefly, where tradition exerts a feeble influence, that, prior to the appearance of Sänger's exhaustive monograph, the suture has had anything like a fair trial; and Sänger strongly reinforced his argument in favor of its employment by the successes obtained through its agency by Pohn, Brickell, Jenks, and Lundgren. Of these Brickell is specially deserving of honor. For twenty years, in spite of sneers and ridicule, he insisted on the employment of the suture, and foresaw that the suture was destined to remove the Cæsarean section from the category of happy-go-lucky expedients to the level of a legitimate surgical procedure.

But, however others may have contributed to the foundations, it has been the glory of Sänger to crown the work by indicating with precision the manner in which the vast experience acquired of recent years in abdominal surgery could be made available for the rehabilitation of the Cæsarean section. Leopold, the first to test the improved method, has now operated 13 times with 12 recoveries, and in Crede's clinic there have been 7 operations (4 by Sänger) with no deaths. These figures represent the possibility of the operation. In Leopold's fatal case the cervical dilatation had been prevented by old cicatrices. Cæsarean section was performed after twenty-seven hours of hard labor. The lower uterine segment was bruised, inflamed, and œdematous from long-continued head pressure. Death was due to peritonitis. In similar cases Leopold now advocates the removal of the injured organ by the method of Porro.[1]

These results sustain the dictum of Sänger, that the Cæsarean section, supplemented by deep and symperitoneal sutures, is devoid of danger if performed before the exhaustion of the patient—before the occurrence of infection—and in consonance with the principles of antiseptic surgery.

In Crede's last report (Mittheilung aus der Geburtshülflichen klinik, in Leipzig, Arch. f. Gynäk., vol. xxx. p. 328), the number of patients operated upon by Sänger's method was increased to 50, with 36 recoveries, and 14 deaths. Since then there have been published 6 more cases, viz: those of Döderlein, Perret, P. Bar, Lusk, Parrish, and Ohage. Of these the first four ended in recovery, and the last two in death. The total mortality thus far is 28¾ per cent.; but America furnishes seven cases, with but one recovery. If we deduct these, the mortality falls to 20$\frac{29}{40}$ per cent. It is, therefore, particularly becoming in us, as chief contributors to the death-rate, to inquire into the causes and complications that have led to the fatal endings. The results of such an investigation are very interesting.

1. Garrigues. *Am. Journ. Obst. Case of lumbo-sacral kyphotic pelvis.* The patient had caries of the sacrum and lower vertebral, with synostosis of left iliac joint, contraction of left knee, and talipes equinus. She had had hæmoptysis, and was suffering from cystitis and vaginitis. For a month previous to operation the patient rarely left her bed, and suffered from nearly constant vomiting, and had to be nourished from time to time by enemata. Owing to ante-partum hemorrhage, she was, at the time of the Cæsarean section, weak and suffering, pulse 124, lips blue, and with cold hands and face. It was not thought by those in attendance that the patient could survive any operation. She lived 48 hours.

2. Beumer. *Arch. f. Gynäk.*, vol. xx. p. 409. *Cervical myoma.* Patient had cystitis and pyelonephritis. Both kidneys were nearly destroyed. Death occurred in 36 hours.

3. Krukenburg. *Arch. f. Gynäk*, vol. xxviii. p. 411. *Conjugata vera estimated at less than two and a half inches.* Patient a dwarf three and a half feet high, rachitic and scorbutic. She had been twenty-five and a half hours in labor, and was extremely feeble at the time of the operation. After the latter, hemorrhage due to complete atony of the uterus occurred. Death from collapse. Fasola, in a similar case of inertia, associated with grave internal hemorrhage following upon the performance of Sänger's operation, amputated the uterus. The mother recovered.[2]

In the following cases death resulted from exhaustion or septic infection due to extreme prolongation of labor. In all the indications for Cæsarean

[1] This plan he has since followed in a case where the uterus was infected at the time of the operation. The woman recovered. Leopold: Arch. f. Gynäk., vol. xxviii p. 120.

[2] Fasola: Gaz delle Cliniche, Nos. 24 and 25, 1886.

section were indisputable at the outset. They in no sense illustrate the dangers of the operation, but rather the folly of postponing action until the seeds of death have been sown.

4. Münster. *Centralblatt*, 1886, p. 82. *Pelvic tumor.* Patient, after four days of labor, was conveyed to Königsberg, a railway journey of seven hours. Obstruction due to large pelvic tumor. Operation performed after four days of labor, twelve hours after rupture of membranes. Escape of fetid gas. Endometritis septica before operation. Death in four days.

5. J. R. Weist. *Med. Rec.*, March 13, 1886, p. 301. *Retrocervical myoma.* Operation four weeks after rupture of membranes, and nine days after labor had begun. Death in twenty-four hours.

6. Drysdale, *vide* Harris. *Amer. Journ. Med. Sci.*, October, 1885. *Retrocervical myoma.* Labor lasted two weeks. Septic infection at time of operation. Child putrid. Death in twenty-six hours.

7. Breisky.

Finally there remain a limited number of cases in which death was due to some defect in the antiseptic precautions.

8. Ehrendorfer. *Arch. f. Gynäk.*, vol. xxv. p. 128. *Fibroma of fascia, invading pelvic cavity.* Patient had had three living children, membranes ruptured at 3 A. M., on September 28th. At 4 P. M., on the 29th inst., Cæsarean section; escape of meconium into abdominal cavity. Ligature around left tube to prevent hemorrhage. Death in five days, from peritonitis purulenta ichorosa. Uterine cavity contained strips of decidua infiltrated with pus, with necrosis of tissue between the sutures.

9. Jewett. *N. Y. Med. Journ.*, August 29, 1885. *Uterine Cancer.* Profuse hemorrhages in latter part of pregnancy, constant pain, no sleep. Death from septic peritonitis forty-four hours after operation, infection probably due to case of erysipelas at the time in the hospital.

10. Ohage. Report received from Dr. Harris. *Conjugata vera under two inches.* Rachitic dwarf, labor induced; operation twelve hours later, when os was the size of quarter of a dollar. Death on fifth day from diphtheritic endometritis.

In addition to the above, Credé reports three cases communicated to him by letter, one operated upon by Neugebauer-Bieganski, of Warsaw, one by Bieganski, of Warsaw, and one by Morisani, of Naples, where the operation, though performed under apparently favorable conditions, was followed by death due to infection.

The more these cases are studied the more evident it becomes that the deaths were the results of preventable causes, except in instances where the operation was fatally handicapped by antecedent disease; indeed, the prognosis of the modified Cæsarean section appears to be favorable whenever performed with due surgical skill, and under circumstances which admit of surgical success.

As regards the saving of infant life, the results have been hardly less gratifying. In times past the anti-Cæsarean school has furnished statistical record showing a heavy infantile mortality associated with the operation, but in the fifty-six cases in which the Sänger precautions were employed only six children were born dead, and of these four were putrid at the time the operation was performed.

In Germany proper there have been thirty-five operations with the recovery of thirty-one women, and the saving of thirty-three children. In this country, in seven operations, there have been saved one women and three children. In view of this unflattering discrepancy it seems well worth our while to inquire in what way we can so improve our methods that our results may no longer give to the modern Cæsarean section a sinister aspect not justly its due.

Now, in the first place progress is not to be expected on our part until our professional men as a body make themselves familiar with the import of the various forms of pelvic obstructions, and learn to discriminate, during pregnancy, the conditions which indicate, respectively, the induction of premature labor, the Cæsarean operation, craniotomy, or a Fabian policy. Of course, the discussion of these and similar questions is not germane to my subject, but it may not be out of the way to note that craniotomy is not available in cancerous degeneration of the lower uterine segment and vagina, in obstruction due to fibroids and other tumors occupying the pelvic cavity, and in cases where the conjugate diameter measures less than two and a half inches. I do not pretend to claim that craniotomy furnishes no good results in these cases, but that the operator takes a gambler's risk, with the odds heavily against him. Even when the conjugate measures from two and a half to three inches the Cæsarean section still seems to me to be the preferable choice, as with those dimensions, unless the transverse diameter happens at the same time to be spacious, a most exceptional occurrence, craniotomy is extremely hazardous, requiring a complete obstetrical armament, and great experience on the part of the operator to enable him to avoid inflicting serious if not fatal injury to the tissues between the child's head and the pelvic brim.

To be sure, Barnes asserts that "craniotomy done under fair conditions, such as are postulated for the Cæsarean section—that is, done at a chosen time with due skill, does not involve any natural mortality," but a careful perusal of all his subsequent remarks shows that the statement was intended to apply to women with minor degrees of contracted pelvis only.[1] Merkel[2] reports 100 cases of craniotomy from the Leipsic Clinic, with 8 deaths. He congratulates the clinic upon results never obtained elsewhere. Thorn[3] reports 80 cases from the Halle clinic, with 10 deaths. How simple these cases were, for the most part, is shown by the fact that in Merkel's list of 68 multiparæ 49, and in Thorn's list of 56 multiparæ 39 had previously given birth to living children.

[1] Barnes (British Gynecological Journal; part viii., 1866, p. 315) argues that by sacrificing the living child at term, the woman's life is saved, and subsequently, by the employment of premature labor, she becomes the mother of living children. But with less than three inches in the conjugate even premature labor affords but little encouragement so far as to hope for the preservation of the child.

[2] Arch. f. Gynäk., vol. xxi. p. 461.

[3] Thorn: Arch. f. Gynäk., vol. xxiv. p. 437.

Unquestionably defective diagnosis has so far in this country proved the most serious bar to progress in obstetric surgery. Every year I witness cases where horrible mutilations, due to ineffective attempts at delivery, have been inflicted before it was suspected that the obstruction was insurmountable. American woman have in times past enjoyed so large a degree of immunity from the more pronounced forms of dystocia, that our practitioners are too much disposed to regard Dame Nature as invariably kind to the parturient woman. Very few, indeed, attempt to realize the pernicious influence of spinal curvatures and hip disease upon the pelvic contours, or try to acquire the art of pelvimetry, and yet these belong to the A. B. C. of practice. A knowledge of them should constitute the difference between an educated physician and an experienced monthly nurse. This is delicate ground, and I do not refer to it in any carping spirit. I know that the lack of interest exhibited is due to a sense of the remoteness of the contingencies which will render such knowledge available. But more artificial modes of life, the pressure of population in large cities, and an unprecedented immigration are already working among us a perceptible increase in the causes of difficult labor, and with the departure of the old easy-going order of things comes the need of better equipment and an increased sense of responsibility on the part of medical attendants.

It is of good omen that Parish, armed with the weapons furnished by Harris's statistics, presented to the members of the American Gynecological Society, a year ago, a most eloquent appeal to give this subject their earnest thought and attention. I add my voice in the same direction from a sense of duty, and trust the time is at hand when all our leaders will lend their aid and advocacy to the work.

It is not to be expected that in every case, after a correct diagnosis has been made, and the necessity of the Cæsarean section has been recognized, that the practitioner should undertake the operation himself. It is not desirable that the Cæsarean section should be performed without assistants, without proper instruments, or without preceding orderly arrangements. Nor ought the operator to trust to the inspiration of the moment, but should possess at least a theoretical familiarity with every detail that experience has shown to contribute to the patient's safety. If the physician is timid, or is not so situated that he can operate under advantageous conditions, it will generally be easy, where the diagnosis has been made prior to the advent of labor, for him to entrust the case to an expert in abdominal surgery.

We have many laparotomists operating with brilliant results. They are not all upon the seaboard or in large cities, but are so scattered as to form centres accessible to extensive areas. They possess the experience, and needful preparation. With the general cooperation of our professional men, there is no reason why they should not rival the successes won in Leipsic and Dresden. They need, however, to open their eyes to the work of our neighbors, and to equip themselves for this special field of saving infant life. Mr. Tait has doubtless accomplished great good in teaching surgical means for the relief of tubo-ovarian disease, but it would be an added glory to our laparotomists, if they would on occasion round out their work of sterilising women by conferring upon them the blessings of maternity.

OBSERVATIONS ON THREE CASES OF SYMMETRICAL HAND AND FOOT DISEASE.

BY JAMES NEVINS HYDE, A.M., M.D.,
PROFESSOR OF SKIN AND VENEREAL DISEASES, RUSH MEDICAL COLLEGE, CHICAGO

THE cases reported below are given in brief but essential detail, with a view to illustration of one phase merely of the pathological condition which they are believed to represent, and which is described later.

CASE I.—C. S., aged nineteen years, a resident of Indiana, applied for advice on the 23d of May, 1887. He was an intelligent, bright-looking lad, then attending school. He used no tobacco in any form and denied all history of venereal disease. His father was living and in good health, fifty-four years of age; his mother the same, aged forty-nine. Four sisters were living and in good health. One brother died in infancy. One sister was married and had five healthy children. There was no history of cutaneous trouble in any member of the family. He gave no history of disease prior to the occurrence of the present ailment. All the bodily functions were properly performed. He stated that three years before the present date he noticed the first signs of his present disorder on the tips of the fingers. Somewhat later the toes were affected, and soon after that the palms of the hands and the soles of the feet. Since the beginning of his trouble the local affection had very slowly and gradually increased until the present condition has been reached. His complaint now is chiefly of stiffness and inflexibility of the hands and some soreness of the feet.

The state of the patient when examined was as follows: weight, 135 pounds, and gaining at the rate to be expected at his years. Vision, as tested by Snellen's types, in both eyes, normal. There was no sensori-motor evidence of disease of the nervous system. The hands and feet were symmetrically involved. The palms of the hands and the palmar faces of all the digits were the seat of a dense, inelastic, epidermal thickening, which had proceeded to such an extent as to render the complete extension of the digits slightly uncomfortable. The tylosis of the palmar surface of hands and fingers alike, was defined with tolerable clearness at the margins between the palmar and dorsal surfaces, to such a degree that the latter were, with only the exceptions noted below, exempt from involvement. Within the limits described, the sclerosis of the tissue was uniform and unbroken. The color of the palmar surfaces of the hands was markedly different from that of the plantar surfaces of the feet, having a reddish yellow tint, somewhat suggestive of the diffuse eczema of the palms observed in certain mechanics, whose occupation has induced such disorder. He gave no history of other subjective sensations in connection with the local ailment than

pain and a sensation of stiffness. A few linear fissures near the thumb were productive of slight discomfort. There was no history of itching, nor of any pathological discharge from the surface.

All the nails of the fingers of both hands were similarly involved and apparently to the same degree. The free border of each, which had evidently been carefully trimmed short, was tilted away from the axis of the phalanx; and in the angle thus formed, in consequence of a species of onychauxis, appeared a yellowish-white and irregular stratum of horny material. The body of the nail was manifestly thickened and its transverse diameter apparently increased. The nail-substance itself was dry, friable, rugous, and destitute of the normal polish. When closely questioned upon this point he stated that his nails were thicker and dryer than before, that they fractured with unusual readiness, and were on that account particularly tender. He had within a short time noticed some sweating of the hands, a circumstance which until lately had not attracted his attention.

Both feet were cold and damp, and were the seat of a slight bromidrosis. The sole of each, with the exception of a narrow portion contiguous to the instep, was the seat of a uniform, smooth, firm, inelastic tylosis, which spread irregularly upward around the point of the heel, and involved to a less degree, the plantar faces of the distal phalanges of the toes. The color of this indurated and thickened epidermis was a whitish-yellow, strongly suggestive of the hue of wet wash-leather. The coldness and dampness of the organs were not limited to the regions affected by the tylosis, but were not noticeable over the entire surface.

All the nails of the toes of both feet were involved in an onychauxis, precisely similar in character to that described in connection with the fingers. The nails were tilted up at the free border from the nail-beds, and between the two lay a substratum of sclerosed epidermis. The nails were lustreless, rugous, transversely enlarged, and cut short on account of their undue friability. The soles were the seat of a moderate anæsthesia.

The pulse was registered at 84 per minute. There was no history of headache or backache, no cardiac murmur, and no marked deviation from the normal standard in the tendon-reflexes.

Case II.—N. B., female, unmarried, aged twenty-four years, lymphatic temperament, a servant by occupation, was first brought to my clinic from the County Hospital, where she had been a patient for several previous weeks in the spring of 1884. She stated that her parents, two sisters, and one brother living in Scotland, were healthy and free from symptoms of her disease. She had been admitted to the hospital for relief of a symmetrical, recurrent tylosis of the feet, and failing to secure relief there applied elsewhere. Some months later, she was admitted to the Presbyterian Hospital and was under my observation in that institution till the spring of 1887. During all this time her physical symptoms were practically repeated in a recurring cycle of changes. About one year previous to her original admission to hospital, she first began to suffer from her disorder, though insignificant symptoms of it had been noticed some time before the date referred to above.

When carefully examined in hospital, her condition was as follows: Her intelligence was above the standard to be expected in one of her position. Her nutrition was fair, menstruation and functions of the alimentary canal properly performed. In the sitting posture, the cardiac pulsations averaged between fifty and sixty per minute, and were often counted at fifty. No organic disease of the heart could be recognized. The hands were constantly cold and bathed in a profuse sweat. This perspiration was poured out to such excess as to be a constant source of annoyance to her. All the nails of the hands were slightly discolored, somewhat rugous, their free borders slightly separated from that part of the nail-bed adjoining the tip of the finger. In the angle thus formed was a grayish, irregular mass of tissue, proliferated from the bed of the nail. This condition was very much less marked than the similar onychauxis to be noticed in the toes. There was no tylosis of the palms or symptoms of anæsthesia in those organs; the skin of the hands was soft and supple, though clammy and macerated with sweat.

The soles of the feet, including the plantar faces of the distal phalanges of the first and fifth toes, were symmetrically involved and displayed a uniform, grayish-yellow, thick, firm, and closely adherent callosity, whose surface was exceedingly rough and irregular. It was absent over but a small area of the sole, next the instep and plantar faces of the second, third, and fourth toes. On account of the habitual shedding and recurrence of this plantar shell, the feet had been at times exceedingly tender, and the inability of the patient to pursue her usual vocation on foot, resulting from this cause, had first induced her to seek hospital relief. While she was under observation, the truth of her statements relative to the periodical sloughing of these horny casts of the feet was abundantly substantiated. She was, while under treatment, subjected to repeated macerations of the soles of the feet for weeks at a time in water of various temperatures and medicated in various ways; in oil; with shampooings by the aid of green soap and alcohol; and treated also by external applications of caustic potash, mercury, tar, pyrogallol, and other substances, in the face of all which every six or eight weeks there was a reformation of the thick plantar callosity on each foot. When it was removed, either spontaneously or as a result of the soapings and scrapings practised by the patient herself, a sound tissue was never recognized beneath, but always an irregularly roughened, yellowish-gray and softish, macerated, horny layer of the epidermis. As a result, whether the cast were forming, formed, or recently shed, the soles of the feet were tender and locomotion correspondingly impeded. The feet were habitually cold and wet, and there was some anæsthesia as far as the ankle. Two peasized callosities on the dorsal surfaces of the fourth and fifth toes of one foot, participated in all these changes.

The nail of each toe was so deformed as to make the wearing of the usual coverings of the feet pain-

ful. Each nail was enlarged, irregularly thickened, unusually friable, deprived of its polish, and tilted up often at an angle of thirty degrees from its bed. In the groove thus formed had accumulated an irregular mass of tissue, which resembled to a certain extent the uneven surface of the sole of the foot when the callous plate which covered it had been partially scraped off. The dorsum of the foot, though cold and macerated with constantly effused sweat, was apparently otherwise unaltered. Throughout the time during which this patient was under observation, no tendency whatever to ulceration beneath the plantar encrustation could be recognized: nor did the patient appear to be in the slightest degree permanently affected by either the internal or external medication which had been pursued, the former including the administration of arsenic, cod-liver oil, and the ferruginous tonics.

CASE III.—In July of 1886, M. D., male, pattern-maker, a Scandinavian, twenty-eight years of age, with an excellent family history, no tobacco habits, and no record of venereal disease, presented himself, complaining of loss of hair on the lower extremities. He was well-nourished and weighed 175 pounds. He had for two years noticed the alopecia for which he sought relief. His lower extremities were numb at times; this sensation annoying him often at night when wakeful in bed. In the daytime he had felt occasionally as though the lower limbs were yielding under the weight of the body. Questioned more closely he gave no history of prior disease; but remembered that fifteen years before, in his thirteenth year, he had been struck on the vertex of the head with a brick. This had not produced insensibility, but somewhat later a degree of cephalic pain in the vertex, for which a surgical operation was performed in the site of his former scalp wound, that gave him relief. He was uncertain as to the precise nature of the operation, but believed that a piece or pieces of bone had been removed from the skull. Lately he had again suffered from a peculiar pumping pain in the head, which prevented steady attention to his work.

When examined, a linear cicatrix, two inches in length and slightly attached to the bone was discovered to the left of the anterior terminus of the sagittal suture. The hands and feet were habitually cold. Broad areas of the skin, vertically disposed, extended from the middle of each leg downward, chiefly on the outer aspect of each, where no single filament of hair could be found. Anæsthesia was marked in both lower extremities; more so on the right side where also the alopecia was most distinct. Each nail of those on the hands exhibited a distinctly outlined, and unusually large and pale lunula. The nails of the index and fourth fingers of each hand were singularly flecked with shining, white, stellate, and irregularly outlined, translucent maculations. Careful investigation disclosed no removal of the free border of the nails from the nail beds. Vision, tested by Snellen's types was normal; tendon reflexes unaltered.

Says Mr. Charles Atkin, in commenting on a disorder, which I take to be identical with that represented in the three cases described above: "As the pathology is as imperfectly understood as the treatment is unsatisfactory, I think every one who meets with a case is in duty bound to give a faithful account of its coincident symptoms and progress, so that in time a more definite idea of the disease may be formed." These pages are written with a view to making some response to that plea, and with a full conviction as to the unsatisfactory state of our knowledge on the general subject.

Of the several names for the group of disorders which in this connection we have reason to believe should be designated by a common title for identification, some are confusing, some indefinite, some imperfect, others positively misleading. The name *mal perforant du pied*, Latinized as "malum perforans pedis," the "perforating ulcer of the foot" of English and American authors, was first employed by Vésigné. It seems to be a permanent survivor of other names used in this connection, though defective in that we now well know the disease it designates may affect the hands as well as the feet, and may not be productive at any time of a perforating ulcer. The title of the present paper has been selected, not merely with a view to indicating the general character of the affection under discussion, but to permit of a brief glimpse over the wide field of which it is believed but a very small part is covered by cases of the kind represented in the clinical sketches just given.

Two chief reasons may be assigned for the uncertainty and confusion that seem to have attended the discussion of this subject. First, may be named the very wide multiformity of the symptoms presented in each case, as well as the differences exhibited by any two cases in the same general category. Second, as a result of the fact last stated, the circumstance that a number of English and French surgeons have named, described, and treated the prominent surgical complications of these singular hand and foot disorders, leaving to neurologists chief consideration of the nervous phenomena evident in another group; and to dermatologists the symptoms displayed for the most part in the skin.

Glancing over the entire field, it seems to me that we can establish tolerably distinct relations between four classes of symptoms displayed in these cases. They are not, strictly speaking, either stages or varieties of a single disease, though they may be indicative, in occasional instances, of periods of evolution of a single affection.

In the first class, relatively limited as to the number of symptoms displayed, we can recognize merely functional or transitory disturbances in the affected organs. Here, as in other classes, we find involved either the hands alone, or the feet alone, or both hands and feet. In this event a preponderance of symptoms may be noted either in the former or the latter. Among these symptoms may be named symmetrical hyperidrosis, limited to the organs affected, accompanied by a sense of both subjective and objective coldness. To this class belong the cases described by Mr. Hutchinson and other English authors, as "symmetrical asphyxia" of the extremities; and also those popularly named

in Great Britain "dying of the hands and feet," a phenomenon occasionally noted as following the immersion of these organs in cold water. Bromidrosis is another symptom noted by Atkin and others, both in hands and feet. The bond of union between these disturbances and those mentioned later is to be sought in the nervous and vascular systems. With the local phenomena are often associated a pulse ranging, with rapid variations in adults, from fifty to one hundred and twenty-five to the minute; local anæsthesia, claimed by Schwimmer as a constant symptom; suddenly occurring giddy and dizzy sensations; unusual spells, supposed to be of faintness; and vague pains, popularly believed to be rheumatic in character. No distinct line of demarcation separates the first from the second class of symptoms, many cases exhibiting the combined features of the two.

In a second and relatively large group may be collected the cases where, with or without, usually with, the functional disturbance named above, occur symmetrical structural changes in the skin and its appendages without ulceration or other destructive degeneration in the skin and subcutaneous tissue. This group includes many of the cases reported and described by dermatologists, and excludes many of those recorded by surgeons and neurologists. The first and most common of the symptoms here noted, in addition to the habitual blueness, coldness, and wetness of the hands or feet, or hands and feet, is a dystrophia unguim. This may involve all of the nails of the twenty digits, whether the two hands only or the two feet only are the seat of the hyperidrosis. Here the changes vary from slight roughness to extreme gryphosis. In some of Hutchinson's cases there was hyperidrosis with changes in every nail. Here should be included the same author's "true psoriasis of the nails contrasted with chronic onychitis;" his "chronic inflammatory disease of many finger-nails," and his "symmetrical slight disease of the nails in a young boy." In Elliott's case, lately discussed before the New York Dermatological Society, and reported under the title of "trophoneurotic affection of the nails," the nails of the ring-finger of each hand were first changed, and later all save that of the right index. In this connection the nail-change is described as a dystrophy, waiving for the present purpose any discussion of its, pathological character; though I may add that the term onychauxis, employed in the description of my two cases, expresses my belief in the fact that there is at first certainly hypertrophy, and not atrophy, of the nail-substance.

As strictly cutaneous symptoms in this group of cases, may be named tender, painful, or insensitive maculations of the hands or feet, or both; pigmented patches, both palmar, plantar, and dorsal in situation; livid, dull crimson, or lurid blotches; persistent "erythemas," vesiculation, "ichthyoses," and "eczemas." The latter terms may, in this connection, be misused, since they may have been employed by a writer unfamiliar with dermatological distinctions, in order to point merely to the dry, slightly reddish condition of the palms seen in the first of my cases, resembling certain forms of eczema squamosum. Another symptom less frequently observed is a local alopecia or hypertrichosis, the hairs either entirely absent or multiplying or growing to an unusual and conspicuous length over the organs affected. The symmetrical tylosis, or callosity, which may involve the palms or soles, either or both, is well illustrated by two of the cases here reported. It may be partial or general, and persistently of one type or characterized by a spontaneous exfoliation and recurrence of a horny cast of a part or the whole of a palm or sole. With it, as appears from what has preceded, there may be symmetrical involvement of all the nails; it is reasonable to believe, from the gross appearance of such nails, that their beds are the seat of precisely the same pathological process as that resulting in the tylosis. An unusual multiplication and cornification of the cells constituting the nail-bed would, particularly if that change were limited strictly to the nail-bed and did not affect the matrix of the nail proper, tilt up and distort the nail-substance so as to explain in part the clinical deformity described above. The free border of the nail would thus be carried further from the nail-bed than the proximal border, which, being next the matrix, would be least involved, and therefore far less dislocated.

With these phenomena may be observed the common anæsthesia, the loss of tendon-reflexes, the wetness of the hands and feet; and pains simulating those occurring in rheumatism. Kirmisson reports seven cases with symptoms of glycosuria; and Heusner confirms this with his observations.

In a third division may be grouped the symptoms exhibiting ulcerative or other degenerative sequelæ. Here may be catalogued most of the surgical cases first described by Nélaton, to which Vésigné gave his name, "perforating disease of the foot," including the well-known phenomena first completely described by Messrs. Savory and Butlin. Even in this group we find the name defective from a descriptive point of view. Hancock, Nélaton, Térillon, Treves, Trélat, and others, report symmetrical ulcers of the hands as well as ulcers of the feet, which conditions are also represented in a number of faithful wood-cuts. Here we find the surgeons dilating upon the difference between suppurating ulcers beneath a corn (Callender, Erichsen), a tuberculous ulcer of the sole, and the lesion of malum perforans pedis. Here we find them also figuring and describing the shortening of the digits, and even of the entire foot (Jones), resulting from the same process. Some report spontaneous healing; some, a healing only after operative interference; some, a recovery if only the hands and feet are disused—one reports a case with resulting bony ankylosis.

In the same group may be placed the reported cases of symmetrical ulceration and dry gangrene of the extremities. Here may be named Atkinson's "case of multiple cutaneous ulceration," ending in recovery, where the lesions of hands, arms, feet, and legs began with pruritus, anæsthesia, papulation, and vesiculation, and terminated in ulceration and loss of phalanges. In this case there were also buccal and labial ulcerations. Here, also, should be in-

cluded Smith's cases of "multiple cachectic gangrene," beginning with vesiculation and ascribed by the author to the occurrence of thrombosis, even though congenital syphilis was present in the two children. The cases reported by Eichhoff and Cæsar Boeck, cited by Dr. Atkinson as closely related to his, seem to me to have no such connection. Weiss accurately describes these conditions in discussing Raynaud's disease, referring them to a central neurosis, "involving symmetrical (for the most part) portions of the hands and feet (phalanges), more rarely other regions of the body, in gangrene of a peculiar character." One French author does not hesitate to set in the same category the symmetrical gangrenous affections of the feet occurring in the senile condition.

In a fourth and last group, may be collected the fatal cases, those fatal by reason of a gravity of the general pathological condition, aside from any septicæmia or other cause originating in local disease of the extremities. Here may be cited Hutchinson's "form of inflammation of the lips and mouth, which sometimes ends fatally, and is usually attended by some disease of the skin." Here we find reported, as in other of the grave cases, the same changes in the nails and symmetrical involvement of the hands and feet. In this group also the cases observed by neurologists may be included, which embrace Charcot's disease (pied tabétique); and a series of grave disorders, such as progressive posterior spinal sclerosis betrayed in hand and foot ulcerations.

Surveying this rather formidable category of symptoms, we find the widest divergence among authors as to their etiology and mutual dependence. One discovers an absence of the axis-cylinder in a nerve; another, thickening of the neurilemma; another describes evidences of arterial disease; yet another, explains an increase of endoneurium, by the results of pressure upon the hands and feet.

Kaposi, in the latest edition of his work, explains some of these cases by paralysis of the vaso-constrictors; some, by the occurrence of thrombosis. Others find the motor nerves intact and the sensory nerves only diseased. Hereditary influences, tuberculosis, and spinal injury, have been held to explain some cases. Duplay and Moret account for another case by discovering a hydatid cyst compressing the scrotum. Some have observed the disease only in women; and Ogston and Baker are inclined to this view. Treves and Fox, of New York, are on record as pronouncing some of them "purely local" manifestations. No more striking illustration of the purely neurotic origin of some of these cases can be cited than the interesting symptoms observed by Tilden, after injury to the median nerve of one side.

If we can agree that these phenomena are, from first to last, in some way related, we have taken at least one step forward. On this point it seems to me that most can agree. Bromidrosis, vesiculation, papulation, ulceration, hypertrichosis, alopecia, hyperidrosis, tylosis, onychauxis, or (if the name be preferred) distrophia unguium—these are certainly multiform symptoms, but they are, several of them, displayed in the immense majority of all cases grouped in the four classes described above. The most conspicuous likeness between them all is that, with few and usually grave exceptions, they are limited to the hands and feet, and the regions nearest those organs, such as the wrists, ankles, forearms, and legs.

Now there are few strictly regional affections of the body characterized by marked multiformity of symptoms. In syphilis, for example, the multiformity is remarkable, but never limited to one organ or set of organs.

In view of these considerations, the suspicion arises that, whether always of strictly trophoneurotic or vaso motor origin, the key to these resemblances and the link which connects them, is their distinctly regional limitation. They are all hand and foot diseases. These organs are farthest removed from the great centres of nervous and vascular force. They are also to a far greater extent than any portions of the body, subject to the important influences of the force of gravity and the effects of friction. Further, in any attempt at explaining some of this long series of symptoms, we cannot forget anatomical peculiarities of those organs possessing a striking significance. For example, Hoyer has shown that capillaries springing from the arteries, empty directly into lacuna like veins in the nail-bed. This is a provision undoubtedly intended to furnish a safety-valve for occasions of temporarily increased vascular pressure, as for example, when the hand is constricted in toil; and its working even in severe paroxysmal asthma is visible to the naked eye.

In brief, admitting all that Atkin says, in the sentence quoted at the outset of this discussion, relative to the imperfect knowledge of the pathology of this disorder, or this group of many symptoms, I have striven to call attention to the fact that regional limitations may explain some of the obscurity which has hitherto invested the subject. We shall, for example, search in vain for the name of any disease whose pathology will explain the chain of symptoms that has resulted in a given scar on a man's leg. But the mind so readily replaces the links that satisfy our conception of the case, that we follow its connections no farther. First came a venous enlargement, whether from traumatism, from pressure effects, or from causes unknown to us, operating on one leg and not another. Then followed an *eczema e venis varicosis*; then an ulcer; then cicatrization; and lastly, deep pigmentation in the periphery. We may not demand for these diseases of the hand and of the foot the same links of the self-same chain. We may, however, look to see some of their phenomena explained by as simple a process of reasoning.

NOTES ON THE USE OF MEDICATED RUBBER PLASTERS IN CERTAIN CUTANEOUS DISEASES.[1]

By HENRY W. STELWAGON, M.D.,

PHYSICIAN TO THE PHILADELPHIA DISPENSARY FOR SKIN DISEASES, AND TO THE DEPARTMENT FOR SKIN DISEASES OF THE PHILADELPHIA AND HOWARD HOSPITALS.

During the past few years the subject of fixed dressings in the treatment of skin diseases has received considerable attention, and as a result, important therapeutic advances have been made. To-day the gelatin, collodion, gutta-percha solution, and similar dressings are widely employed and in some instances seem indispensable. Unna's plasters belong among this class of applications, and are excellently made and efficient, but unfortunately are in this country expensive and difficult to obtain.

About a year ago the idea of incorporating medicaments in the well-known rubber plaster suggested itself, and at my solicitation, the manufacturers, Seabury & Johnson,[2] kindly made a number of plasters —containing pyrogallic acid, salicylic acid, chrysarobin, ammoniated mercury, and oxide of zinc. They were remarkably adhesive, and when once applied would remain several days or even weeks. At the time the plasters were sent me, duplicates were forwarded, so I have been informed, to several other gentlemen interested in dermatological practice, of whom one or two have already reported on their use. While these plasters are an addition to our means of treating special cases, it must be admitted that as at present manufactured their use is somewhat limited. They are not adapted for acute and subacute cases. In this respect they are inferior to Unna's plasters referred to. The manufacturers show every disposition to perfect them, and doubtless in a short time these plasters will be found all that is desired. Their special field, according to my experience, is chiefly in the treatment of chronic, sluggish cases of eczema, in the larger patches of psoriasis, in ringworm of the scalp, in callosities, and in lupus and epithelioma. In these diseases, so far as my observations have gone, the sample plasters sent me have been of positive value.

In several cases of chronic papular and scaly eczema, in which the disease was limited to one or two palm-sized patches, a plaster containing twenty per cent. of ammoniated mercury was employed; the results were satisfactory. A single plaster would remain on for one or two weeks without loosening, a renewal being made about every ten days. The parts became gradually paler and the infiltration disappeared.

In psoriasis, in the large thickened chronic patches, chrysarobin plaster acts admirably. The scales are first removed by washing, the plaster cut to fit the patches and applied. As a rule, it remains adherent a week, and should then be removed, the parts washed and a fresh plaster applied. In the several cases of this disease in which it was employed, the objectionable properties of the remedy as ordinarily used, were not observed. In a few instances a single application of the plaster was sufficient to promote the disappearance of the diseased area, but in others a second and even third application became necessary. In those cases in which the disease is more or less general, and the spots small, the plaster treatment is not practicable; but in those instances where the disease persists in several large, inveterate patches it proves particularly useful. Chrysarobin plaster is serviceable, also, in ringworm. In three cases of ringworm of the scalp, in which the affection existed as two or three well-defined areas, the plaster was used with favorable results. The hair on and surrounding the diseased patch was removed by shaving, and the plaster applied. A renewal was made every week or ten days, the diseased stumps coming away with the old plaster. After six to eight weeks' treatment the disease seemed at an end, and the applications were discontinued; several months later, in two of the cases at least there had been no return, the third case failing to report.

A plaster of salicylic acid, ten to twenty per cent. was found of advantage in callosities. In one case in which both soles were involved to a marked degree, the condition was removed in a few weeks. The plaster remained adherent for a week without renewal. In certain cases of lupus the advantages of a fixed dressing are evident. In two suitable cases a pyrogallic acid plaster, twenty per cent., was applied, a renewal being made every third or fourth day. The result in these instances was equal to that obtained from the use of a pyrogallic acid ointment, without the additional trouble and uncleanliness of the salve applications.

The same may be said of the use of this plaster in the treatment of certain cases of epithelioma. In this disease, as well as in lupus, where the action of

[1] Read at the eleventh annual meeting of the American Dermatological Association, September 1, 1887.

[2] These plasters are equally well made by Johnson & Johnson; their samples sent me, I have since used with good results.

the remedy is necessarily destructive, the plaster must be renewed at frequent intervals.

Without additional comment, the advantages of these plasters may be briefly expressed in the words cleanliness, simplicity, and saving of time and trouble. As already intimated, while their field of usefulness is at present somewhat restricted, it may be expected that as the various plasters are finally perfected and made to meet the requirements, their therapeutic application will be considerably broadened.

1421 SPRUCE STREET, PHILADELPHIA.

ANTIFEBRIN IN TYPHOID OR ENTERIC FEVER.

BY J. SOLIS COHEN, M.D.,
PHYSICIAN TO GERMAN HOSPITAL, PHILADELPHIA.

THE alleged superiority of antifebrin over antipyrin in reducing excessive temperature without injury, led me to employ it during my present term of service in the German Hospital. The few attempts made to reduce high temperature in enteric fever, herewith recorded, present it as a much more dangerous agent than I have found antipyrin to be in a very extensive experience with that agent.

So powerful an agent has antifebrin proved in the few cases in which I have used it, that, as will be seen, three grains, or even one, will effect very decided results on temperature.

The inference is that small doses should be prescribed, say three grains, and that the patient should be visited at the end of an hour and examined as to the reduction of temperature before a second dose is administered; similar precaution being taken as to ordering a third dose; and that when the influence is seen to be marked, subsequent doses should not exceed one grain. The dose usually recommended has been eight grains. This has been far too large in my hands.

Temperature records are appended, illustrating the effect of antifebrin, and showing a remarkable and rapid return of high temperature after initial reduction, with subsequent reduction, and rebound next day without further administration of the drug.

Recent numbers of foreign journals, received since my own observations have been made, contain cautions as to the use of antifebrin, from experience similar to my own.

I append notes of examples of the effects of antifebrin, manufactured by Merck, on cases of enteric fever:

CASE I.—Boy, aged seventeen. Ninth day of disease, temp. 103.6°. Seven grains *antifebrin given at* 5 P.M., *and repeated in one hour.* Effect: *1st day* of antifebrin, 6 P.M., temp. 103.2°; 8 P.M., 98°; 9 P.M., 96.4°; 12 midnight, 97°. *2d day*, 4 A.M., 102.6°; 6 A.M., 103°; 8 A.M., 103°; 9 P.M., 96°; 10 P.M., 97.4°. *3d day*, 2 A.M., 102.2°; 7 A.M., 102.8°; 7 P.M., 104.8°. *five grains antifebrin given:* 8 P.M., 101.2°; 10 P.M., 99°; 12 midnight, 101.6°. *4th day*, 4 A.M., 104.2°; 8 A.M., 102.8°; 7 P.M., 103.8°, *three grains antifebrin given;* 10 P.M., 98°; 12 mid night, 98.4°. *5th day*, 4 A.M., 104.8°; 7 A.M., 101.2°. Orders to discontinue antifebrin and resume routine treatment of the ward.

CASE II.—Married woman, aged twenty-two. Fourth day of disease. Evening temp., 100.4°; fifth day, *first day of antifebrin*, 7 P.M., temp. 103°, *three grains antifebrin given;* 8 P.M., 98°; 10 P.M., 96°. *2d day*, 2 A.M., 98°; 4 A.M., 95°; 6 A.M., 98°; 8 A.M., 102°; 7 P.M., 99°. *3d day*, 8 A.M., 96.6°; 8 P.M., 103.8°, *one grain antifebrin given;* 9 P.M., 99°; 12 midnight, 98°. *4th day*, 4 A.M., 99°; 7 A.M., 103°; 5 P.M., 103°. *5th day*, 6 A.M., 98°; 5 P.M., 100°.

CASE III.—Boy, aged nineteen. Temp. 5 P.M., 103°. *five grains antifebrin given:* 8 P.M., 101.4°; 9 P.M., 100°; 10 P.M., 97.6°. *2d day*, 2 A.M., 99.2°; 7 A.M., 99.8°; 7 P.M., 102.8°. *3d day*, 7 A.M., 100°; 5 P.M., 102.6°.

CASE IV.—This was a case of so-called recurrent typhoid, reëntering the hospital: 7 P.M., 104.8°; *three grains antifebrin given;* 10 P.M., 100.2°; 12 midnight, 103.2°. *2d day*, 4 A.M., 102°; 7 A.M., 103.8°; 5 P.M., 103 6°.

CASE V.—Temp. 8 P.M., 104.2°, *one grain of antifebrin given:* 10 P.M., 104°; 12 midnight, 104°; *two grains antifebrin given:* 2 A.M., 102.8°; 8 A.M., 102.8°; 5 P.M., 102°.

HOSPITAL NOTES.

PHILADELPHIA HOSPITAL.

Service of BARTON C. HIRST, M.D.

HIGH GRADE OF RACHITIC PELVIS; LABOR INDUCED; PRESENTATION OF TRUNK; COMBINED VERSION BY THE HEAD; SUCCESSFUL DELIVERY BY THE POULLET-V. HECKER FORCEPS.

(Reported by RICHARD C. NORRIS, M.D., Resident Physician.)

M. H., aged twenty-two years, colored, II-para, was admitted to the hospital with a history of having ended her last menstrual period on December 1, 1886. The customary examination with pelvimeter was made, and the following diameters were noted: Iliac spines, 20½ cm.; iliac crests, 23½ cm.; external conjugate, Baudelocque, 18 cm.; internal conjugate, diagonal, 10 cm.; true conjugate, estimated, 8 cm. Vaginal examination; pelvis smooth; promontory well marked and sharply defined. Husband of patient brawny and large-boned. Abdominal palpation showed the child to be well developed in size, occupying a transverse position, the breech somewhat lower and to the left. Fœtal heart sounds could not be heard, the left side being low down.

Induction of labor was proposed, and consented to. On July 28th a solid, flexible, hard-rubber bougie, No. 12, was inserted between the posterior uterine wall and the membranes, and pushed obliquely upward, toward the left about six inches, and allowed to remain. Twenty-four hours later the os had softened somewhat, and a second bougie, No. 17, was similarly introduced, and both allowed to remain twelve hours longer. At this time the os was slightly dilated, and quite soft. The pains had not been at all marked. Barnes's dilators (three sizes) were then introduced at short intervals, and the cervix well dilated. The membranes were then

ruptured, and an attempt was made at the same time to convert into a breech by external manipulation. This failed. The patient was etherized, and combined version by the head to left occipito-anterior position was followed by the application of the Poullet_v. Hecker forceps. The head was soon brought below the brim of the pelvis, and the delivery was then completed with Simpson's forceps.

Throughout the management of the case there was a striking absence of uterine contractions. The child is quite vigorous, weighs five pounds and six ounces, is seventeen inches in length, and has the following measurements of the head: Bitemp., 7 cm.; biparietal, 8¼ cm.; occip. frontal, 10½ cm.; occip. mental, 12 cm.; trachelo-bregm., 8 cm.; circumference occip. frontal, 31 cm.; circumference trachelo-bregm., 29¼ cm.

The mother recovered with no bad symptoms, and at this time (seventh day) has had no elevation of temperature, pain, tenderness, or discharge, and promises a speedy convalescence.

MEDICAL PROGRESS.

The Influence of Antifebrin, Salicylic Acid, and Carbolic Acid on Bodily Temperature.—Dr. Hare, in a series of researches reported in the *Therapeutic Gazette* for June, July, and August, 1887, reaches the following conclusions:

1. *Antifebrin* effects *marked* depression of normal bodily temperature.

2. During the depressing action of antifebrin on normal temperature it seems to cause a slight fall in arterial pressure, although this is by no means a constant result, as it may cause a rise.

In the opinion of the writer, however, this drug in lowering temperature acts as an arterial sedative.

3. Notwithstanding the fact that antifebrin influences to such a marked degree normal bodily heat, it seems to possess little power against the pyrexia produced by the introduction of pepsin into the blood, since under these circumstances the hitherto depressed pressure rises, as does also the bodily heat.

This curious fact must depend on some organic changes produced by the digestive ferment.

4. This drug reduces *normal* temperature apparently by influencing both production and dissipation.

5. Antifebrin in fever chiefly reduces the high temperature by decreasing heat production, and is, therefore, a valuable antipyretic.

1. *Salicylic acid* has the power to reduce slightly normal bodily heat.

2. *Salicylic acid*, according to the writer's experiments, has but little power over pyretic temperature.

3. *Salicylic acid*, when acting on either normal or abnormal temperature, does not seem to have much influence on the circulation either in regard to pulse-rate or arterial pressure. Any change, when it occurs, seems to be an increase of arterial pressure rather than a decrease, and this increase occurred more markedly in the normal than in the pyretic animal.

4. *Salicylic acid*, in reducing normal temperature, probably acts on both functions, namely, production and dissipation, while it seems to act very uncertainly and irregularly when reducing high temperature, failing frequently, as before stated, to prevent an increase of bodily heat.

1. *Carbolic acid* possesses considerable power in lowering normal bodily temperature.

2. It possesses more influence over pyretic temperature than does salicylic acid, generally preventing a rise or causing a fall of temperature, but sometimes failing to do so.

3. *Carbolic acid* probably decreases arterial pressure when lowering temperature.

4. That its mode of decreasing normal bodily temperature is as yet not fully understood, although it would seem probable that it acts on both heat functions.

5. When influencing bodily heat in fever it acts chiefly by decreasing production, although it affects both functions.

The Treatment of Abortion for Three Years in the Obstetrical Clinic of Florence.—Fasala has observed the following rules in the treatment of abortion, with good results:

1. An expectant course is pursued when the cervix uteri is closed, and can be dilated with difficulty, and if no signs of the decomposition of the fœtus are present.

2. Under conditions favorable for the introduction of instruments or the hand, the ovum and its appendages are promptly removed.

3. If decomposition has begun, the cervix is dilated by laminaria tents or metallic dilators, and the ovum is removed.

4. Intra-uterine injections for antisepsis are made with warm solutions of bichloride of mercury, 1 to 2000; in case of hemorrhage, hot solution of bichloride of mercury, 1 to 4000, and tamponing the vagina, are used.—*Annali di Obstetricia*, March, 1887.

Antipyrin in Scarlatina and Bronchitis among Children.—Friedländer, of Russia, reports fourteen cases of scarlatina, all of whom recovered under the use of antipyrin in doses of nine grains once to three times in twenty-four hours. Profuse perspiration, fall of temperature, and in nearly all cases refreshing sleep of two hours, followed the use of the drug. The dosage was according to age, the maximum dose is that stated. In acute bronchitis nine grains of antipyrin sufficed to influence children under two years of age favorably for twenty hours; while thirteen grains, with children under five years of age, were sufficient to lower temperature for twelve or fifteen hours; this dose was generally given twice in twenty-four hours. Profuse perspiration, lessened cough, sleep, and general improvement followed. During convalescence, half the doses given during the height of the disease were used. In addition, the following was found useful:

℞—Caffein . . . . gr. $\frac{5}{6}$ to gr. 3.
Sodii bicarb. . . . gr. 23 to gr. 45.
Aquæ fœniculi . . 3 15.
Syr. ipecac $\bar{a}\bar{a}$. . . 3 7½—M.

Sig.—One-half to one teaspoonful every half hour or every two hours.—*Therapeutische Monatshefte*, August, 1887.

The Action of Tobacco.—Recent observations by Russian experimenters have resulted in the following

conclusions. The assimilation of nitrogenous matter is lessened by tobacco. Digestion is prolonged. The assimilation and elimination of potassium iodide was accelerated by smoking. The influence of tobacco is most marked at the commencement of its use. The examination of 1000 workers in tobacco, compared with a series of control experiments on animals, resulted in finding among the workmen dilatation of the pupils; cardiac neuroses; exaggerated tendon and vasomotor reflexes; trembling hands; dyspnœa. Headache, gastralgia, cramps, and nervous cough, were also present. The respiratory organs were most frequently attacked after the nervous system.

Phthisis was not especially frequent.

The same symptoms were produced by injecting $\frac{1}{10}$th to $\frac{1}{5}$th of a drop of nicotine in rabbits, $\frac{1}{20}$th to $\frac{1}{10}$ of a drop in dogs, and keeping them also in a tobacco-impregnated atmosphere.—*Bulletin Général de Thérapeutique*, July 15, 1887.

SPLENOTOMY FOR LEUCOCYTHÆMIA.—DR. STRONG reports in the *Western Medical Reporter* of September 15, 1887, the removal of a leucocythemic spleen weighing nine pounds nine ounces. The spleen was freely movable, no adhesions to the abdominal wall or intestines existing; the tail of the pancreas was so firmly united to the hilus of the spleen that no attempt was made to separate it, it was ligated with the pedicle of the splenic tumor. The greater curvature of the stomach was adherent to the spleen and was separated, and from this surface blood oozed persistently.

The patient died four hours after the operation from hemorrhage from the adherent surfaces which had been separated. Microscopic examination of the blood before operation showed a leucocythemia of 50 per cent.

PHOSPHATE OF COPPER IN THE TREATMENT OF PHTHISIS PULMONALIS.—The following formulæ have been employed by LUTON, of Reims, and are reported by him in the *Revue Générale de Clinique et de Thérapeutique* of September 8, 1887:

℞.—Cupri acetat. neut. . . . gr. ½.
Sodii phosphat. cryst. . . . gr. ¾.
Liquiritiæ pulv.
Glycerin. . . . . aa q. s.—M.

For each pill.

Also,

℞.—Cupri acetat. neutral . . . gr. ½.
Sodii phosphat. crystal. . . gr. 8½.
Mucilag. acaciæ.
Aquæ . . . . . ℥ss.—M.

Sig.—Dose, a teaspoonful as indicated.
For hypodermatic use.

℞.—Cupri phosphat. (newly precipitated) . . . . . 1 part.
Glycerin.
Aquæ dest. . . . . aa 2½ parts.

To be mixed at the moment of administration.

PHYSIOLOGICAL PROPERTIES OF ACETO-PHENETIDINE.—HINGSBERG and KEST are quoted by the *Centralblatt für die medicinischen Wissenschaften*, No. 9, 1887, in reporting their experiments with this substance as follows: It is a derivative of anido-phenol, crystalline, very soluble in ether and acetic acid, less soluble in water. Doses of 15 to 30 grains produced no physiological effects upon dogs. From 45 to 75 grains produced respiratory paralysis, vomiting, stupor, and cyanosis, which disappeared after a few hours. When used as an antipyretic a dose of 8 grains lowered temperature several degrees in three or four hours, producing moderate transpiration without collapse or cyanosis. Arterial tension was increased. The urine of animals which took this substance was colored yellow; when hydrochloric acid was added the urinary salts were precipitated. Salts of copper were reduced, and polarization to the left occurred. The substance is an analogue of antifebrin, which it resembles.

A SUCCESSFUL NEPHRORRHAPHY.—DR. LLOYD reports in the *Practitioner* for September, 1887, his method of operating in a recent successful case as follows:

I purposely stripped off a portion of the capsule over an area one inch in diameter, and then secured the kidney to the lumbar tissues by carrying two stout catgut sutures, by means of a medium-sized curved needle, through the skin, fascia, and muscles, then entering the proper capsule and kidney substance close to one edge of the exposed area, passing completely across and beneath this area to emerge at a point corresponding to that of its entry on the opposite side, and then returning to the surface through muscles, fascia, and skin. A stout drainage tube was inserted down to the kidney. The lips of the wound were closed with deep silver sutures, and finally the transfixing gut ligatures were securely tied, thus bolting up the raw kidney surface to the deeper end of the wound through the soft parts. After several months the result is perfectly satisfactory: the organ which formerly "jumped" from the loin on to the front of the lowest lumbar vertebra, each time the patient tilted toward the opposite side, is now firmly at anchor and free from the slightest movement. This methodical excision of kidney capsule is, I believe, novel, and appears to have certain advantages over other procedures. Adhesions forming from the more lowly organized fibrous tissue of the kidney capsule are less abundant than those which will develop when the more highly organized kidney substance is concerned. Again, there usually remains a certain thickness of delicate connective tissue mesh about the capsule after we look upon it as being quite bared, and it is to this loose tissue that the connecting fibres will often form attachments. This delicate intervening layer may subsequently stretch indefinitely, just as it has done before to allow of that mobility to remedy which the operation is performed. When, on the other hand, the kidney substance is uncovered, there can be no doubt that the resulting scar will be incorporated with the organ we wish to secure, and not merely with a layer of yielding tissue around it. The kind of cicatrix we desire in nephrorrhaphy is like that which results from certain diseases attended by loss of bone substance.

HOT WATER ENEMATA.—TRIPIER, of Lyons, has obtained excellent results with enemata of very hot water in rectal and vesical tenesmus in those afflicted with locomotor ataxia, and also lead colic. His results

were especially striking with dyspeptic patients. For children from eight drachms to one ounce was used; for adults, a quart; the temperature of the water was from 113° to 118° F.—*Journal de Médecine*, July 31, 1887.

Mydriatics and Their Uses.—Dr. Jackson, of Philadelphia, is quoted as follows by the *Ophthalmic Review* for August, 1887, on this subject:

Simply to dilate the normal pupil, a single drop of either of the following solutions suffices:

Cocaine hydrochlorate, gr. j, water, ♏ xxv,
or about 1 to 25;
Homatropine hydrobromate, gr. j, water, f℥j,
or about 1 to 500;
Atropine sulphate, gr. j, water, f℥v,
or about 1 to 2500;
Duboisine sulphate, gr. j, water, f℥x,
or about 1 to 5000;

or daturine, hyoscyamine, or hyoscine salts used of the same strength as duboisine.

Of the above the homatropine solution renders the pupil rather the most rigid, and its effects pass off in from twenty to fifty hours, but *cocaine is the most generally valuable dilator of the pupil*. The dilatation it produces lasts but ten or twenty hours, is never so great in strong as in feeble light, so that there is less annoyance from exposure to the light; it produces proportionately the smallest impairment of accommodation; and the dilatation it produces can be promptly overcome by the use of eserine, making it especially valuable after middle life, when there is a chance of the occurrence of glaucoma. And this drug has yet another advantage. In spite of the readiness with which it yields to myotics, in spite of its inability to prevent entirely the reaction to bright light, tested in a weak or moderate light, *cocaine produces a wider dilatation of the pupil than any other mydriatic*. And this superior power of cocaine is especially manifest in old people, whose pupils often do not dilate well under other mydriatics.

To paralyze the accommodation completely, from two to five instillations of a drop of either of the following solutions usually suffice:

Homatropine hydrobromate, gr. x, water, f℥j,
or about 1 to 50;
Atropine sulphate, gr. iv, water, f℥i,
or about 1 to 120;
Duboisine sulphate, gr. ij, water, f℥j,
or about 1 to 240;

or daturine, hyoscyamine, or hyoscine in the same strength as duboisine. Homatropine should be instilled at intervals of from five to fifteen minutes; with the other mydriatics, to avoid constitutional effects, the intervals must be much longer. Cocaine in any strength cannot, in most cases, completely control the accommodation.

Of the above, for diagnostic purposes, homatropine is to be preferred. It reduces to a minimum the period of disability for eye work, recovery from it being nearly complete in from thirty-six to forty-eight hours against five or six days for duboisine or ten or twelve days for atropine. It causes no noticeable or distressing symptoms, like the dryness of the throat, flushing of the surface, incoördination of motion, or even delirium, which are liable to follow the use of the other mydriatics, although it does usually to some extent influence the action of the heart.

Nasal Croup.—Hartmann, of Berlin, reports six cases of this affection which occurred epidemically in children between three and nine years old. The disease pursued a mild course, becoming a simple nasal catarrh in from eight to fourteen days. Treatment was removal of the membrane by cotton, and the free use of iodoform in powder.—*Deutsche medicinische Wochenschrift*, July 21, 1887.

Abdominal Gestation; Operation; Recovery.—Takaki, a Japanese Surgeon, reports in the *Sei-I-Kwai Journal* for July, 1887, the case of a multipara, aged twenty-eight, who gave a history of irregular discharges from the uterus, abdominal pain, and the presence of a tumor. On examination, a tumor was found on each side of the abdomen below the umbilicus. They were elastic, painless, and not connected with the uterus. Aspiration of the left tumor gave blood; of the right fluid resembling ovarian fluid. On opening the abdomen, encysted abdominal pregnancy was found. The fœtus and appendages, the sac and its adhesions were removed, the abdomen disinfected, and closed by deep and superficial stitches. Recovery followed in fifteen days. The partially disorganized fœtus weighed about one and a quarter pounds.

Treatment of Pediculi.—Vartanian, of Constantinople, has had excellent results in the destruction of these parasites by frictions with flannel dipped in the following:

Acid salicylic	2 to 3 parts.
Vinegar	25 "
Alcohol (80°)	75 "

—*Revue de Clinique et de Thérapeutique*, July 28, 1887.

Disinfection of Typhoid Stools with Boiling Water.—Wiltschur, in the *Vratch*, No. 26, 1887, has tested the action of boiling water upon cultures of typhoid bacilli and found that twice the volume of boiling water will destroy bacilli, and three times their volume will destroy spores of the bacilli. In experimenting upon typhoid stools he found that from two and a half to three volumes of boiling water destroyed bacilli in stools, and four volumes were sufficient to destroy their spores.

The Effect of Antifebrin upon the Blood.—Henocque reported at a recent meeting of the Society of Biology of Paris, his observations on the blood of animals intoxicated with antifebrin. The change of oxyhæmoglobin to methæmoglobin is the phenomenon observed. In the human subject, while therapeutic quantities of from 15 grains to 50 grains daily are used this change is only observed when cyanosis supervenes. The quantity of oxyhæmoglobin must have been reduced to 6 5 per cent. before the line characteristic of methæmoglobin is seen in the spectroscope. Clinically this condition may be diagnosed by observing the capillaries of the thumb. When in those vessels the percentage becomes eight it is indicated that the activity

of nutritive processes is much lessened, and the drug should not be used continuously.—*Revue Générale de Clinique et de Thérapeutique*, August 4, 1887.

CALOMEL, HYPODERMATICALLY.—SMIRNOFF, of Vienna, proposes a mixture of one part calomel and ten parts glycerine, which he puts in dark glass bottles, tightly stoppered with glass, each containing thirty grains of calomel and five drachms of glycerine. When required for use, the bottle is to be thoroughly shaken, and the hypodermatic syringe introduced through the wide mouth.—*Therapeutische Monatshefte*, August, 1887.

TREATMENT OF SCARLET FEVER.—The *Lancet* of September 3d, states that the present epidemic in London is, for the most part, of a mild nature, but considerable attention has to be given to the throat, which seems to suffer in a marked degree, the glandular swelling being correspondingly marked. Hence it will be found that gargles of all kinds, and especially those of an antiseptic nature, are freely used, together with compresses of various degrees of heat and moisture applied to the neck. Most practitioners, even those of the most expectant schools, employ topical applications to the throat and nose. Many articles are used to relieve the thirst and sensation of dryness, but nothing is more effective than ice and a little raspberry vinegar. It is important to keep the nostrils and nasal passages sweet and clean. For cerebral symptoms, nothing is better than the application of cold, either in the mild form of lint soaked in iced water and applied to the shaven head, or in the more effective capilline tubes, with irrigation. Compression of the carotid arteries and bleeding are seldom practised nowadays, either in scarlet or any other fever. Aconite in minute doses, frequently repeated, is still the favorite drug of many practitioners, but its employment needs the exercise of clinical discretion, especially in children. Actual bathing in cool or tepid water is practised by but few physicians, though the number of practitioners who recommend the use of cold or tepid sponging, the patient lying in bed on a mackintosh, appears to be largely on the increase. Most of the alleged specific and curative agents have long since lapsed into discredit. Belladonna finds but few adherents, and carbonate of ammonia almost none. Considerable difference of opinion exists on the merits of inunction with fat, cold cream, and the like, two of the most recent authors on the diseases of children taking opposite views, DR. GOODHART advocating and DR. ANGEL MONEY opposing universal inunction, though the latter sees no objection to relieving the tension of the palms and soles by the application of geoline or vaseline scented with eucalyptol.

TERPINOL IN PILLS AND CAPSULES.—The following formulæ are advised by RABOW in the *Therapeutische Monatshefte* for August, 1887:

℞—Terpinol.
Ammon. benzoat.,
Ceræ flav.,
Mass. pil. . . . . āā ʒ 2½.
Mucilag. tragacanth. . . q. s.
Fiant pil. 100 in num.

Terpinol may be given in capsules as follows:

℞—Terpinol.
Sodu ben. . . . . āā gr. 15.
Sacch. alb. . . . . q. s.
For ten capsules.

Sig.—One pill or capsule every one or two hours.

HYPODERMATIC INJECTIONS OF SOLUTIONS OF MARINE SALT FOR ANÆMIA.—HEGAR has obtained good results from the injection of a solution of 6 to 1000 of marine salt, pure and recrystallized, in anæmia. Sphygmographic tracings showed an improved condition of the circulation.—*Revue de Thérapeutique*, August, 1887.

THE BEST SUTURE MATERIAL.—VEIT, of Berlin, in an article in the *Therapeutische Monatshefte* for August, 1887, decides in favor of catgut, concluding that the healing of the wound does not depend upon the suture material used, but upon its antiseptic condition, and this is more easily secured with catgut than with silk; every physician can easily possess antiseptic catgut, and its absorption when allowed to remain in the tissues, is also greatly in its favor.

ODONTALGIA OR NEURALGIA?—The great difficulty occasionally experienced in diagnosticating whether neuralgic pain of the fifth nerve is due to peripheral irritation from disease of the teeth or to some affection of the nerve trunk, made PROF. VICTOR HORSLEY'S paper on this subject at the Odontological Society of considerable interest, especially to dental surgeons. The principal points of distinction may be summed up under the following heads: 1. Trophic changes, such as muscular wasting in the parts to which the pain is referred, chronic congestion, or alternating dilatation and constriction of the bloodvessels, point to mischief in the trunk of the nerve. 2. Alterations in sensation, anæsthesia or hyperæsthesia of the skin, especially when gently touching the skin causes extreme pain, while firm pressure causes no pain at all, are, he believes, never due to dental irritation. 3. The origin and character of the pain are sometimes useful as a means of diagnosticating the two conditions. When the pain begins in the skin or bone, and subsequently is referred to the teeth, the probability is that the lesion is in the nerve trunk; if it is stated to begin in the teeth, it may or may not be due to them. Professor Horsley expressed the view that *constant* pain is in most cases of peripheral origin, whereas intermittent pain is due to trouble nearer the nerve centre; but this is opposed to the experience of most dental surgeons, intermittent pain being a frequent accompaniment of dental disease. Lastly, the existence of "tender spots" along the course of the nerve or its branches, is generally an indication of irritation along the whole course of the nerve, but occasionally occurs in cases of peripheral irritation.—*Lancet*, September 3, 1887.

FIBRINOUS PNEUMONIA.—CASPAR, of Greifenberg, derives the following conclusions from the study of twenty cases occurring in his practice, and a review of the literature of the subject:

Fibrinous pneumonia is an infectious disease; contagious; having an incubation period of generally four days. Low temperatures, moisture, and strong winds, favor its inception and spread.—*Berliner klinische Wochenschrift*, July 25, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, OCTOBER 8, 1887.

THE VALUE OF THE SULPHATE OF SPARTEINE.

WITHIN the last year or two this drug has been tested both by the bedside and in the laboratory by so many observers that we have at the present time a large mass of literature concerning it. But little investigation as to its influence on the system has been undertaken either in this country or England, by far the greater number of results having been obtained by French or German observers.

Unfortunately these reports have produced such varying and opposite results that the clinician hesitates to use the drug, since, while one writer lauds it to the skies, another may report absolutely negative or untoward effects from its use. MASIUS, of Brussels, has, perhaps, more carefully than any other observer, tested its action from a physiological standpoint, and reaches the following conclusion, that in small doses it does not influence the circulation, in moderate doses it depresses the vagus and accelerates the pulse-rate with a corresponding decrease of the quantity of blood expelled from the heart at each contraction. In poisonous doses it palsies the pneumogastric and produces asphyxia, and in the healthy subject has no influence on the renal excretion. He also believes that the influence of the drug on the heart and kidneys is uncertain and not to be depended upon.

On the other hand, GLUZINSKI in *Fezegad de karski*, No. 1, 1887, and *Vratch*, No. 3, 1887, has obtained results, which in some points are absolutely contradictory to those of Masius. Thus, he found that sparteine slows the heart and increases blood pressure in the first stage after its administration, that in the following stage the pulse may become rapid, while in the third stage the pulse again becomes slow and the pressure high. He explains the secondary condition by imagining some pathological change in the irritability of the vagus or heart muscle, which change only lasts until the advent of the third stage. The third stage is accompanied by failure of respiration, and it is therefore evident that Gluzinski is right in confining the drug's usefulness, as a therapeutic agent, to the first period. He believes it to be less powerful than digitalis, but more rapid in its action.

The researches of VOIGT and LEO are equally contradictory. The former found that sparteine in the dose of $\frac{1}{65}$ to $\frac{2}{85}$ of a grain stimulated the heart, increased its contractions, and raised the blood-pressure. He does not think it, however, a diuretic of the first rank. He would recommend its use in valvular disease with failing compensation, or in those cases where compensation being complete the heart needs a tonic and sedative, and also in the palpitation of "weak heart" without valvular disease. Lastly, he recommends its use in pericarditis and as an adjuvant to digitalis. Leo, who, in comparison with Voigt, gave enormous doses of the drug (as much as one and a half grains) reached favorable results in only nine out of twenty-four cases, and in these nine, objective improvement was scarcely noticeable. In eight others subjective improvement occurred, while in seven no result whatever was obtained.

In Leo's hands the drug did not increase the blood-pressure materially, but did, in some cases, increase diuresis. Here, again, Leo's results clash with those of GERMAIN SÉE, who places sparteine and digitalis side by side, as increasing arterial tension. Notwithstanding the large doses used, he observed no toxic effects.

In the *Berliner klin. Wochenschrift* of September 5, 1887, DR. PRIOR contributes quite an exhaustive article on this drug, in which he states that sparteine regulates the pulse-rate, induces diuresis, and is free from cumulative action. He believes with Leo that it is neither a first-rate diuretic nor cardiac stimulant.

Last of all, we have the paper of DR. CLARKE in the current number of *The American Journal of the Medical Sciences*, in which he reaches the conclusion "that sparteine belongs to the digitalis group." According to this observer, we have in sparteine a remedy for cardiac hypertrophy, of an excessive type, combined with one possessing powerful properties as a cardiac stimulant where the heart is overtaxed, and also a remedy which resembles digitalis, yet increases the rapidity of the pulse. As is well known, cardiac hypertrophy contraindicates digitalis, and digitalis always slows the heart, except in cases of advanced poisoning, and it is, therefore, difficult to determine where the similarity of action exists.

Unfortunately, but little of the confused matter

before the profession can be unravelled, except by further careful research. The varying results of Voigt and Leo, and the doses used by each, certainly show that one of them did not use true sparteine, or else that his specimen of it was most impure. Some of the other discrepancies may be partly set straight by variations in the manner of administration, and like influences, but nevertheless an actual knowledge of the drug scarcely warrants its use unless as an experiment.

INTERMITTENT ALBUMINURIA.

DUBREUILH has contributed to the *Revue de Medicine* for August, a critical study of the subject, from which we learn that sex has an important influence on the etiology, as shown by the occurrence of the condition in forty-nine males out of the fifty-five cases. The majority of the cases were under twenty years of age; sixteen occurred between the ages of sixteen and twenty; only thirteen between the ages of twenty and thirty, and three cases above this age. Three instances are given of the affection in brothers.

The quantity of urine passed is usually normal, the specific gravity rather above the average, ranging from 1.020 to 1.030; the color not very deep, and the reaction acid. There is very commonly an excess of uric acid and oxalates. In typical cases the albumen is not abundant, not exceeding 15 grains to the quart. Heat and nitric acid have been the tests usually employed. In three cases globulin was found, and peptone has also been noted.

The most remarkable feature of this form of albuminuria is the periodicity, whence have been derived the names intermittent and cyclic. In a large proportion of the cases, the urine secreted at night, which is passed on rising, is free from albumen. Before noon, as a rule, the albumen appears, attains its maximum in the afternoon, and diminishes toward evening. In many cases food is quite without influence, in others it seems to play an important role. Exercise, cold, and emotions, particularly mental strain, appear as exciting causes in some of the records. The general condition of those affected may be excellent, and in many instances the discovery has been accidentally made, on the examination for life insurance or for one of the services. In other cases there are headache, lassitude, general feebleness, dyspepsia, and palpitation of the heart. The diagnosis is not difficult in typical cases, the periodicity, the frequent increase by exercise, or food, the absence of tube casts, and of cardio-vascular changes, are sufficient to exclude the various forms of nephritis. The chief difficulty arises in cases of interstitial nephritis, in which, as is well known, the albumen may vary very much, and the nocturnal urine may be almost, or completely, free. The age, and the occurrence of tube casts, and the circulatory changes will be the important guides.

We scarcely know enough about these cases to speak decidedly upon the question of prognosis. For years the health may remain good, but indicating, as the albumen certainly does, either a defective metabolism, or a feebleness of the renal tissue, such patients should exercise special care in food and drink. In some cases the condition has lasted for only a few months, in others for a period of years. No perfectly satisfactory mode of treatment has yet been found, but such tonics as iron and arsenic have proved beneficial in improving the general health, though the albumen may not have been influenced in the slightest degree.

CIRRHOSIS OF THE LIVER IN CHILDREN.

IN the current number of the *American Journal of the Medical Sciences* DR. PALMER HOWARD, of Montreal, presents an elaborate study of this rare condition, based upon two cases occurring in his practice and sixty-one instances recorded in the literature. From this somewhat extensive material we may gather information which throws light on the general etiology of cirrhosis.

Considering the causative relations of the cases analyzed, we find that in 10 the children were addicted to the use of spirits: in 7 there was a clear history of syphilis: in 7, perhaps 8, cases tuberculous disease coexisted: but in more than one half of the cases the etiology was obscure. It is possible, as Botkin originally suggested, that the infectious diseases may originate chronic inflammatory changes in the organs, in proof of which may be cited Klein's discovery of an acute interstitial hepatitis in 8 cases of scarlet fever; but in only 9, of the 38 cases which cannot be referred to any of the established causes, had acute infectious disease preceded, by a longer or shorter interval, the cirrhosis.

For the remaining cases Howard is inclined to favor Budd's suggestion, that the products of faulty digestion and certain stimulating kinds of food conveyed to the liver may excite interstitial hepatitis. Among such products the ptomaines may be important, and it is possible that they may be as irritating, or even more so than alcohol. Unquestionably in cirrhosis we must take into account the special constitution—the personal equation, so to speak—of the liver tissue. How resistant it may be to the injurious effects of alcohol, after years of exposure in some instances, how vulnerable in others! In certain children, a rich, stimulating diet may act injuriously, as alcohol, on an organ constitutionally prone to interstitial change. That such a tissue weakness may exist is suggested by the occasional

occurrence, as in Howard's cases, of the disease in members of the same family.

Of the character of the cirrhosis in the 50 non-syphilitic cases, in 19 the organ was atrophic, in 13 hypertrophied, in 6 of normal size, and in 16 this point was not mentioned. The symptoms are practically identical with those of cirrhosis in adults. Fever is by no means uncommon, but this occurs in ordinary cirrhosis more frequently than is generally supposed, or taught.

DIVERSE APPLICATIONS OF ANTIPYRIN IN THERAPEUTICS.

In The Medical News of May 28, 1887, we called attention to the results obtained by Germain Sée in the treatment of certain painful neuroses by antipyrin, his original observations being recorded in *L' Union Médicale* of April 26, 1887. Since that time Professor Sée has not been content with so limited a use of the drug, and in the same journal of September 10 and 13, 1887, we find records of the application of the remedy to a very large number of diseased conditions associated with pain. Among these we may mention both acute and chronic articular rheumatism and the acute paroxymal pains of gout, lumbago, sciatica, and the neuritis of ataxics.

In the second division of his paper, Sée records his use of this drug in painful conditions associated with disorders of the viscera, chiefly abdominal. Chief among these are renal and hepatic colic, colic of a gastro-intestinal type, and that associated with the uterus. Passing on, he speaks of its efficacy in the pain of angina pectoris, and of anæmic heart. Finally, he compares it with antifebrin, and gives no small amount of praise to the drug of which he writes. In the *Centralblatt für klinische Medicin*, No. 35, is a paper by Dr. Seifert, of Würzburg, on the same subject, in which he speaks of the value of antipyrin in hemicrania, angina pectoris, and chorea. This writer also speaks very favorably of the drug as used in these conditions. In view of the results so uniformly attained, by observers on the other side of the water, it is a little surprising that reports of its use by American practitioners should be so few and meagre.

Dr. Samuel G. Dixon has been elected Professor of Hygiene in the University of Pennsylvania, to succeed the late Prof. N. Archer Randolph.

Dr. St. John Roosa's *Treatise on the Ear* has been translated into German by Dr. Ludwig Weiss, and will be published early in the coming year by August Hirschwald, of Berlin.

Fourteen of the immigrants who arrived on the steamship "Alesia" a fortnight ago, have died of cholera at the hospital on Swinburne's Island, and there are still ten cases under treatment. The health authorities have had the vessel thoroughly fumigated, and she has been allowed to pass quarantine. Three of the cabin passengers were allowed to come up to New York last Monday.

SOCIETY PROCEEDINGS.

AMERICAN DERMATOLOGICAL ASSOCIATION.

Eleventh Annual Meeting, held in Baltimore, August 31, and September 1 and 2, 1887.

Wednesday, August 31st.—Morning Session.

The Association was called to order by the President, Dr. H. G. Piffard, of New York.

Dr. R. W. Taylor, of New York, read a paper on

THE TOXIC EFFECTS OF IODOFORM.

He reported the details of 24 cases, 9 of which came under his personal observation. 16 of these cases were accompanied by constitutional disturbances while in 9 the rash existed alone without any apparent systemic symptoms. A large number of cases have been reported in which toxic constitutional effects have followed the use of iodoform. It is evident that the toxic effects of iodoform are more frequently manifested by systemic irritation than in cutaneous manifestations.

The skin affections may be classed under the general head of dermatitis, but for the sake of accuracy may be further subdivided according to their relative frequency, into erythema, eczema, and purpuric spots. The erythema due to iodoform may present many of the features of similar eruptions. Its mode of invasion is prompt and extension rapid. It may commence at the point where the application has been made, or other patches of erythema may begin in other parts and extend to meet that from the original point. Erythema may follow from simply smelling the iodoform. The eruption completes its evolution in a few days and under favorable circumstances this eruption rapidly undergoes involution, behaving very much as an ordinary exanthematous eruption. Various forms of erythema have been noted. Sometimes it is very superficial; in other cases it is still superficial but of a deep red hue, and may be termed scarlatiniform. In exceptional cases, usually those presenting grave constitutional symptoms, the erythema presents points of resemblance in hue and brawny feeling to erysipelas. Other cases may be placed under the head of erythema multiforme.

The eczema resulting from the use of iodoform is usually of severe form and rapid evolution, and may begin at the point of application or in parts at a distance. It may also result from simply smelling the drug. Its character is pronounced from the first. A large surface is involved and in all respects it is similar to ordinary eczema malidans. The involution is, as a rule, almost as rapid as the evolution, if the drug is removed. In some instances, however, the eruption shows a tendency to become chronic. It is usually amenable to treatment. Eczema occurred in 9 of the 25 cases reported.

The time of the appearance of the eruption was noted as follows; in 12 cases it began within a few hours or within the first day; 2 on the second day; 3 on the third day; 1 on the ninth day; 1 on the twelfth day; and 2 on the fourteenth day. This is in contrast with the statistics of the onset of the symptoms when systemic poisoning results. In the majority of these cases the morbid symptoms begin in the second week. As a rule, it may be stated that in proportion as the rash is slow in appearing, so are the concomitant symptoms severe. Statistics seem to show that the cutaneous manifestations are most frequent in youth and middle age, while the systemic symptoms occur most frequently in the aged. The erythema appearing upon the hands of dressers in hospitals as a result of the direct contact of the iodoform was regarded as being related to the ordinary hyperæmia induced by mustard and other irritating applications and not to be considered as belonging to the class of cases just described.

DR. J. NEVINS HYDE, of Chicago, had seen the eczematous form of eruption, and also erythema multiforme, and in one case there was a bullous type of eruption resulting from the use of iodoform. This occurred in a young man who had an operation performed for necrosis of the tibia. Iodoform was used in the dressing of the wound. The recovery was complicated with recurrences of erythema upon the surface of the body. This occurred in the form of large areas of a vivid bright color, afterward becoming dull. Scattered over these surfaces were large bullæ containing a clear, transparent fluid, and when ruptured produced superficial excoriated surfaces. The condition was finally traced to the iodoform application and within ten or twelve days after the discontinuance of the iodoform the eruption disappeared and did not recur.

DR. J. C. WHITE, of Boston, had seen a number of cases of eruptions due to the free use of iodoform in the treatment of surgical injuries. He had never seen systemic manifestations where there was dermatitis. The form of eruption has varied from simple hyperæmia up to the vesicular form and going no further in most cases. In occasional instances there appeared a furuncular form of inflammation owing possibly to mechanical obstruction of the cutaneous follicles by particles of the powder. The eruption is almost always found in the immediate vicinity of the point of application.

DR. I. E. ATKINSON, of Baltimore, then presented

A CLINICAL STUDY OF ERYSIPELAS IN CHILDREN.

He considered erysipelas to be a contagious, infectious disease. During the first month it is extremely fatal, but the mortality gradually diminishes up to the end of the first year. The fatality at this period is probably to be attributed to its dependence upon the poison of puerperal fever. He reported the detailed histories of three cases of erysipelas in young children. In two a cellular, board-like induration occurred as the result of intense œdema and cellular infiltration. In neither of these cases was there suppuration. He thought that erysipelas should be considered the expression of the effect of one of a number of specific causes, and in that sense should be regarded as a symptomatic inflammation.

DR. J. C. WHITE asked if the author personally knew of a case in which erysipelas was directly transferred from one person to another; and if he regarded the tincture of the chloride of iron as having any specific therapeutic action in the treatment of the disease.

DR. ATKINSON replied that he had not seen an instance of the direct contagiousness of erysipelas, but there are a number of well-authenticated cases on record. He could not say that the tincture of the chloride of iron was a specific, but in his experience it has had a more favorable influence on the course of the disease than any other remedy that he has employed.

DR. J. C. WHITE had never seen a case of facial erysipelas transferred from one individual to another. If at all contagious, it must be so with extreme rarity. He regards tincture of the chloride of iron, and all other internal remedies, as useless in the treatment of this form of erysipelas. For five years he has given no internal medicine in the treatment of erysipelas, and has not seen a case in which the erysipelatous eruption did not disappear in from five to ten days. In his experience, infantile erysipelas has been so wholly different in its clinical aspects and course, with or without treatment, from ordinary traumatic erysipelas, that it seems to be quite a distinct disease.

DR. HYDE had seen one case which seemed to indicate the contagious nature of erysipelas. A young mother, soon after confinement, had her ears pierced for ear-rings. This was shortly followed by typical erysipelas, spreading over the face and scalp. Soon the nursing child was affected with the disease, and presented typical erysipelas, from which it died. He agreed with Dr. White, that tincture of the chloride of iron is useless in the treatment of this affection.

DR. ATKINSON said that in those cases of erysipelas which may be termed septic, whether the disease depends upon ordinary septic poison or not, he had no doubt that benefit is derived from the administration of the tincture of the chloride of iron in large doses, as much as half a drachm, three or four times a day.

DR. R. B. MORISON, of Baltimore, then read a paper on

LEUCOPATHIA UNGUICUM, A PECULIAR AFFECTION OF THE NAILS.

The ordinary white spots found upon the nails are well known. These are gradually forced to the outer edge of the nail by the growth of new nail behind. The time occupied in this process varies from four to six months. These spots are usually irregular in shape. A lady, twenty years of age, recently came under the author's observation, in whom these spots presented a uniform appearance. Examination of the nails showed white bands one-sixteenth of an inch in width, extending across the nail, from border to border. The nails were perfectly smooth, and in other respects normal. The general health was good, and there had been no acute disease. These white bands across the nail had been regularly appearing for many months. During the previous summer the lines had disappeared almost entirely, the toenails were not affected and the hair was not gray. Portions of the nails were subjected to microscopical examination. Sections were made, cutting the white lines at right angles. By direct light these lines appeared of a pure white, while the rest of the section was of dark color. The application of acetic acid and

other agents caused a gradual disappearance of the lines. Canada balsam also caused their rapid disappearance. It, therefore, seemed plain that these white lines were due to air spaces in the nail; the disappearance being caused in the one case by the swelling of the adjacent cells, induced by the acetic acid, and in the other, by the filling of the spaces with Canada balsam. Examination of several white spots gave similar results.

Dr. Hyde then reported

THREE CASES OF SIMULTANEOUS HAND AND FOOT DISEASE.

(See page 416.)

Dr. L. A. Duhring, of Philadelphia, has regarded the affection as dependent upon a want of nutrition in the nail tissues, and had employed arsenic with satisfactory results. This acts upon the nervous system, improving the nutrition of the whole member, and of the finger-nail in particular.

Dr. P. G. Unna, of Hamburg, said that the presence of air in the horny tissues is always a secondary phenomenon. The horny masses must be changed before they will allow the entrance of air. These white spots in the nails are analogous to medullary substances.

He had seen cases similar to those described by Dr. Hyde, and had allied them with eczema. His principal reason for so doing was that in some cases he had seen combined with the disease of the hands patches of eczema on various portions of the body.

Dr. R. W. Taylor, of New York, regarded Dr. Hyde's cases as cases of tylosis of the hands and feet.

Dr. Le Grand N. Denslow, of St. Paul, regarded the cases as instances of callosities. In his last case, in the person of a hotel porter who was unable to perform his duties on account of the tender condition of the soles of the feet, he first removed the callosities by the application of a saturated solution of salicylic acid in collodion, and then made a false sole for the feet by the application of belladonna plaster spread upon kid. By this means he is able to attend to his work in comfort.

Dr. E. Wigglesworth, of Boston, had now under treatment a case similar to those described by Dr. Hyde. He regarded it as a case of tylosis. In the treatment he employed a 20 per cent. solution of salicylic acid in emplastrum saponis until the callosities were removed. He then dressed the parts with equal parts of belladonna and mercurial plaster spread on kid. Regarding the condition as dependent upon lowered nutrition, he also employed tonics with good effect.

Dr. Hyde, of Chicago, stated that he had at first regarded these cases as instances of tylosis, but a large experience showed that this view was not correct. In one case he had watched the course of the disease for three years. The parts have been macerated for days and weeks at a time. He knew that there is a constant new formation of these masses, and that the nails are continually undergoing a similar process. These cases are entirely different from the ordinary forms of tylosis and callosities.

Afternoon Session.

Dr. L. D. Bulkley, of New York, presented some

CLINICAL NOTES ON PRURITUS.

Pruritus may be defined as a functional disturbance of the nerve elements of the skin, resulting in itching not dependent upon local irritation or local lesion. Out of a total of 5000 cases of general skin diseases he had records of 80 cases of pruritus, a proportion of about 1.75 per cent. Thirty of the patients were females and fifty males. In the majority of cases there was some chronic disease, such as gout, albuminuria, and chronic bronchitis, or marked evidence of lowered general vitality. Temporary benefit was obtained in some cases while in others no relief resulted from treatment. The author was of the opinion that in many cases the condition resulted from reflex irritation. In 115 observations which he had made in all but three the reflex occurred on the same side as the point of irritation.

Dr. F. B. Greenough, of Boston, presented some

CLINICAL NOTES ON PEDICULOSIS.

He had been induced to examine this subject on account of the fact that the statistics of the Association had shown that there was a greater proportion of cases of pediculosis reported from Boston than from any other city. The only explanation of this fact that can be offered is that the difference is more in observers than in the number of cases of the affection. An observer in one city may put under the head of eczema capitis, a case which would be considered in Boston as one of pediculosis capitis.

Dr. J. C. White, of Boston, said that in the treatment of pediculosis of the pubic region and of the head he always used crude petroleum. This does not produce the slightest irritation upon the most inflamed surface. It is allowed to remain in contact with the hair for two or three hours.

D. J. C. White then read

AN INTRODUCTION TO THE STUDY OF THE INFLUENCE OF DIET IN THE PRODUCTION AND TREATMENT OF SKIN DISEASES.

Many articles of diet are considered, both by the people and by the profession, as injurious in certain affections of the skin. He held that in regard to many of these articles there was no evidence of their injurious effects, with the exception of popular belief, and that they should not be discarded until more proof was advanced against them. Among various substances considered injurious in skin diseases, butter was mentioned, but he regarded pure, uncooked butter as entirely harmless so far as the skin is concerned. Oatmeal and buckwheat have been classed in the same category, but there was no foundation for such a belief. The same remarks apply to fish and meat, which have been regarded as harmful by some dermatologists. He then mentioned certain articles which in his experience had seemed to be prejudicial in certain skin affections. Alcohol aggravates the course of inflammatory conditions of the skin. In some lager beer will produce a crop of acne over the lower part of the face. The eating of acid fruits may cause an acute eczema. Strawberries often cause urticaria. Apples are said to produce an acneform efflorescence about the mouth. Some nuts, especially the English walnut, may produce inflammation of the mucous lining of the mouth. Shellfish and crustaceans may occasionally give rise to urticaria. Other meats may at times produce similar effects. The worst case of giant urticaria that he had seen had followed the use of roast turkey.

Dr. Hyde agreed with the speaker in regard to most of the articles mentioned. He should, however, put oatmeal on the black list. Where urticaria follows the use of the grape, he thinks that it is principally due to the fact that the seeds and skin of the grape are also swallowed.

Dr. P. G. Unna, of Hamburg, had seen urticaria produced by strawberries in cases where the berry had not been swallowed but simply placed in the mouth.

Dr. Bulkley had more than one patient who cannot take raspberries without having urticaria. In some cases pineapples have a similar effect. He had seen many patients in whom injurious effects have followed the use of milk with the meals. If taken between meals it produces no injury. He had found that nearly almost every case of acne is aggravated by soup taken with the food.

Thursday, September 1st.—Morning Session.

At the business meeting the following were elected

OFFICERS FOR THE ENSUING YEAR:

President.—Dr. I. E. Atkinson, of Baltimore.

Vice-President.—Dr. P. A. Morrow, of New York.

Secretary and Treasurer.—Dr. G. H. Tilden, of Boston.

The report of the Committee on the

CONGRESS OF AMERICAN PHYSICIANS AND SURGEONS

was received and adopted. Dr. I. E. Atkinson, of Baltimore, was appointed representative to the Executive Committee of the Congress, and Dr. G. H. Tilden alternate.

Dr. L. A. Duhring, of Philadelphia, read a paper on

THE DIAGNOSIS OF DERMATITIS HERPETIFORMIS.

He had been led to believe, from the perusal of various reports of cases, that this affection was not thoroughly understood. Its chief characteristic is the multiformity of the lesions manifested in the natural evolution of the disease. Blebs, vesicles, and pustules, may appear together or separately. Mixed eruptions are the most common, vesicles predominating. In one attack or another only one kind of lesions may be present. The disease presents clearly defined characters in distinct elementary lesions, and certain distinctive abortive lesions. Secondary forms of lesions also exist. Pigmentation of a dirty yellow or brownish hue, and variegated, is usually a marked feature in chronic cases. In no other affection are such varied combinations of lesions met with as in dermatitis herpetiformis. Erythema and vesicles, or vesicles and blebs, or blebs and pustules, frequently exist side by side in close proximity with more or less pigmentation, excoriation, and secondary changes. Itching is usually a most distressing symptom, and is most severe in the vesicular variety. In the purulent form, subjective symptoms may be wanting. The disease is extremely chronic, extending over a number of years. In two cases, under the author's observation, the duration had been thirteen and eleven years respectively, and the disease was still active with no prospect of cure.

Some cases of dermatitis herpetiformis closely resemble cases of erythema multiforme, but the lesions of the former disease are less sharply defined, and the course of the two affections is different, erythema multiforme being an acute disease of short duration. The disease occasionally resembles herpes iris, but the chronicity of the affection would exclude herpes iris. The lesions are also more virulent and accompanied with a more profound degree of cutaneous disturbance. Herpes iris is a benign affection, running an acute course, and terminating in recovery, although subject to relapses. When the bullous varieties exist alone they may resemble pemphigus vulgaris, the combination with other lesions will, however, prevent any confusion in the diagnosis.

Dr. P. G. Unna, of Hamburg, read a paper on

THE TREATMENT OF LEPROSY.

After referring to the fact that leprosy was usually considered incurable, and that as a consequence treatment was not resorted to, he stated that he had recently treated five cases of this affection with encouraging results. The treatment consists in the external use of the following ointment:

Chrysarobin	5 parts.
Ichthyol	5 "
Salicylic acid	2 "
Vaseline	100 "

This is applied to the nodules on all parts of the body with the exception of those on the face, neck, and hands. In the latter situations pyrogallic acid is substituted for the chrysarobin in the above formula. Such an application may be continued for months. For some of the older nodules this is not sufficiently strong; for these the author employs salicylic acid or salicylic acid and chrysarobin in the form of a plaster on muslin. This is allowed to remain two or three days or a week. Under this application the tubercle drops out.

In the five cases treated by this method there has been a rapid disappearance of the leprous matter in the skin. There also was in these cases a decided improvement in the general condition, although no internal remedies were given, the object being to test the efficacy of the external applications.

Dr. P. A. Morrow, of New York, had recently had the opportunity of treating a number of cases of leprosy, and he believed that certain cases of leprosy are as responsive to chaulmoogra oil as are cases of syphilis to mercury. In the case of a Norwegian, the subject of tubercular leprosy, the lesions had disappeared, and he had apparently recovered under the use of chaulmoogra oil. On a number of the nodules of the face he used caustic potash, and they disappeared very rapidly. Some cases, however, fail entirely to respond to this treatment.

Dr. Piffard some time ago treated a case of leprosy in a young man from Bermuda. When he entered the hospital he was unable even to dress himself. He was given a preparation containing strychnia, and in six weeks was engaged in rowing the boat across the river. He also used nux vomica in as full doses as the patient would tolerate. He was in the habit of associating this with the external use of chaulmoogra oil.

Afternoon Session.

Dr. H. W. Stelwagon, of Philadelphia, read a paper on

THE USE OF MEDICATED RUBBER PLASTERS IN CERTAIN CUTANEOUS DISEASES.

(See page 421.)

Dr. Unna said that in the plasters which he employed the plastic mass was spread upon muslin much more flexible than that on which the rubber plaster is spread. The adhesive material which he employed had been either the oleate of aluminium, or the best India-rubber. As little of the adhesive material as possible was employed, not more than two to five grammes to the square metre. The strength of the plaster is reckoned, not by percentages, but as so many grammes of the active agent to the metre.

Dr. H. G. Piffard, then read a paper on

SALT IN DERMAL HYGIENE AND THERAPEUTICS.

In vigorous individuals psoriasis and chronic eczema will often be benefited by a short sea-bath, followed by rubbing. If the patient be feeble, or the bath prolonged, the result will be unfavorable. Prickly heat, pruritic affections, and furuncles, are often benefited by sea-bathing.

In acute eczema the use of ordinary water is, as a rule, followed by temporary aggravation of the trouble. In these cases a full bath of 5 per cent. to 1 per cent. salt solution had been used with great comfort to the patient. In subacute eczema, psoriasis, furuncles, in irritable summer rashes, whether papular or pustular, and in ulcerating syphilides, a 5 per cent. solution of salt may be used with great advantage. The salt-water bath should be used as hot as can be borne, continued fifteen to twenty minutes, and should be taken just before retiring. Genuine sea salt is not so good for the bath as coarse white salt, on account of the slimy feeling which is left. The therapeutic effects are identical.

Adjourned.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Special Meeting, September 19, 1887.

The President, J. Solis-Cohen, M.D., in the Chair.

Mr. Lennox Browne, F.R.C.S., of London, read a paper on

AN UNRECOGNIZED CAUSE OF SOME THROAT AILMENTS.

In accepting the very flattering invitation of your President to speak a few words to the members of the Philadelphia County Medical Society, it appeared to me both more becoming and more profitable to offer you some practical remarks explaining the *rationale* of some of the commoner of throat ailments, than to attempt to magnify the office of the laryngoscope by the relation of rare and wonderful cases. I was the more inclined to this view because I was well aware that, through the assiduous industry and well-known skill of your President and other members of your Society, you have for some years been kept thoroughly posted in all that is new in laryngology.

It is now some ten years since first I sought an objective explanation of the condition known as *globus hystericus*, and since I commenced to make a systematic examination with the laryngoscope of every patient who came to me with this symptom. The result was communicated in a paper to the Congress of Laryngologists held at Milan in 1880. I found that but very few cases indeed are of a hysterical character—that is, of the nature of a phantom sensation—though uterine or ovarian disorder is a not infrequent predisponent, or, at least, concomitant of the throat condition in the female sex.

Extending the term *globus hystericus*, I find that, with hardly an exception, all and every other subjective sensation in the throat is symptomatic of an objective cause. The chief of such feelings are those of a heat, a prickling, a swelling, a weight, a straw, a hair, or other foreign body. A few patients—one especially, a hale farmer—have complained of a feeling of intense cold, which is sometimes relieved, sometimes aggravated, after food-taking. In some instances there is actual pain with spasm, cramp, and a sensation of choking, and not infrequently there is cough; this symptom varies in degree from a slight hacking, to the loud hyena like bark known as nervous laryngeal cough. Many of the cases of so-called laryngeal vertigo, or, as I prefer to call it, of laryngeal epileptiform seizures, are capable of explanation and cure, on the lines I am at present taking.

On examination of the throat of a patient with symptoms such as I have described, one may or may not see chronic congestion and relaxation of the fauces and uvula, enlargement of the tonsils or obstruction by caseated material of the orifices of the crypts, granular pharyngitis, or even laryngeal hyperæmia. Where any one of these conditions is present, treatment thereof may or may not give relief; but none of them represents the class to which I would draw your attention, namely, that in which there is no generally recognized morbid state of local significance.

The results of laryngoscopic investigations in my hands have shown that there is:

1. A varicose, and even truly hemorrhoidal, condition of the veins at the base of the dorsum of the tongue, sometimes at the under surface and sides, in which last case it may be symptomatic of mitral insufficiency, or of severe hepatic derangement, or even of cerebral lesion. There is often a similar varicose state of the vessels in the superior surface of the epiglottis.

2. An enlargement of the circumvallate papillæ at the back of the tongue, causing the epiglottis to be hindered in its movements—imprisoned, as your President first called it.

Just drawing attention to the fact that the structure of these glands is very similar to that of the tonsils, I may mention that in a few instances I have seen actual blocking of the orifices, similar to the condition known generally as chronic follicular tonsillitis.

I may also note that it is not possible to see these things either with a tongue depressor or in the laryngeal mirror as ordinarily employed. Many observers, especially beginners, seem to consider that their sole aim is to see the vocal cords, and, if these are sound, they write down, "larynx normal;" but they omit to look well to the frame-work. To see this condition of lingual varix and glandular hypertrophy, the mirror must be placed high up in the throat.

Where, as is often the case, there is no actual or noticeable enlargement of the thyroid gland, it will be observed, in passing the hand gently over the front of the throat, that there is a distinct fulness of the thyroid isthmus. If the least pressure be made at this situation, the patient—not necessarily a female—will complain that the abnormal sensation is at once excited, and, on

being questioned, will admit that when it occurs the collar is felt to be too tight for the neck.

Inquiring into the general health, and happily failing to find any of the more serious lesions to which I have alluded, it will be noted that habitual constipation and a generally defective circulation are both frequent symptoms, while in others there will be concomitant evidences of a varicose diathesis, as rectal hemorrhoids, varicocele, or varicose veins of the extremities.

In females the menstrual flow is often morbidly frequent or excessive, and there are other evidences of an enfeebled vasomotor control. Abuse of alcohol and tobacco are excitants of the condition; and in the cases or public speakers, defective methods of filling the lungs —forcing the lower registers upward, or other functional fault which may lead to undue strain on the palato-pharyngeal muscles and engorgement of the vessels in this region—are fruitful predisponents.

In this connection, I may refer to the accurate explanation offered by your fellow-citizen, Dr. Carl Seiler, of the etiology and pathology of chronic pharyngitis when occurring to voice users.

Some of those obscure cases which come under our occasional notice, of the presence of small quantities of blood in the mouth, or of the taste thereof on rising from sleep, will be explained by the leakage of one or other of these enlarged and hemorrhoidal venous capillaries in the region now under consideration.

A few words as to treatment. If the case is not of long standing or of aggravated character, correction of the main constitutional cause—cessation of the faulty method of voice production, or prohibition of a vicious habit or indulgence—may be sufficient to effect a cure, but this is rarely the case. Of remedies, I give chalybeates and aperients with digitalis or ergot, as may be indicated. Locally, astringent applications, especially of chloride of zinc or perchloride of iron, are by no means without avail; they can be applied by the patient himself. Gargles as ordinarily employed are useless, and occasionally are productive of exacerbation of the symptoms. Not so if employed by the method known as that of Von Troeltsch. Of lozenges, I find those of muriate of ammonia much more active in leading to resolution of the venous congestion, than those of red gum, rhatany, etc.

Recent investigations show that the astringent properties of tannin have been exaggerated. Where the uvula is relaxed, the snipping of an elongated portion, especially if other functional or constitutional faults are corrected, may lead to a cure; but in a certain proportion of patients in which the promises of the specialists as to the good effects to be gained by the procedure are not realized, the cause of failure will be found in non-recognition of the varicose vessels. Treatment of these is best effected by the galvanocautery point, and it is necessary to seal each individual enlarged vessel. For this purpose it may be necessary to make more than one application. Lastly, there is often a hyperæmic tumefaction of the vessels, glandules, and submucous tissues of the pharynx, naso-pharynx, and turbinated bodies; these will also be best treated by galvanocautery.

In conclusion, I would say that if it be objected that the conditions I have described are but representative of an advanced chronic congestion, I do not deny that such occasionally may be the case. In the majority, however, there are no such antecedents; and where the two exist, the practitioner will fail to cure his pharyngitis, or what not, until he has recognized and treated the varix.

And it is in this light that I have ventured to call attention to the subject as one that is not generally recognized, for beyond a short communication made at Milan at the same time as my own, by my deceased colleague, Llewelyn Thomas, I have seen no allusion to it in any text-books or archives, and no notice is taken of it by the great teachers of Vienna. I therefore make no apology for having occupied your time with considerations that may, on first hearing, appear trivial, or of exaggerated importance.

DR. CARL SEILER quite agreed with the speaker, that the *globus hystericus* is rarely of purely imaginary origin. Some chronic inflammation of the upper air passages usually accompanies this distressing condition. As he truly says, pharyngitis is one of the most common causes of this symptom. At the same time the pharyngitis is to his mind, as a rule, the consequence of remote causes which may be looked for in one of three different directions—in a disturbance of the gastric system, in a disturbance of the respiratory function of the nose and naso-pharynx, and finally, and most commonly in public speakers and singers, in a faulty use of the organ of voice. The latter condition is frequently met with in those who simply use the voice for ordinary conversation. The constant irritation thus produced leads to hyperæmia and chronic inflammation, which extends upward, rather than downward, into the trachea. In the treatment of the condition described, he thinks that little can be accomplished by the application of remedies to the apparent seat of the disease, but that the cause must be looked for and removed.

CORRESPONDENCE.

A GOOD BANDAGE.

To the Editor of THE MEDICAL NEWS,

SIR: In your issue of September 24th, under the head of "Flannel *versus* Rubber Bandages," you speak of the various forms of material used for bandaging purposes. My object is to call your attention, and that of the profession, to an article made of cotton, and woven in tubular form in the manner of hose, which combines the permeability of flannel, without the great disadvantage of shrinkage upon washing, also the roughness preventing slipping, greater elasticity than flannel—yet less than rubber—and not least, at much less cost than either.

This material, made at the suggestion of Dr. Stelzner, of Dresden, by H. Müller of that city, in widths varying from 2 to 22 inches, is largely used by him, by Nussbaum and others, in all dressing requiring elastic support and pressure. Not its least advantage is its ready and easy application in the hands of the class usually with varicose ulcers, etc.

There exists, in my opinion, no better material, and a variety of uses suggest themselves. Moderately filled with plaster, it makes a most excellent splint. For encircling the thorax, where the extreme rigidity of mus-

lin is objectionable, it appears to me to be the very best afflicted material.

The inclosed specimen will, I trust, speak more eloquently of its good qualities than any note.

Yours, respectfully,

O. Czarnowski.

New Orleans, September 28, 1887.

[The sample inclosed we find has all the merits claimed for it, and in practice should prove excellent. —Ed.]

NEWS ITEMS.

A Congress at Amsterdam.—There will be a Congress for Natural Science and Medicine, at Amsterdam, on September 30th, and October 18th. Professor Donders will be President of the Section on Medicine.

Sanitary Police in Italy.—A corps of sanitary police has just been created by the Italian government, and Dr. Pagliani, Professor of Hygiene in the Turin University, has been placed at its head.—*Sanitary News*, September 10, 1887.

The Cremation of Infectious Bodies.—It is now an imperial regulation in Brazil, that persons who die from yellow fever shall be cremated, the State bearing the whole expense. This decree might be extended judiciously to all contagious diseases.—*Sanitary News*, September 10, 1887.

Theatre Physicians.—The ordinance recently put in force in Paris for the regulation of theatres, provides that each theatre must have a corps of physicians proportionate to the size of the theatre, one of whom must be constantly in attendance during the performances. In the physician's office must be placed an ambulance call.

The Avoidance of Overpressure in Schools.—The Committee of the French Academy of Medicine reported as follows on this question: "The Academy of Medicine calls the attention of the public authorities to the necessity of modifying, in conformity with the laws of hygiene and the necessities of the physical development of children and young people, the present arrangements of our scholastic establishments. It thinks that the colleges and lycées for boarders should be removed to the country; that wide, open spaces should be set apart for games; and that the class-rooms should be improved as regards lighting and ventilation. Without dealing with the course of study—which it desires to see simplified—the Academy calls special attention to the following points: Increase of the time for sleep, as regards young children; for all the pupils a diminution of the time devoted to study and classes—that is to say, to sedentary occupations—and a proportional increase of the time for amusement and exercise; the absolute necessity of submitting all the pupils to daily exercise in physical training, proportioned to their age—namely, walking, running, jumping, formations, evolutions, regulated and prescribed movements, gymnastics with apparatus, fencing of every kind, games of strength, etc." —*British Medical Journal*, August 13, 1887.

Professional Secrets.—A Belgian physician has been several times condemned by the courts for refusing to give the name of the mother of a child whom he delivered. The Minister of Justice, in reviewing the case, holds that no legal power exists which can oblige the physician to betray a patient's confidence.

Antisepsis in Duels.—In a recent duel between French journalists, the seconds had taken the precaution to dip the swords of the combatants in carbolized solution; as the result, their wounds healed without suppuration, and they were about in a few days after their encounter. *Le Progrès Médical* suggests that in duels with pistols, bullets which had been sterilized by immersion in proper liquids, or treated at proper temperatures, be employed. We suggest that germs previously agreed upon by the combatants be selected in place of bullets and swords, and that duels by inoculation be instituted as a refinement characteristic of Nineteenth Century medicine.

A Medical Journal in Manitoba.—The *Manitoba Lancet* will represent medical journalism in this advance post of the profession.

Amputation of the Cervix Uteri during Hypnotic Sleep.—In July last, Dr. Pio Masetti, at the hospital of San-Giacomo, at Rome, amputated the cervix uteri while the patient was hypnotized. The experiment was completely successful. No evidence of pain was given by the patient.

Swill Milk.—*Science*, of September 30, 1887, closes its inquiries regarding the use of swill milk as follows: There appears to be some difference of opinion as to the exact chemical composition of distillery swill, under different circumstances; so that in carrying out any experiments the following points, as suggested by Professor Law, should be ascertained and recorded: (1) Is the swill fresh? (2) Has it undergone any other than the alcoholic fermentation? (3) Is it uniform in quality as supplied from day to day? (4) At what heat is it fed? (5) Does it contain the simple original grain-products—gluten, salts, etc.—or has there been added any chemical agent used in the manufacture of the alcoholic liquid? These inquiries are necessary, because the effect of swill when fresh may be entirely different from swill in an acid or decomposed state, and the allegation has also been made that injurious chemical agents are added. The temperature of the stables in which the experimental animals are housed should also be recorded. In short, every condition which is liable to enter as a factor into the problem should be intelligently regarded. Dr. Salmon advises that biological analyses of the milk should be made, in order to determine the relative number of germs as compared with milk from country pastures.

Hitherto chemical analysis has been mainly relied on in determining the quality of the milk; but, as Dr. Sturtevant remarks, "while this is of assistance, it cannot alone determine the questions relative to healthfulness. The question should be investigated from the chemico-physiological standpoint: determine whether substances not met with in ordinary foods can be traced through the animal to the milk; whether bacterial

germs exist in the food, and whether such can be traced through the animal to the milk; whether animals of a delicate nature will succumb, or show indication of disease, when fed with suspected milk, while other individuals thrive upon a milk considered of a fine quality. The development of ptomaines in feeding substances through neglect of proper precaution should also receive investigation, as a food otherwise useful may at times become dangerous on the neglect of ordinary precaution.".

Dr. Salmon does not regard the studying of milk from healthy cattle, fed upon swill under favorable hygienic conditions, as of much value toward elucidating the practical questions involved. "The question," he says, "is not, whether a small quantity of cool and fresh swill fed with a suitably prepared ration of other articles of food to healthy cows, having clean roomy stables, and plenty of exercise, is injurious to the milk, but it is this: Is wholesome milk produced by feeding swill under the conditions in which it is fed in practice, and must be fed in order to make it a profitable industry?" And finally, as Professor Rohé so well expresses it, "a scientific solution of the question will not be furthered by prejudiced appeals or unreasoning denunciation. Patient investigation, keeping in view all circumstances of the question, and avoiding all one-sidedness in considering the matter, will alone bring about the object desired."

With these suggestions to those having in charge the experiment stations, we leave the subject with our readers. We shall be glad to record any observations or experiences which any one may send us in the future; so that, even if public interest cannot be sufficiently aroused to bring about a proper investigation of the subject at the present time, it may, by a reminder from time to time, be kept alive until the demand for such an inquiry becomes irresistible.

THE PROHIBITION OF POISONOUS COLORING MATERIALS.—Sweden has also passed laws against the use of poisonous coloring materials in goods for household use, such as woven fabrics, yarn, shades, sealing wax and wafers, wall paper, artificial flowers, blinds, etc.—*American Analyst.*

MR. RICHARD QUAIN.—This well known physician and writer on medical subjects, died at London, September 15, 1887, aged eighty-seven. He was one of the founders of the Pathological Society, President of University College, and a Fellow of the College of Surgeons. In addition to many contributions to medical journals, he published in 1844, Quain's *Anatomy of the Arteries of the Human Body*, a standard work in the English language. He was one of the first to draw attention to the pathology of fatty degeneration of the heart.

IN MEMORY OF DR. JOSEPH C. HUTCHISON.—At a meeting of the Medical Staff of the Brooklyn Hospital, September 24, 1887, the following minute was adopted:

The long and active connection of our friend and associate, the late Dr. Joseph C. Hutchison, with the Brooklyn Hospital, was characterized by earnest and unfaltering devotion to its interests. His preëminent professional skill, his large and varied experience, his conservative and accurate judgment, his genial manner and the inspiration of his native kindnesss and Christian manhood, were ever ready for his professional associates as well as for those who sought the shelter of this institution for help; and were ever intent on all suggestions that served to keep the Brooklyn Hospital first and most liberal among the charitable institutions of the city.

Contributing as he did by his dignified presence and his many graceful accomplishments to the adornment and advantage of the enterprise, culture, and benevolence of the city, the Brooklyn Hospital was nearer to his heart than any other, and to it we re given his utmost care and the best of his gifts.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM SEPTEMBER 27 TO OCTOBER 3, 1887.

SMITH, A. K., *Lieutenant Colonel and Surgeon.* Granted leave of absence for one month and fourteen days, to take effect upon his being relieved from duty at the U. S. Military Academy. —*S. O. 223, A. G. O.*, September 24, 1887.

DIETZ, W. D., *First Lieutenant and Assistant Surgeon.*—Leave of absence extended one month.—*S. O. 223, A. G. O.*, September 24, 1887.

KNUDLER, WILLIAM L., *First Lieutenant and Assistant Surgeon.*—Ordered to accompany Light Battery "F," Fourth Artillery, from Fort Snelling, Minnesota, to the International Military Encampment, at Chicago, Illinois.—*S. O. 97, Department of Dakota*, September 20, 1887.

CABELL, J. M., *First Lieutenant and Assistant Surgeon.*—Relieved from further duty in connection with the competition of the "Team of Distinguished Marksmen," at Bellevue Rifle Range, to take effect October 1, and will return to his station, Fort Omaha, Nebraska.—*S. O. 95, Department of the Platte*, September 27, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING OCTOBER 1, 1887.

MEANS, V. C. B., *Assistant Surgeon.*—Ordered for examination preliminary to promotion.

DERR, E. Z., *Passed Assistant Surgeon.*—Detached from the Navy Yard, New York, and ordered to the "Alpine."

ASHBRIDGE, RICHARD, *Passed Assistant Surgeon.*—Detached from the Naval Academy, Annapolis, Maryland, and wait orders.

RUSSELL, A. H., *Passed Assistant Surgeon.*—Ordered to the Naval Academy, Annapolis, Maryland.

HERNDON, C. G., *Passed Assistant Surgeon.*—Detached from the Naval Dispensary, at Washington, D. C., and ordered to the "Enterprise."

ARTHUR, GEORGE, *Passed Assistant Surgeon.*—Detached from the Museum of Hygiene, Washington, D. C., and ordered to the Naval Dispensary.

GRIFFITHS, S. H., *Passed Assistant Surgeon.*—Ordered to the Museum of Hygiene, Washington, D. C.

SPEAR, J. C., *Medical Inspector.*—Leave of absence granted until July 1, 1888, with permission to leave the United States.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL LECTURES.

ON THE GENERAL ETIOLOGY AND SYMPTOMS OF CHOREA.

BASED ON THE RECORDS OF 410 CASES AT THE INFIRMARY FOR NERVOUS DISEASES, PHILADELPHIA.

Two lectures delivered at the Infirmary during the Summer Session.

BY WILLIAM OSLER, M.D.,

PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.

LECTURE I.

GENERAL ETIOLOGY.

ALREADY from this hospital a large number of important contributions to the clinical history of chorea have been made. These are embodied in Mitchell's *Lectures on Diseases of the Nervous System*, in Sinkler's article on "Chorea" in Pepper's *System of Medicine*, and in numerous papers by Mitchell, Sinkler, Gerhard, Allison, and Morris J. Lewis.[1] By the kindness of my colleagues I am enabled to utilize the rich clinical material which has accumulated since 1876, and these lectures represent our combined experience.

Historical Note.—The recognition of chorea as a distinct disease dates from Sydenham, whose *Schedula monitoria* (1686) and *Processus Integri* (1699) contain brief but very accurate accounts of the affection as we now know it. During the fourteenth, fifteenth, and sixteenth centuries, under the influence of religious excitement, there were epidemics of dancing mania, particularly in the Rhenish provinces. Pilgrimages were made to various shrines in search of relief, and as that of St. Vitus, in Zabern, was specially famous the dance became known by his name. Elsewhere it received other names, as St. John's or St. Anthony's dance. The epidemics gradually died out, but curiously enough, as Charcot states,[2] an annual pilgrimage of dancers, in perpetuation of the custom, is still made to the church of St. Willibrod, in Luxembourg; and Hirsch[3] refers to a "procession of the jumping saints" which is still commemorated at Echternach. It is interesting to note that in Kentucky and Tennessee, in the early part of the century, during periods of intense religious enthusiasm, there were epidemic convulsions, similar in some respects to the dancing mania of the middle ages. In 1805, Dr. Felix Robertson described them in an "Essay on Chorea Sancti Viti," in his doctorate thesis at the University of Pennsylvania.[1] It was unfortunate, to say the least, that Sydenham should have given the name chorea to an affection which had nothing whatever to do with the Chorea Sancti Viti of the older writers. However, there need not now be any confusion, as custom has sanctioned the use; and this is not the only instance in medicine in which we know a disease by a name the original signification of which has long been lost. The affection which Sydenham described is known as chorea minor, in contradistinction to chorea major, a term which has been applied both to the dancing mania and to the graver form of the ordinary disease. Commonly, however, we employ the term chorea, or St. Vitus's dance, alone to designate the disease of children, and use qualifying terms when we refer to varieties or symptomatic forms.

It would be ungrateful in a historical note, however brief, not to mention certain of the authors to whom the profession is specially indebted. From the monographs of Bouteille (1810), in France, and Bernt (1810), in Germany, we may date the modern study of the disease. In the former country Trousseau, Roger, and Sée, whose essay (1850) has served as a model for many succeeding workers; in the latter country, Romberg, Steiner, and Ziemssen. In Great Britain, the Guy's Hospital physicians Bright, Babington, Addison, Hughes, Wilks, and Pye-Smith, have made special contributions, while Todd, Begbie (Sr.), Kirkes, Ogle, Hughlings-Jackson, Broadbent, Dickenson, Hillier, Tuckwell, Bastian, Sturges, Gowers, and more recently Money, Horsley, and Stephen Mackenzie, have striven to place the disease on a firm anatomical and clinical basis. In this country, in addition to the works already mentioned from this hospital, there have been many reports of cases and careful studies of the disease by Levick, Wood, Mills, Jacobi, Hammond, Hamilton, Haven, Hutchinson, Huntington, and Putnam.

Definition.—Chorea is not only burdened with old associations, but recent studies have so widened our knowledge of choreiform symptoms that it is somewhat difficult to define the precise limitations of the disease. Indeed, there are those who would deny its existence as a separate entity, and claim that it is merely a symptom, not a disease. In our present knowledge the following is a convenient classification based on that adopted by Charcot.

1. *Chorea*, a primary and independent disease of unknown causation, affecting children, more rarely adults, and characterized by involuntary and irregular contractions of the muscles, and a variable amount of psychical disturbance. Certain forms occur under special conditions, as chorea gravidarum, senile chorea, habit chorea, chronic chorea, and the hereditary form; but it is quite probable that subsequent investigations

[1] Among these may be mentioned Gerhard: Report on thirty case of chorea, Phila. Med. Times, 1874; Report on eighty cases of chorea, Amer. Journ. Med. Sciences, 1876. Sinkler: Chorea in the aged, Journal of Nervous and Mental Diseases, vol. viii. 1881; Chorea in the negro, THE MEDICAL NEWS, 1882. Alison, Amer. Journ. Med. Sciences, 1877. Morris J. Lewis: THE MEDICAL NEWS, 1886.

[2] Les Demoniaques dans l'Art, 1887.

[3] Geographical Pathology, vol. iii.

[1] See, also, David Yandell on Epidemic Convulsions, Brain, vol. iv.

will separate some of these varieties from the common chorea with which at present they may be provisionally grouped.

2. *Pre-* and *post-hemiplegic chorea*, a symptomatic affection, first described by Mitchell, characterized by incoördinate, irregular movements, of the same nature but slower, less brusque, than those of common chorea, usually unilateral and dependent upon a lesion in the pyramidal columns between the bulb and the gray cortex. Athetosis, hemi-ataxia, hemi-sclérose en plaque, and hemi-paralysis agitans, are some of the names given to this condition.

3. *Rhythmic chorea*, in which the involuntary movements follow a more or less regular rhythm, often imitating certain expressive acts, such as dancing—saltatory chorea—or the performance of professional acts, as hammering, weaving, etc. Cases of this kind are usually hysterical.

I propose to consider only the common chorea and such of its varieties as have come under observation at our clinics.

Sex.—The greater liability of the female is shown by the following figures:

Males	125
Females	282
Sex not noted	3
	410

This gives 1 male to 2.25 females, a somewhat lower proportion of females than is usually stated.

Age.—Chorea is essentially a disease of childhood and of adolescence.

The age incidence is shown in the following table:[1]

	Total	Under 4	4–	7–	8–	9–	10–	11–	12–	13–	14–	15–	16–	21–25	26–30	31–35	36–40	Over 40
Males	117	7	3	8	7	7	13	9	11		12	4	8		1			
Females	273	11	11	13	21	26	17	23	24	22	11	16	17	32	2	1	1	1
	392	17	13	21	28	33	22	32	35	22	23	20	25	41	3	1	1	1

Arranged in decades the figures are as follows:

First decade	268
Second decade	183
Third "	4
Fourth "	1
Above fourth decade	1

The second and third hemi-decades are the most important periods, containing more than three-fourths of the entire number. Thus:

First hemi-decade	30 cases,	or 7.5 per cent.
Second "	179 "	" 42.1 "
Third "	143 "	" 34.8 "
Fourth "	40 "	" 9.7 "

The age incidence seems earlier in females than in males. Thus, in the females the second hemi-decade contained the greatest number of cases, 129, or 46.9 per cent., while the third hemi-decade in males contained the largest proportion, 54, or 46.1 per cent. After the age of fifteen the preponderance of females is greater than in children.

It is interesting to note that chorea in this country appears to attack children at an earlier age than in Great Britain and on the continent. Thus, in the recent report of the Collective Investigation Committee of the British Medical Association,[1] in which Dr. Stephen Mackenzie has analyzed 439 cases, the greatest incidence of the disease was in the third hemi-decade, and in our table a much larger number of cases, 30, occur in the first hemi-decade against only 6 in the English report. Under four years and over twenty chorea is a very rare disease. It is difficult to determine the earliest age at which the affection begins. Possibly it is in some cases *congenital*. There are two instances in the case-books stated to be of this nature. One of these is given by Sinkler, in his article in Pepper's *System of Medicine*.

A girl (Case 246), aged nineteen, whose mother while pregnant was frightened at the sight of a choreic child. The movements were general and continuous. The intellect was not impaired.

In Case 104, a boy, aged (now) fourteen, the movements were noticed within a few months after birth and have persisted ever since, with variations in intensity. When seen a few weeks ago there were irregular choreic twitchings of the muscles of the face, arms, and trunk. No paralysis; no spasm; head small, and intellect feeble.

In Case 162, a lad, who was at the hospital in 1882, and who returned for examination a few weeks ago, the mother, an intelligent woman, states that she was born with it, and that her mother had chorea very severely while carrying her. The jerky, irregular movements of the infant for the first three or four months of its life are essentially choreic, so that it is very difficult to determine whether, in any instance, the disease is really congenital. Similar, probably identical, in character are the movements of the fœtus in utero.

Senile chorea is even more uncommon. Case 72, was a woman, aged eighty-two. Sinkler has reported this case[2] with one other, the only instances I find recorded in this country. Saundby[3] has collected twelve cases, the ages ranging from fifty to eighty-six, six of each sex. It seems to be an intractable affection, similar in many respects to the juvenile form, not often associated with rheumatism, and the subjects of it are very frequently demented.

Although we meet with cases of chorea in all ranks

[1] I have to thank Dr. Burr, the Resident Physician, for these statistical details.

[1] British Medical Journal, February 26, 1887.

[2] Journal of Nervous and Mental Diseases, 1881

[3] Lancet, 1884.

of society, it is so much more frequent in the pauper and working classes that our knowledge of the disease has been drawn largely from the experience of hospital physicians. In Mackenzie's report to the British Medical Association, the returns, which were largely furnished by general practitioners, give 72.27 per cent. of the cases as belonging to the lower classes.

The *race relations* of chorea have been carefully studied at this hospital by Dr. Mitchell. From a large number of replies to inquiries sent out regarding the prevalence of chorea in the South, he concluded that it was rare in the negro. This appears to be the common experience of those who practise among the colored people. Here and there, however, we find it stated that the children of both races are equally affected. Sinkler[1] confirms Mitchell's statement, and has seen but one case in the full-blooded negro. On this point the records of the institution are very conclusive. So far as I can ascertain, no negro child of pure blood has ever been under treatment here for the disease, and there have been only three or four mulatto children. It is estimated that the proportion of colored population to the white is in Philadelphia about 1 to 25, at which ratio we should have had a very much larger number of colored patients were chorea as common in them as in the whites.

Recently Mulheron, of Detroit, has recorded a case in a negro boy.[2]

I have made inquiries as to the occurrence of chorea among the Indians. Dr. Waldron, of the Hampton Normal and Agricultural Institute, Hampton, Va., writes that he has never seen a case in an Indian, and that there had not been any in the school since its foundation. Dr. McLelland, of the Lincoln Institution of this city, writes to the same effect. Dr. O. G. Given, Physician to the Indian School at Carlisle, Pa., states that during the five years in which he has had medical charge of the children there has been only one case, and that was in a scrofulous and epileptic subject. Professor Robert Bell, of the Canadian Geological Survey, who has studied the habits and diseases of the Indians from Gaspé to the Rocky Mountains, and from Lake Huron to Hudson Bay, has neither seen nor heard of a case. Chief Peter Jones, a physician who has practised for twenty years among the Misissaquis and Six Nation Indians at the Reserve near Brantford, Ontario, informed Prof. Bell that he had seen three cases in half-breed girls, and had heard of two others. He does not think that it ever occurs among the full-blooded Indians. Dr. R. M. Stephen, Government Physician to the Indians of Manitoulin Island, has not met with a case in five years' practice. In twenty-five years' experience in the Canadian North-West, Dr. Schultz has seen only one case, and that was in a half-breed.

Dr. Bell has also made many personal inquiries for me on this point, and concludes that the disease does not occur in the full-blooded Indian, and is exceedingly rare among the people of mixed blood.

Seasonal relations.—For some years past the relation of chorea to the season of the year has been made the subject of careful study at the Infirmary, and in a paper by Gerhard,[3] in Mitcheli's lectures, and, more recently, in a communication by Dr. Morris J. Lewis,[1] we have almost all the data of value which have been collected on this subject. Lewis's work covers our records to date, and is based on a study of 437 separate attacks of chorea. October and November are the months with fewest attacks, 4.1 and 4.3 per cent. respectively. The number increases in December, and in January reaches 8.2 per cent. The greatest number of attacks occurred in March, 15.3 per cent. There is a fall in April, a rise in the number in May and July, and then there is a steady fall until October, when the lowest point is reached. In this country, it is the experience of most hospital physicians, that with the changeable weather of March, April, and May, the cases of chorea applying for treatment greatly increase in number. Lewis's studies include a careful comparison of the number of attacks of chorea with the mean relative humidity, the mean barometer, the mean daily range of thermometer, and the amount of sunshine or cloud. There appears to be a slight "increase in the number of cases with a fall in the mean relative humidity and barometer tracings." The cold, moist months of December, January, and February, show a smaller proportion of cases than March, which has a higher temperature. There is a striking correspondence between the chorea tracing and that of the storm centres passing within a circle of 400 miles radius described around Philadelphia. The smallest number of storms occur in August; there is a rapid rise in the number until December and January. In February there is a slight fall, and in March the highest point is reached, after which there is an irregular fall until August. This seems the most interesting, as it is the most positive, fact brought out in Lewis's study of the seasonal relations of the disease, but, as he remarks, a storm is a very complex disturbance, and it is difficult to say which factor is the baneful one, or how it acts.

Special antecedent conditions.—Temperament plays an important rôle as a predisposing cause of the disease. High-strung, as we say, nervous children, members of neurotic families, are much more liable to the disease than others. The notes do not give exact figures in this matter, but the phrases "bright, excitable child," "alway nervous," come often enough in the records to give a basis to the current opinion. In 59 instances, 14.3 per cent., there was a history of attacks of chorea in other members of the family. In only seven instances is it stated that the mother had also had the disease. In Case 162 the mother and grandmother had both been affected.

Mental conditions.—Psychical disturbance, in some form or other, is a prominent special condition determining the onset of chorea. Fright was given as the exciting cause in 76 cases, or 18.5 per cent. In a majority of these cases the statements seem clear and specific. Thus, to take at random from the list, here are some of the assigned causes of the fright: dogs (very common), house on fire, fright in a boat, burglar, father drunk, brother burned to death, etc. We could wish for more definite details, in many instances, as to the interval of time which elapsed between the fright and the onset of the symptoms. In a few cases the attack seems to have come on at once. Thus, R. R.,

[1] The Medical News, October, 1882.

[2] Medical Age, June, 1887.

[3] Loc. cit.

[1] Loc. cit.

aged seven, mother had chorea; was healthy until July 27th, when she cut her foot on a piece of glass and was exceedingly frightened. The choreic movements began at once, rapidly became general, and the speech was affected. The attack was severe, and lasted between two and three months. Oddly enough, just one year later, she returned with a second attack, which the mother said was excited by the peck of a duck.

More commonly there is an interval of one, two, or more days between the fright and the appearance of the movements; in very many cases the attack is simply *post-hoc*.

In twelve cases there was a history of injury preceding the attack, usually a fall. In two cases wounds of the fingers appeared to be the exciting cause.

Various other sources of mental worry or excitement are mentioned, such as "trouble at home," "a scolding master," a "cross foreman," "excitement of a revival meeting."

A really important factor is the strain of education, particularly in young girls during the third hemi-decade. Although in only thirty cases "overwork at school," "examinations," "worry about lessons," are given as exciting causes, I feel sure that in a much larger proportion the stimulation of school life is responsible for conditions which favor, if they do not actually precipitate attacks. Keen, active-minded little girls, from ten to fourteen years of age, anxious to do well at lessons, stimulated in their efforts by parents and teachers, form a large contingent of our cases. In London, Sturges has for some time studied this question with great care, and his papers on school-made chorea call attention to a serious danger in the forcing system which prevails so largely in our modern methods of education.

Reflex irritation is thought to influence in many cases the onset of chorea, but I have looked through the records in vain for a good instance. The presence of worms was noted in seven cases; in three it is distinctly stated that the expulsion of the parasites had no effect on the disease. The *chorée vermineuse* of some of the older French writers has no place in the Infirmary records. Perhaps certain of the cases which followed injury might be regarded as reflex in character. Jacobi[1] has called attention to the important part which nasopharyngeal irritation plays in some cases of local chorea, particularly of the face. It is a point worthy of close attention.

Imitation does not appear to have influenced the onset in a single case. Trousseau and other French writers have laid stress upon this factor, which may prevail in institutions containing a large number of children, but in Dispensary practice mimicry need not be taken into account. In Mitchell's lectures will be found a graphic description of an epidemic of convulsive seizures, with choreiform movements, which affected the inmates of the Church Home for Children in 1850. In this instance imitation played a most important part in the extension of the disease.

Antecedent illness.—Naturally, in inquiring into the history of children, we have statements of the attacks of the various fevers and infantile disorders, but there is one special disease, *rheumatism*, which has long been known to have close associations with chorea, and which, in this respect, takes the first rank. It is important to separate the cases with a clear history of articular disease from those with vague pains in the joints and limbs. In the records there are 63 cases, or 15.3 per cent., with rheumatism; I have included here all cases in which there was distinct articular swelling with heat and pain. Some of the cases were slight enough to be called subacute. We find two groups of cases, the one in which the chorea comes on with or follows immediately upon an attack of acute rheumatism, and the other in which the rheumatism antedates some months or years the onset of the chorea. In 31 cases the movements followed the arthritis, usually during convalescence. In some instances it was impossible to say which came first, and, indeed, there are cases in which the rheumatism follows long after the chorea. In 11 cases the rheumatism had preceded the chorea for periods of from two to twelve years, and did not recur before or during the attack. In a number of cases the chorea followed "some months" after the rheumatism and there was no joint trouble at the time of the onset. We may conclude from our records that about 15 per cent. of the cases show antecedent rheumatism, but in only 7.5 per cent. was the rheumatism immediately associated with the chorea.

To the lay mind rheumatism is a convenient term embracing many affections, and I do not place much weight on answers given to queries regarding the occurrence of rheumatism in the family, but it may be noted that in 49 instances the father, mother, brother, or sister had had this affection.

It is interesting to compare these Infirmary figures with those of the Collective Investigation Report of the British Medical Association. The percentage of cases with antecedent rheumatism was 26, but it is not stated in how many of these cases the chorea followed immediately upon the joint trouble. Our records show a much smaller percentage than in the majority of English or French statistics which are to be found in the special monographs and treatises.

As great care appears to have been exercised in this inquiry, I think the Infirmary records afford reliable information in this respect, and we may safely conclude that in more than three-fourths of all the cases there was no history of *articular* rheumatism. In 23 cases there were pains in various parts, sometimes described as rheumatic but not associated with joint trouble. Whatever may be their nature, it is important to separate these cases from those of true rheumatism with distinct articular swelling. It is quite possible that many of these cases are truly rheumatic, as the joint trouble in children may be quite trifling, yet, in going through the records it was found impossible to make any separation between cases in which the pains were truly rheumatic and those in which they were the vague so-called growing pains so often complained of by children. Assuming all such cases to be rheumatic and adding them to the 63 cases of positive rheumatism, it would raise the percentage to nearly 21.

Of other diseases, scarlet fever was an antecedent in 95 cases, or over 23 per cent. In a few cases the chorea followed or came on with a rheumatic complication of this disease.

There was a record of measles in 42 cases, and of whooping cough in 13, but doubtless less strict inquiry

[1] Amer. Journ. of Med. Sciences, 1878.

was made regarding these diseases. It is to be regretted that the notes were not more full on the question of whooping cough, as Sturges[1] states that this disease has more than double the frequency in choreic children that it has in others.

Other antecedents were anæmia, worms, marasmus, typhoid fever, malaria, chicken-pox, smallpox, and diphtheria, but the cases coming under each heading are too few for any practical purpose. Anæmia is more frequently, I think, a sequence than an antecedent, though in some instances there was marked pallor with failing health some time before the chorea began. There is at present in attendance at the Medical Dispensary of University Hospital, a case of chlorosis in which hemichorea developed while under observation.

Kinnicutt, of New York, and Kingsley[2] have written upon the possible association of chorea with malaria. There are five cases in which the children are stated to have had intermittent fever, but I cannot gather that there was any connection between it and the onset of the chorea.

ORIGINAL ARTICLES.

THE PATHOGENIC CONDITIONS OF ALBUMINURIA.

NEW EXPERIMENTS AND CLINICAL INVESTIGATIONS.

By DR. MARIANO SEMMOLA,
PROFESSOR IN THE UNIVERSITY OF NAPLES, ITALY.

The conditions which determine the passage of albumen into the urine should form the basis of any explanation of the mechanism of albuminuria in the different pathological conditions in which it occurs.

For some years the difficulty of finding a satisfactory explanation of the different kinds of albuminuria has been increased by the admission that there may exist a physiological albuminuria lasting for a variable period, which I believe I was the first to describe in 1875. (See Congress of Brussels.) But I believe that it is not correct to speak of a physiological albuminuria. It might, indeed, be understood in the sense that it may exist in individuals who walk about, eat, etc., like those in good health; but this is not proof that they have not some slight, perhaps transitory disturbance, which is really the cause of their albuminuria, so that we should not describe it as truly physiological. My researches for thirty years past have fully confirmed me in the opinion that albumen is not a principle which is intended normally to pass out of the living economy.

The relation of albuminoids to albuminuria is generally (except in certain kinds of albuminuria of renal origin) the same as that of glucose to glycosuria. In health both these principles circulate in the blood, and neither is intended to be eliminated. Whenever their quantity or quality becomes such that they are no longer suitable for carrying out their physiological purposes, they are eliminated or useless substances, foreign to nutrition. The evidence of this seems to me indisputable. Another fact sustains and enforces this view. In all cases of so-called physiological albuminuria the daily quantity of albumen eliminated is very small, considerably under $3\frac{3}{4}$ drachms, or almost this amount, and this lasts for a limited or intermittent period only. In health no albuminuria of any duration has been observed, in which the daily quantity of albumen eliminated amounts to half a drachm, a drachm, or two drachms and a half, so that it follows that the mechanism of the so-called physiological albuminur a must necessarily be of the same character, as in that of disease. The pathological condition may be insignificant, incapable of producing appreciable consequences, but the presence of albumen in the urine, no matter how small the quantity, should always be considered as a morbid phenomenon, a functional disorder, for which a cause should be sought, and it may occur without any renal disease, as I have shown as far back as 1861.[1]

In following out the admitted theories, I was led, in 1879 (see Congress of Amsterdam and *Revue Mensuelle de Médecine*, Paris, 1880), to study the passage of albumen into the urine in relation to the three factors which preside over the secretion of urine in the normal state, that is to say:

1st. Mechanical conditions of the circulation of the blood.

2d. Physico-chemical constitution of the blood.

3d. Histological condition of the kidney.

In preceding papers (see *Archives de Physiologie*, Paris, 1881, 1884, and *Bulletin de l'Académie de Médecine de Paris*, September 7, 1886) I have shown beyond question that as soon as the albuminoids of the blood became so changed in their chemico-molecular constitution as to be dialysable and unassimilable, they will be eliminated by the kidney.

Whether this foreign body be albumen derived from the food which from any cause whatever has not completed the chemico-molecular changes to fit it for fixation in the tissues, or an excess of chloride of sodium, of water, or of any poison whatever, either introduced from without or formed within the organism, it is all the same: the kidney is charged with removing it from the body, which remains normal because of this incessant removal. It is useless to seek for the cause of the passage of albumen in the greater or less porosity of the membrane of the glomeruli, or in the greater or less resistance of the glomerular epithelium (Leube). These hypotheses are gratuitous and quite at variance with good physiology. Indeed, that albumen is eliminated by the kidney because of its non-assimilability is proved beyond question by the fact that when we attempt to repair the loss of albumen by increasing the nitrogenous elements of the food, albumen becomes more abundant in the urine, because the increase in the albuminous load intensifies the vice of nutrition which occasioned defective assimilation of albuminoids.

I need not now discuss the pathogenic conditions of the great majority of cases of albuminuria. The principal object of this paper is to examine those conditions in relation to increased blood-pressure and histological alterations of the kidney, hitherto

[1] International Medical Congress, London. Transactions, vol. i.
[2] St. Louis Medical and Surgical Journal 1881.

[1] Gazette des Hôpitaux, Paris, 1861, No. 101.

considered as the causes of albuminuria, deducing conclusions both from experimental pathology and from clinical observations.

Experimenting first on the mechanism of the circulation, the conclusion was reached that increased pressure in the glomeruli may cause albumen to appear in the urine. But contradictory results are not wanting, and it may be asked whether these do not lead to the conclusion that the experiments have not taken account of derangements not connected with mere change of blood pressure. This error too often occurs in the researches of experimental pathology, and we should always remember that when we experimentally produce a serious derangement in the relation of different functions, it is impossible to come to exact conclusions as to the true mechanism of the symptom which we wish to elucidate. Thus, for example, the ligature of the aorta (Robinson, Meyer, Munck, Senator, etc.) above the renal arteries, alone or in connection with a ligature of the coeliac and superior mesenteric arteries (Litten), produced in the former case albuminuria, while in the latter Litten did not observe albuminuria. Nor were the experiments more conclusive in which albuminuria was observed as a consequence of increased pressure throughout the entire vascular system, caused by injections of pure water (Mosler, Kierulf, Goll), because then another very powerful factor came into play, viz., the derangement of the physico-chemical constitution of the blood, principally as regards the chemico-molecular constitution of the albuminoids, of which a very slight amount may injure or modify the biological relations. So that there is at this time no experiment which can be considered as proving beyond question the hypothesis that increased blood-pressure is one of the causes of the passage of albumen into the urine, especially as this hypothesis has been advanced and received because of experiments, purely physical in their character, made with albuminous fluids and animal membranes under different pressures.

In the course of a long-continued study of albuminuria, I have been often surprised at its absence in a great number of cardiac cases observed at my clinic in which the conditions for a passive hyperæmia of the kidneys were most favorable, and my surprise was intensified when I found on autopsy that the kidneys were cyanosed, and that there was sometimes even an interstitial nephritis, whereas in other cardiac cases, with valvular lesions, venous stasis, dropsy, etc., in patients presenting the same clinical conditions as the preceding, albuminuria was present. Finally, a fact well worthy of note: in these last cases, when by means of treatment we succeeded in restoring the equilibrium of the circulation by controlling the irregular action of the heart, and the venous stasis, dropsy, etc., disappeared, there was at once a more or less considerable diminution in the daily amount of albumen eliminated, but it was never entirely absent. Evidently some other factor existed causing the elimination of albumen and this was the factor I sought to eliminate.

Following out preconceived ideas, some clinicians have explained these differences by alleging the coexistence of a derangement of the renal circulation and an alteration of the epithelial cells, (see *Riforma Medica*, 9, 10, 11, July, 1887, clinic of Prof. Maragliano by his assistant, Dr. Livierato). This explanation much resembles that of porosity advanced by Leube, and, in order to admit it, it must be supported by a preliminary demonstration that the renal epithelium has a different selective affinity for albumen under different nutritive alterations. Without that, it is reduced to a mere hypothesis, and, for my part, I consider it inadmissible.

I have undertaken to reconcile the apparent contradictions by new investigations in experimental pathology, with a view to ascertain whether the blood-pressure alone can cause the passage of albumen into the urine. In order to do this, I had recourse to a very simple expedient, viz.: the transfusion of a certain quantity of blood from one animal to another of the same species, taking care to measure the pressure before and after the operation. It is evident that in this way we can effect an increase of pressure in the entire circulatory system resembling that observed in diseases, without producing serious functional derangement and thus complicating the experiment with other factors. The following is the result of my experiments.

Experiment I.—*April 12, 1887.* I took two dogs, the larger having a weight of 9.3 kilos., and the smaller 4.5 kilos. Before commencing the experiment the dogs were kept separate, each upon the same diet of bread, broth, meat, and milk. For three days an analysis of urine showed no trace of albumen and no morphological morbid element. The fourth day I firmly fixed the two dogs after the method of Bernard, and connected, by a transfusion apparatus, the carotid of the larger dog with the femoral vein of the smaller. Before opening the communication I took the blood-pressure of the smaller dog by the hæmodynamometer of Trauck, and found the initial pressure to be 29 mm. The blood was then allowed to pass for ten minutes. The hæmodynamometer went up gradually to between 36 and 37. Fifteen minutes the hæmodynamometer remained steady at 33, the little dog, weighing 5 kilos., having gained 450 grammes in blood. The dog was returned to his kennel, and an assistant collected the urine as it was voided. The diet was the same as before the experiment. The animal voided 300 c. c. of urine in twelve hours. The urine was reddish, under the microscope hæmoglobinuria was observed, and there was a trace of albumen corresponding to the amount of blood in the urine.

Experiment II.—*April 13, 1887.* A very large dog weighing 15.4 kilos., and a small dog weighing 5.3 kilos. were used with the same precautions as in the preceding experiment. No albumen in the urine. Initial pressure of hæmodynamometer in the small dog was 29.30 mm. Transfusion for twelve minutes from the carotid of the large dog to the femoral vein of the small dog. The hæmodynamometer went up and stood between 41 and 42 mm. At twenty minutes after the transfusion the pressure went down and remained steady at 35 mm. After the experiment the animal weighed 5.950 kilos., having gained 550 grammes of blood. Half an hour after the experiment terminated the little dog vomited a thick, glairy, and sanguinolent liquid; weighed again, he had lost 105 grammes; within twenty-four hours he voided 550 c. c. of urine. Color sanguinolent, spec. grav. 1.007, albumen 1 in 1000. Under the microscope a considerable number of red globules appeared. There was evidently polyuria and hæmoglobinuria.

19th. The animal was depressed, weighed 5.2 kilos. He ate only meat soup, passed but 90 c. c. of urine, which was still more sanguinolent and contained many granular casts. Spec. grav. 1.032, albumen 3 in 1000, evidently arising as before, from the hæmoglobinuria.

20th. Forty-eight hours after the transfusion, the animal weighed 4.92 kilos. Urine for twenty hours 110 c.c., until 6 A. M. next day (death of the animal). Spec. grav. 1.030. Color, slightly reddish. Contained some blood globules and a great number of granular and granulo-epithelial casts. Trace of albumen. Refused all food and drink.

21st. Died sixty eight hours after the transfusion. The *autopsy* showed the kidneys slightly swollen, dark red on section; cortical substance engorged with blood with brighter red and some yellowish points. Liver engorged with blood; on section deeper red than normal. Heart showed slight hypertrophy of the left ventricle.

Microscopical examination. Hemorrhage at many points of the medullary and cortical substance both between the tubes and into the cap-sules of Bowman. In other glomeruli there was observed a slight dilatation of the vascular loops. In some capsules there was observed a small quantity of granular substance.

Epithelium of the tubuli generally normal, rarely the epithelium was wanting and a small quantity of a granular substance observed. In one tube a cast was seen, besides this the large vessels contained a granular mass.

This experiment was repeated with four other dogs with identical results. In two experiments I transfused only 250 and 280 grammes of blood. In the first the difference shown by the hæmodynamometer was 3 mm., the weight of the animal being 4.85 kilos. In the second experiment a difference in the hæmodynamometer of 2 mm., the dog weighing 5.3 kilos. In the last two experiments the microscope showed but few globules of blood, the color of the urine being normal, no appreciable albuminuria, microscopical examination showing but slight hyperæmia.

The conclusion to be drawn is clear. Increase of pressure in the renal circulation produces first polyuria, as Charcot has already shown, without producing albuminuria properly so-called, and a more or less considerable hæmoglobinuria, and perhaps, also, a true blood extravasation, corresponding to which there is present a certain quantity of albumen. The kidneys are always hyperæmic without alteration of the epithelium of the tubuli. The granular substance which is observed within certain capsules and tubes here and there should be ascribed to the blood which has been extravasated and altered for three previous days.

In order to make these experiments still more conclusive, I repeated them, on the one hand, using transfusion upon a little dog, and then trying on another dog an intravenous injection of defibrinated blood which I had drawn immediately after the conclusion of the former experiment from the large dog, already used for transfusion.

It is evident that in these new experiments I intended to reproduce the same mechanical conditions, that is to say, the same general increase of blood-pressure in the two smaller dogs, employing in the one case dead blood drawn from the artery and defibrinated by whipping, so that the same physico chemical conditions did not exist as in the living, and circulating blood transfused from the other dog.

16*

Experiment, May 1, 1887 (10 A. M.).

I took three dogs:—

1st. A large dog, for transfusion, weight . . 22.600 k.
2d. Two other dogs, which I will distinguish as
A, weighing . . . . . 5.950 k.
B, " . . . . . 5.900 k.

For four days the same conditions of uniform diet were followed as in the previous experiment. Urine normal, non-albuminous, except a slight opalescence, not susceptible of estimation, in dog A.

The following is the analysis of the urine twenty-four hours before the experiment:

	Dog A.	Dog B.
Urine,	500 c. c.	350 c. c.
Sp. gr.,	1.015	1.011
Reaction,	Acid.	Acid.
Color,	Straw.	Yellowish.
Appearance,	Slightly turbid.	Limpid.
Albumen,	Opalescence.	None.
Urea,	12.781 gr. per 1000	10.232 gr. per 1000

Transfusion was effected from the carotid of the large dog into the femoral vein of dog A. Initial pressure in the carotid of dog A, before the transfusion, 27 to 28 mm. After five minutes of transfusion the pressure oscillated between 34 and 35. The operation was stopped, the weight of the animal found to be increased 410 gr. An hour after the operation the animal voided 85 c.c. of urine, sp. gr. 1.013, albumen; opalescence greater than before the operation. Three hours later he again voided 100 c.c. reddish urine, sp. gr. 1.011; slight hæmoglobinuria, a trace of albumen.

While waiting there had been drawn from the same carotid of the large dog nearly half a kilogramme of blood, and having defibrinated it by whipping, 350 gr. of it were injected into the external saphenous vein of dog B. Initial pressure in the carotid oscillated between 27 and 28 mm. The injection was made slowly, the operation lasting ten minutes. After the intravenous injection the hæmodynamometer marked 31 to 32, and remained there. Animal weighed 6.250 k.

An hour after the injection, 70 c.c. urine voided, containing 0.50 c. c. of albumen; color nearly normal. Under the microscope a few scattered red blood globules. During the two hours following the injection the animal three times vomited the milk, soup, and bread which he had previously eaten.

In order to compare more readily the experiments I have placed in the following table the results of the analysis of urine during forty-eight hours after.

May 2.

	Dog A. (transfusion). [Ate during the 24 hours nearly half his food, meat, broth, bread, milk.]	Dog B. (injection). [merely drank the broth, refusing the rest.]
Weight . . .	5.820 k.	5.600 k.
Urine in 24 hours .	390 c. c.	180 c. c.
Sp. gr. . . .	1.014	1.023
Reaction . . .	Neutral.	Alkaline.
Color . . .	Reddish yellow.	Bright yellow.
Appearance . .	Slightly turbid.	Slightly turbid.
Urea per m. . .	14.881 gr.	15.431 gr.
Albumen per m. .	0.50 gr.	8.100 gr.
Microscope .	Large number of red globules; epithelial cells; no casts.	A few scattered red globules; epithelial cells; no casts.

May 3.

	Dog A. (Eats very little.)	Dog B. (Refuses all food and drink.)
Weight . . .	5.350 k.	5.065 k.
Urine in 24 hours .	255 c. c.	190 c. c.
Sp. gr. . . .	1.029	1.020
Color . . .	Reddish yellow.	Dark yellow.
Reaction . .	Acid.	Neutral.
Appearance . .	Slightly turbid.	Quite turbid.
Urea per m. . .	22.190 gr.	14.260 gr.
Albumen per m. .	0.65 gr.	12.50 gr.
Biliary pigments .	Trace.	A notable quantity.

	Dog A. Eats very little.	Dog B. Refuses all food and drink.
Microscope	Many red globules; epithelial cells; a few hyaline casts.	Hyaline and granular casts; epithelial cells colored yellow; a number of fresh bacteria.

Dog A, strength feeble, yet stood up. He was killed on the morning of May 4.

Dog B, had been all the time very dull, and was found dead at 7 A.M. May 4.

The microscopical examination of the kidneys of dog A gave similar results as the first experiment, but less in amount, and more limited in character.

The microscopical examination of the kidneys of dog B showed diffuse hemorrhage everywhere. In the tubuli of both the medullary and cortical substance true casts were seen, some quite large. In other tubes some epithelial necrosis was found. In the glomeruli the epithelium was in rather good condition. There was an accumulation of a granular or grumous substance, and its behavior with acetic acid and picro-carmine led me to believe that it was an albuminous substance which, after traversing the glomerulus without undergoing any appreciable alteration, had passed into the tubuli, where it had coagulated, forming casts. As a consequence, in some tubuli the epithelium was found to be more or less altered.

From these experiments conclusions can be clearly drawn. On the one hand, they show that in consequence of transfusion and simple increase of blood pressure there is no passage of albumen, and that, on the other hand, a death of the circulating albuminoids is sufficient so to change their physico-chemical constitution that they become a foreign substance to be totally eliminated, although the blood pressure was less than in the transfusion experiments.

Another fact naturally presents itself, and again proves what I demonstrated several years ago, namely, that the functional strain that the kidney must undergo in order to eliminate useless albuminoids sets up secondary irritative action that simple blood extravasation does not. This is shown clearly in the histological changes in the kidney of dog B compared with the almost normal condition of the kidneys of dog A, excepting the mechanical hyperæmia and the presence everywhere of red globules.

In order to complete these experiments I had yet to clear up a doubt which had arisen in my mind with regard to those cardiac diseases associated with albuminuria, in which after an improvement in the circulatory mechanism by proper treatment, there was a considerable diminution but not a complete disappearance of albuminuria. This had led me to believe that if the increase of blood pressure alone was incapable of effecting a filtration of albumen we still might suppose that it was capable of sensibly increasing it when another fundamental, pathogenic condition preëxisted, namely, the dyscrasic condition of the albuminoids, or, as may be said, the pressure of a large quantity of dialysable albumen in the blood stream which ought to be forcibly eliminated as incapable of playing its part as an assimilable substance, and on that account foreign to the organism.

I believe that I have succeeded in demonstrating in a very conclusive manner the hypothesis which I had conceived.

I took a dog weighing 8.3 k. and put him under observation on a diet of broth, meat, and milk soup for three days together to assure myself that the urine was normal and free from albumen. I commenced subcutaneous injections of 60 grains of white of egg diluted with 20 grains of distilled water, dividing this dose into four injections during twenty-four hours. After a few hours albuminuria became manifest, and the amount of albumen eliminated in twenty four hours increased slowly. Ten days after the injection the animal voided 3.51 grains of albumen during twenty-four hours.

I effected a transfusion of blood into this dog from a larger dog under conditions similar to those of the experiment of May 1st. The urine of the large dog was quite normal and without albumen. Initial pressure in the carotid of the albuminuric dog before transfusion 28 to 29 mm. Transfusion lasted eight minutes, pressure oscillated between 33 and 36, becoming steady at 34. Animal weighed after transfusion 8.85 k. gaining 5.5 grains of blood. In the urine collected during twenty-four hours after the operation, there was found 620 grammes of albumen, nearly double what the albuminuric dog had voided before the transfusion.

This clearly proves that when there already exists in the blood, as I have before stated, a certain amount of albuminoid principles, which, by their physico-chemical constitution are not assimilable, the increase of blood-pressure increases filtration in an almost mechanical manner, in the same way as occurs when water produces polyuria. In this phenomenon the renal filter is passive, and the experimental results fully confirm the hypothesis which I had put forward to explain—the phenomena of albuminuria persisting in cardiac cases after the restoration of the vascular equilibrium. But in practice another thing may happen. When we put these cardiac patients under a treatment of tonics, and of remedies which regulate the heart, and at the same time on a vigorous milk diet, then the albuminuria totally disappears, because with the curative action of the change of blood-pressure, there is also a reconstructive action of the albuminoids of the blood under the influence of the milk diet, due, doubtless, to the truly enormous assimilability which occurs in derangements of nutrition.

It now remains to finish the second part of my work, that is to say, to determine the influence which alterations in the renal filter may have on the albumen of the urine. In order properly to judge of this question, it will be sufficient to recall the numerous clinical cases in which there is not the slightest trace of albumen in the urine during life, while the autopsy shows the existence of a nephritis, principally interstitial, but coexisting with an epithelial lesion. There is not an observer who has not recorded many facts of this kind. It is evident that if nutritive alteration of the epithelium of the renal filter were necessarily the cause of albuminous filtration, the exceptions just cited could not occur, but experimental pathology may to a certain extent clear up this question. For this rea-on I have repeated the experiments already made by others, especially to determine the relation between the degree of histological renal alteration and the quantity of albumen eliminated. The substance which I have em-

ployed is cantharidine. I produced poisoning, both acute and chronic.

In acute poisoning, produced by injecting under the skin of a hog of medium size (5.14 k.) a solution of cantharidine in glycerine (4 parts glycerine to 5 parts cantharidine), the urine at the end of an hour became sanguinolent, and contained 0.55 of albumen per m. The animal died in three hours. At the autopsy the cortical substance was found swollen and congested. The glomeruli much changed. In some of them the lining epithelium was partly gone, so that half of a glomerulus was still invested with epithelial nuclei, while the other half was transformed into a fibrous mass without nuclei. Lymphatic cells were found in the glomerular cavity with a granular substance, and red blood-globules in great number. As to the tubuli, there was found in their interior an amorphous substance (a product of exudation according to Cornil), and in some places there was a preliminary stage of epithelial necrosis.

Chronic poisoning by cantharidine is still more significant. For three weeks I carried on subcutaneous injections of cantharidine in dogs of about the same size. The daily dose was $\frac{3}{50}$ of a grain. The urine, slightly sanguinolent, especially during the first few days, never showed more than 0.70 to 0.85 gr. per m.), a certain quantity of which related to the exudation of blood due to the inflammation. After three weeks the renal alterations were more considerable. Besides the glomerular alterations already mentioned, relating to the very marked inflammatory action in some places, there was considerable alteration of the tubuli. The epithelium was flattened, and in the lumen of the tube there was found a hyaline substance (exudate). In some places the epithelium of the tubuli had a granular appearance. In other places the convoluted tubes showed cells undergoing granular, fatty degeneration.

Comparing these alterations with the very slight quantity of albumen contained in the urine, it is evident that there is here not only a passage of albumen, pure and simple, but a filtration of serous fluid from the blood, due to the inflammatory condition of the kidney, which is not at all the same thing, and which clearly explains the small quantity of albumen in the urine, while on the contrary, in true albuminuria, characteristic of Bright's disease, there is a considerable quantity of albumen given off in twenty-four hours, at a period of the disorder when the histological alterations of the filter are high, compared with those produced by cantharidine poisoning, though this latter has a degree of albuminuria much less; and to be exact, we must say that this albuminuria is not the albuminous filtration, pure and simple, observed in some diseases, principally in Bright's disease. It is on the contrary, one of the effects characteristic of all inflammatory action.

The final conclusion from these investigations is that the fundamental pathogenic conditions which produce elimination of albumen by the kidney is the dyscrasia of the albuminoids, or, in other words, the peculiar alteration in their physico-chemical constitution which makes them unsuitable for assimilation, and consequently forces them to be eliminated by the emunctories and particularly by the urine and the bile. It is evident that albuminocholia only occurs when there is a condition of dyscrasic albuminuria.

The two other conditions which relate to urinary secretion are not capable of effecting the passage of albumen from the blood through the renal filter, because in their perfectly normal constitution the albuminoids of the blood are not intended to leave the organism, as stated at the beginning of this paper. This is an error of physiology produced by the exaggeration of a purely anatomical point of view. The other factors in the urinary secretion, that is, increase of blood-pressure and histological alterations of the glomeruli and tubule, play an entirely secondary part, and are not concerned in the true albuminuric pathogeny, because the change of pressure occasions albuminuria only when it already exists by reason of a dyscrasic condition, and the histological alterations brought about by inflammatory action necessarily give rise to that slight elimination of albumen which characterizes all inflammatory exudations.

The practical conclusions to be deduced from these investigations are as follows:

1. We should absolutely give up the idea still current in practice that albuminuria must always coexist with nephritis. The most frequent case of chronic albuminuria is that in which albumen filters through the kidneys because of defective assimilation of albuminoids.

2. We must abandon the idea still held by many, that we can supply the loss of albumen by a highly nitrogenous diet, because this can only increase the albuminuria, the overloading of the organism with nitrogen only augmenting the defective assimilation of albuminoids. On the contrary, as soon as albumen is seen in the urine we should at once have recourse to a milk diet, which in a few days is sufficient to cause the albumen to disappear, or at least to decrease considerably.

3. We must banish astringents of every kind in treating albuminuria, especially that of Bright's disease, because we must recognize that the elimination of albumen by the urine is for a definite and necessary purpose, and that by reason of this incessant effort the organism maintains its integrity. The use of gallic acid as an astringent has happily done neither harm nor good, because it was based upon a pharmacological error, for gallic acid is not an astringent, but we still find that certain very powerful styptics, like the preparations of lead and iron, which are unquestionably injurious to patients, are recommended, and I have often found their effects to be very dangerous, aggravating the principal disorder where they succeed in diminishing the filtration of albumen by their action on the capillaries.

THE TREATMENT OF THE FINAL STAGES OF PHTHISIS.[1]

By J. H. MUSSER, M.D.,
PHYSICIAN TO THE PHILADELPHIA HOSPITAL, BLOCKLEY.

The treatment of phthisis is of the most intense interest to the busy practitioner. No discourses in

[1] Read at the meeting of the American Climatological Society, Baltimore, 1887.

medicines are received with more avidity than those which herald a new method for the treatment of consumption, or hurl forth a new specific for its cure. The reason is obvious. But it is quite true, also, that a very large, indeed, too large a share of the monographs deal with the incipient stage of phthisis, and leave the treatment of the final stage to be evolved from the more or less limited experience of the practitioner. In fine, it is too often forgotten that we must alleviate suffering as well as cure disease. The burden of the subsequent, without a doubt most trite, remarks applies to the treatment of the final stage. Neither the first, nor the second, nor the third stage in its entirety, will be considered; only that portion of the third stage which precedes the finale. The racking torment of the beginning has passed; the dreadful anguish of the middle period is gone; the third period is fast waning, and that slowly creeping march of suffering and forbearance, filled with the inspiration of hope, has begun, to end only in the grave.

What are we to do in these final hours of suffering? Are we able to meet the demands upon us? Is the professi in sufficiently taught to administer to the comfort of these afflicted ones? In vain does one look to the monographs and journals for suggestions; no words are uttered in the lecture-room; for aught we gather from medical literature the care of the patient dying of phthisis devolves entirely upon the nurse. Those of us who are hospital physicians alone can scarcely appreciate the mental anxiety and emotional distress of him who daily administers to the wants of a patient, too often a friend, dying of this disease. It is easy for the *chif* to leave such duties to the interne or the nurse. Quite different, however, for the family practitioner. In these cases above all others the powers of the true physician are beautifully displayed. Here it is that the exercise of the high and holy qualities typified of old by the Master Physician are essential.

Yet, withal, a thorough knowledge of therapeutics is required for the pain that is here, and the ache that is there; for the cough of to-day, and the laryngeal spasm of to-morrow; for the dyspnœa of manifold causes; for the vomiting in the morning and the retching at night; for fever and sweating; for wakefulness and sleep; for the thousand and one ills—to relieve which the physician must have a mind fertile of expedient, and abundant of resource.

The suggestions regarding the management of the late stage of phthisis are derived alone from the writer's personal experience; much more profitable though it would be, time prevents detailing the experience of others.

External symptoms.—For the relief of erythema from pressure and moisture, remove the cause, if possible, apply astringent lotions and drying powders. The extract of hamamelis diluted, or the aqueous extract of the shops; borax and alcohol; the latter alone; sulphate of zinc, twenty grains to a pint of water; alum and water; carbolic acid (ten drops) in water (℥j); or alum and alcohol carefully applied, is grateful and remedial. Starch, rye flour, fullers' earth, oxide of zinc, subnitrate of bismuth, iodoform and starch, are drying powders, named in the order of cheapness, that are efficient. For painful erythemata, iodoform, oxide of zinc, and subnitrate of bismuth with starch in combination, answer well.

Iodoform	1 part.
Zinc	2 parts.
Bismuth	2 parts.
Starch	4 parts.

A saturated solution of iodoform in ether, applied every day, or every other day, seems to relieve pain and remove congestion. A mixture of iodoform and surgical collodion relieves pain quickly. One must not forget the conventional soap-plasters, while glycerine, applied frequently, is also of service. Ointments of iodoform, or of zinc, with the extract of opium or belladonna, are often necessary. For bed-sores remove pressure, and apply, by dusting, iodoform, Peruvian bark, oxide of zinc, or subiodide of bismuth. Oakum saturated with balsam of Peru is often excellent. Surgical principles will guide in the treatment of exceptional ulcers.

Œdema of the legs is frequently most distressing; bandages and elevation of the limbs are required. The swollen legs are the seat of a very painful erythema; here again, sedatives, as laudanum, and lead water, or hamamelis, are required. One of the easiest prepared and most soothing applications for any œdematous erythema, is the so-called starch poultice; ordinary starch mixed with water to the consistency of thick cream, spread on linen, and applied.

Apart from the usual pains in the thorax, the patient suffers from general aching and soreness, and from local areas of pain. Rubbing with stimulating applications, alcohol, soap liniment, arnica, chloroform liniment, or with dry heat or applying hot flannels, are necessary. Local pains may be relieved if in the course of the nerves, or in the extremities, or where undue pressure has been exerted, by cannabis indica; laudanum may also be used, but is inferior in value; lanoline is a good vehicle for any substance. Plasters are not generally pleasant; belladonna, opium, and soap may be selected.

Chest pains are usually severe. Use dry heat, by means of hot cloths, hot plates, or hot water bags, or sinapisms, or rubefacient liniments. Pain in the epigastrium and about the heart often occurs in the last week, and is most horrible; dry heat is the most serviceable of external applications. The pain appears to be due to tension on the adherent pleura by collapsing or contracting cavities. The secret of success in the treatment of the general and local pains, is the ability to ring the changes on various articles; the wrought-up nervous system, conjures up, or intensifies pains, which require an agile mind to relieve.

Gastro intestinal symptoms.—For the dry, parched, or fevered lips, use cold cream; camphorated or benzoated oxide of zinc; camphor water and glycerine, with or without borax, or boracic acid; or even glycerine alone, may be used. An erythematous stomatitis is often present; demulcents are required. Decoctions of marsh-mallow, or gum arabic, are soothing; morphia, or the syrup of poppies in a demulcent, relieves the burning distress. The slippery elm

bark of boyhood days, chewed, furnishes a soothing coating to the mucous membrane. The burning that attends erythemata may be relieved by allowing bits of borax to dissolve in the mouth, or by applying boracic acid locally. Ten grains of the latter to a half ounce each of water and camphor water are sufficient. Alkaline waters iced are grateful.

For ulcerative stomatitis and thrush, phenol sodique, Dobell's solution, and Listerine, either of them well diluted, are detergent, and often soothing. If the ulcers are few, iodoform in ether touched on them will quickly heal. Boracic acid and camphor water in distilled water is a cooling mouth wash; myrrh is commonly used by the laity. Alcohol in water can be used; a solution of the bichloride of mercury (1:1000) in iced water seems to be cleansing. Flatulency is a most distressing cause of suffering. External applications of heat, dry or moist, are required. The aromatic spirits of ammonia, spirits of chloroform, Hoffman's anodyne, brandy and lime-water, creasote and charcoal in pill, with or without pepsin, or a mixture of carbolic acid, tincture of cardamom, bicarbonate of soda, with mint water, most frequently relieve it. The recent preparations of pepsin, and pancreatin, are of inestimable value. A bitter before eating, with or without an alkali, prevents a succeeding flatulency: either nux vomica, gentian, and quassia.

Vomiting arises from laryngeal irritation, from cough, from exhaustion, from local gastric irritation, by food undigested undergoing fermentation. Remove the laryngeal irritation by the local application of astringents and anodynes, by glycerite of tannin with or without morphia, or by astringent and anodyne lozenges. The vomiting of food by cough is prevented by administering morphia half an hour before meals, or by taking deodorized tincture of opium before the meal. The vomiting that occurs after rising is often prevented by taking some stimulant with nourishment, before assuming the erect posture: sherry and egg, or milk and brandy. The vomiting and retching that occur from excessive coughing is to be relieved by the anodyne that checks the cough; the more simple the anodyne the better; minute doses of morphia, if not contraindicated, are the best. The vomiting of exhaustion is controlled by stomachics, as quassia, or gentian in infusion; by stimulants, as champagne, brandy, and aromatic spirits of ammonia. Vomiting due to local irritation and congestion, caused by undigested and fermented food, is relieved by antifermentatives: carbolic acid, creasote, bismuth and charcoal; by artificial aids to digestion, by the use of peptonized or pancreatized foods; by alkalies, as iced lime-water, or Vichy water, which act as local sedatives; by carbonic acid water, the effects of which are sedative. The stimulating effect of a sinapism, or the sedative effect of a blister, must be invoked by their respective indications. It must not be forgotten that lying on the right side increases the tendency to vomit, lying on the other side having an opposite effect.

Pain in the epigastrium, a most common symptom from flatulency, from an irritated congested stomach, from a diaphragmatic pleurisy, is to be met by treating the respective causes. A gastric sedative, as subnitrate of silver in pill before meals, with a minute dose of opium, prevents the pain that ensues after food.

Diarrhœa, if colliquative, may be controlled by stimulants, as burnt brandy, ammonia, or camphor; if tubercular, by large doses of astringents. Bismuth, from thirty to sixty grains in each administration, has served the writer as well as any combination of drugs. Logwood is a most valuable astringent, the fluid extract being used most frequently.

Intestinal flatulency is often the cause of diarrhœa, and can be prevented by salicylic acid, by antifermentatives, and by pancreatin. The diarrhœa that follows immediately on taking food is treated by an opiate; preferably, deodorized tincture of opium in small doses, five to ten drops, or the powder one-twelfth of a grain, with silver or bismuth, before meals. A septic diarrhœa ensues also in the last stage, and is to be checked by salicylic acid, by naphthol, or other forms of the naphthaline series recently introduced into therapeutics. The diarrhœa of amyloid diseases can only be controlled by opiates.

To relieve the cough of the last stage is most difficult. Dryness of the upper air-passages is most distressing, and local applications are generally painful. By the aid of a mirror, suitable remedies, always demulcent in character, can be applied to the congested areas about the larynx and epiglottis. Glycerine applied with a brush relieves the dryness; Dobell's solution thus applied is of service. The applications must be made often to the dry areas. Listerine with glycerine is of much value. Inhalations of terebinthinated vapors, or of simple aqueous vapors, are most grateful. The simplest form of inhalation is the best. We frequently have generated the vapor in a sick cup, covering the top and inhaling by the mouth piece. The ineffectual efforts to cough can be aided by hot water, by hot water and brandy, and by the aromatic spirits of ammonia well diluted. Hydrocyanic acid has never been of any service in my hands for cough, while opiates are to be used with caution. A moderate dose of morphia may produce serious, even fatal symptoms. Codeia has disappointed the writer. Hyoscyamus and belladonna frequently add to the distress by producing dryness of the fauces; to relieve the dyspnœa, our utmost efforts are in demand. Ammonia, alcohol, Hoffmann's anodyne, and draughts of hot water are required in turn; external heat contributes to the relief. One of my professional friends says he has seen the air-hunger relieved by quebracho. Inhalations of oxygen should be theoretically of much service; the writer has never used them. The patient must be supplied with fresh, cool air, a source of relief to the distress. Attacks of dyspnœa, of course, are increased by flatulency, and this complication must be removed.

Hemorrhage in the last stage is usually profuse. A knowledge of the pathological anatomy of the lung at once shows the futility of astringents. Rest and opiates are essential, stimulants may be required; ice or cold cloths over the chest are imperatively demanded if it persists.

Laryngeal and faucial tuberculosis increases the distress of the patient. As long as feasible, cocaine

to render the taking of food possible must be applied to the ulcerated pharynx and larynx. Insufflations of morphia alone, or with iodoform and starch, must be practised, and over the larynx frequent fly blisters applied. One-eighth to one-quarter of a grain of morphia, with one grain of iodoform and three of starch, insufflated, or added to treacle and retained by the patient as long as possible in the larynx, gives much relief.

In the late stage of phthisis some means must be used, but not as imperatively as in the earliest stages, to combat fever. Quinine frequently aggravates nervousness, and is inadvisable. The salicylate of sodium, doses of five grains, guarded with a drachm of whiskey, every three hours, is a reliable antipyretic. It is also of much service after the manner of administration by Jaccoud. The general restlessness and nervousness which ensue at this period of phthisis must be prevented or allayed by quiet in the surroundings, by free access of pure air, by the administration of light liquid food only, and by the use of stimulating anodynes, preferably Hoffmann's anodyne; for a similar purpose, valerian and asafetida, by the mouth or rectum, or, if practicable, musk can be used; they are of much value. Gentle frictions allay restlessness, while ministrations with soft voice and gentle action allay an easily perturbed, nervous system. By means akin to these, we can truly administer to the sufferings of our patients. It is quite certain, however, that the firm voice, the truthful countenance, the inspiring touch, sustain and soothe in this trying passage through the valley of the shadow of death.

THE PRACTITIONER.

ON THE EARLY LOSS OF KNEE-JERK IN DIPHTHERIA.[1]

BY R. L. MACDONNELL, B.A., M.D.,

PROFESSOR OF HYGIENE IN McGILL UNIVERSITY, PHYSICIAN TO THE MONTREAL GENERAL HOSPITAL.

Not long after the recognition of diphtheria as a distinct disease, it was observed that certain definite nervous symptoms made their appearance shortly after recovery, and one by one these were carefully studied until we soon came into possession of the knowledge of a certain definite group of nervous phenomena to which the comprehensive title of diphtheritic paralysis has been given. Of this group the most commonly observed symptoms, the paralysis of the veil of the palate, of the laryngeal, of the orbital and ocular muscles, and of the heart, have long been recognized, as well as sensory disorders of various kinds. Such nervous sequelæ occur after all the exanthems, but as very rare events, while so frequently do they follow diphtheria that it is no great exaggeration to say of a case that the non-occurrence of paralysis throws a shade of doubt upon the original diagnosis of diphtheria.

This frequent occurrence of post diphtheritic paralysis is a characteristic feature in those forms of the disease met with in Montreal. Of the eighteen severe cases on which the statements of this paper are based, the nervous system was to our knowledge distinctly attacked in 5, or 27.7 per cent., and of this number two died of sudden heart failure, and though the number of cases cited is small and scarcely sufficient to enable a just comparison to be made with the statistics furnished by others, yet the difference is remarkable when we consider that the proportion given by Roger is 17 per cent., by Sanné 11 per cent., and by Monckton 1.15 per cent.[1] Let it be remembered, however, that two great fallacies come into play, firstly, the diagnosis of the original disease—Was it real diphtheria?—and secondly, were the cases followed up after they left the hospital, the period in which diphtheritic paralysis was likely to develop.

Making all allowance, it is still evident that among hospital cases, in true diphtheria, paralysis is a much more common event than is generally supposed, and this has been made more evident by the observation of Dr. Buzzard in 1882, that Westphal's knee-jerk phenomenon was absent in that form of paralysis commonly called diphtheritic, and by the further observation of Bernhart (Virchow's *Archiv*, Bd. 99), that loss of knee jerk may precede the other symptoms, and may even occur without any other indication of nerve implication, in short, that absent knee-jerk may alone point to a preëxistent diphtheria, so that a diagnosis of tabes dorsalis might readily be made, especially if, as is, indeed, often the case, the eye symptoms from diphtheria happen also to be present.

The object of this paper is two-fold—firstly, to add some evidence in favor of Bernhart's observation, and secondly, to show that loss of knee-jerk occurs with the earliest symptoms of the disease itself, and coincident with the very first appearance of the throat affection.

The cases on which the following observations were made, were all hospital patients. To avoid possibility of doubtful diagnosis, all private cases have been excluded from consideration. Each hospital case was seen by medical men besides myself, and was considered of sufficient severity to be placed in the infectious block of the hospital, and these hospital cases were all my own. I did not borrow any from my colleagues. Then, again, of the cases admitted, three of doubtful diagnosis have been excluded. Thus, during the last six months eighteen cases have been under my care. Of these knee-jerk was absent on the day of admission in 10 and present in 8.

Loss of knee-jerk may precede other nervous phenomena, and be the means of enabling a diagnosis to be made of the nature of the previously existing throat affection. He is an illustration:

A boy, aged fourteen, previously strong and healthy, returned home from the country, where one of his young friends had died of a sore throat. There were at his home four children, three girls and a boy, aged eight to sixteen. On the day of his return the patient looked somewhat anæmic, and complained of feeling weak, owing to the effects of the quinsy he was reported to have had. There was a slight

[1] A paper read before the Canada Medical Association, August 31, 1887.

[1] Ross: Diseases of the Nervous System.

discharge from the nose, but nothing to point to the preëxistence of diphtheria but the absence of knee-reflexes. Isolation was attempted, but too late, and three of the four children took the disease. The patient eventually suffered from very great debility and regurgitation of food, the voice became nasal and recovery was long delayed. The knee-jerk did not become normal for four months. The sisters went to the hospital, where one died, the other two lost the knee-reflex immediately, and subsequently had diphtheritic paralysis.

Now, here was a case in which loss of knee jerk enabled a definite opinion to be formed as to the nature of the so-called quinsy. Such knowledge might be put to practical use in the prevention of infection, though it availed little in this particular instance.

The cases of the two sisters of this boy show that loss of knee-jerk may not only be the first evidence of diphtheritic paralysis, but that it may continue for a lengthened period as the only evidence of that condition. Both these girls, aged nine and sixteen respectively, took the disease immediately after the return of their brother, and both had very severe attacks of the throat affection. In June last, though both had well recovered, yet in both of them the knee-reflex was absent, no other nervous symptoms being present.

Knee jerk in many cases of diphtheria is absent from the very first day of the illness.

In ten of the eighteen cases the knee-jerk was absent on the day of admission to hospital. In the family above mentioned the two girls were admitted to hospital as private patients, in both knee-jerk was absent on admission, and in both paralysis occurred to a limited degree, in the elder one, aged sixteen, taking the form of general muscular debility, with regurgitation of food.

In the case of a French Canadian boy, of seventeen, admitted March 24, 1887, with severe pharyngeal diphtheria, knee-jerk was absent on admission. The three brothers of this patient had also had diphtheria, and in all three paralysis had occurred. Four months after admission, knee-jerk was still absent, and other paralytic symptoms had made their appearance.

It seems probable that early loss of knee-jerk usually indicates the advent of other paralytic symptoms. Thus, of the ten cases in which the knee-reflex was absent, two died, four developed nervous symptoms while in hospital, and of the remaining ones no satisfactory report could be obtained of their condition after they had left the hospital.

But of the eight patients whose knee-jerk was unaffected, paralysis appeared in one, two died, and of the rest no history could be obtained.

Of the causes of death of the two children with lost knee-jerk, one died from laryngeal implication, for which I opened the trachea, and the other of sudden heart failure at a time when other symptoms were abating, while the deaths amongst those with normal knee-reflex were due in both cases to spread of the false membrane to the larynx.

In one of the cases in which there was no loss of knee-jerk at the outset, and in which the growth of false membrane in the pharynx was very extensive, accompanied by very great swelling in the neck, the knee-jerk became lost in the third week of the illness; and at about this time great irregularity of the heart was noticed, and a systolic murmur at the apex was perceptible for some days. Regurgitation of food, loss of accommodation of the eye, and general debility followed. A week ago we were obliged to feed him with the stomach tube, death by starvation threatening on account of the paralysis of deglutition.

In two cases diphtheria was accompanied by a rash, knee-jerk was absent in both, and diphtheritic paralysis appeared in one.

Of two children, brother and sister, admitted on the one day, the brother died of severe laryngeal diphtheria, knee-jerk being present, the sister, in whom it was absent, lived several days free from laryngeal symptoms and doing well, but died suddenly of heart failure.

The conclusions, therefore, to which this observation leads us, are as follows:

1. In a considerable number of cases knee-jerk is lost from the first beginning of the disease, and thus affords a valuable means of diagnosis of the nature of the throat affection.

2. That loss of knee-jerk is the first evidence of the disease having attacked the nervous system.

3 Absent knee-jerk has no influence on the prognosis.

HORNY GROWTH OF THE PENIS—TWO MORE CASES.

By J. F. BALDWIN, M.D.,
COLUMBUS, OHIO.

In the issue of The News of August 6, 1887, is an interesting report of a case of horn of the penis, by Dr. J. H. Brinton, with additional references to fifteen other cases—all he could find. I am able to add to his list two cases, one occurring in my own practice.

Case I.—E. J., aged nineteen, consulted me October 28, 1885, on account of epilepsy. I found he had a tight congenital phimosis, upon which I operated. At the time of the operation I noticed on the under surface of the removed portion of the foreskin, and also on the corresponding side of the glans penis, a soft warty growth, having a sabulous feel. I made no attempt to remove this growth, which I supposed was the result of lack of cleanliness and consequent irritation.

This wart rapidly developed into a veritable horn, and at the same time nearly the entire remaining surface of the glans penis became covered with two horny plates, which encroached seriously upon the meatus. January 5, 1886, I removed the horn, with a liberal slice of normal tissue at its base. The horn had then attained a length of nearly an inch. The cut healed by granulation, but the horn returned, and having by this time reached annoying proportions, was again removed, October 3, 1886. At this operation I thoroughly cauterized the seat of growth with acid nitrate of mercury, and there has been no return. The horny plates I removed at subsequent

operations using the caustic also as before, and the penis is now in good functional condition, though somewhat scarred.

The boy stated, and I have every reason to believe his statement, that he had never been exposed to any venereal disease. He had no return of his epileptic fits for several months after the circumcision.

CASE II.—The *Journal of Cutaneous and Venereal Diseases*, of about a year ago, contained a note, taken from the *Indian Med. Gazette* for January, 1886, of "a Hindoo, aged sixty, who had had gonorrhœa, followed by phimosis, fifteen years ago. Circumcision had been performed, in consequence of preputial irritation, eight months previously, and the growth had developed since then. There were two well-marked horny projections growing from the corona glandis, and the surface of the glans was covered with a cap of similar material. Amputation of the glans, including the growth, was performed with satisfactory result."

This case bears a striking resemblance to that of Dr. Binton, in age of patient, character of growth, and treatment instituted.

MEDICAL PROGRESS.

SOME POINTS IN THE TREATMENT OF TYPHOID FEVER.—BOUCHARD endeavors to secure intestinal antisepsis in typhoid fever by the administration of

Powdered vegetable charcoal .	100 parts.
Iodoform	1 part.
Naphthalin	5 parts.

which is to be mixed with 200 parts of glycerine and 50 parts peptone; this forms a semi-liquid black mass which is absorbed in twenty-four hours, of which a spoonful may be given in a third of a glass of water every two hours. The large intestine is to be cleansed morning and night by an enema of carbolized soap, 1 to 100, each enema containing $7\frac{1}{2}$ grains of carbolic acid in a pint of water. Baths are also given, their temperature being two degrees less than that of the patient at the time, reaching finally a temperature not below 86° F. Quinine is the antipyretic preferred. Free feeding is also a feature of the treatment. The results of the disease, under this treatment, have been a mortality of from 7 to 11 per cent.; the average duration of the disease being nineteen days.—*Revue de Thérapeutique*, September 15, 1887.

TUBERCULOUS PLEURO-PNEUMONIA; PNEUMOTOMY; RECOVERY.—CASINI reports, in the *Rivista Clin. e Therap.*, 1887, No. 1, the case of a man aged forty, whose family history showed that he had come from healthy parents; a brother had died of phthisis. The patient had ten years previously suffered from pleuro-pneumonia on the right side, and since then had complained of frequent pain in the right mammary region, with fever and cough with bloody expectoration. A leech had been applied over the painful spot, and after several days a small tumor formed at the point of application, which, when incised, gave exit to pus. On the day following this incision, fever and the expectoration of a muco-purulent secretion began. The phenomena increased in proportion as the discharge externally lessened; perspiration, emaciation, and diarrhœa were also present. Physical examination showed a cavity in the right mammary region extending from the third rib to the fifth intercostal space. The sputum contained abundant bacilli. CASINI considered from all the circumstances that fresh tuberculous infection was going on, and that it was imperative to open the cavity freely, and disinfect it.

Resection of the fifth rib was performed, and the cavity was thoroughly irrigated with solution of corrosive sublimate 1–1000, and sprinkled with iodoform. After the operation the expectoration lessened, became mucous in character after ten days, and in fifteen days the fever had entirely disappeared. Bacilli were not found in the sputum. The patient recovered, and was free from fever and cough.

Casini feels justified in drawing the following conclusions:

1. Surgical interference is justified when we have to do with a circumscribed tuberculous process, and a large cavity should be treated as a tuberculous cavity in bone.

2. Under certain conditions lung cavities have a tendency to localize tuberculosis, and when such foci are promptly destroyed general infection may be checked.

3. The depth of lung cavities is no counterindication against attacking them.

ERGOTIN AS AN ADJUVANT TO DIGITALIS.—ROSENBACH, in the *Berliner Klinische Wochenschrift*, No. 34, 1887, reports good results from the combination of these remedies in (1) aortic insufficiency; (2) in idiopathic dilatation of the heart, with alterations in the elasticity and contractile power of the bloodvessels; (3) in arterio-sclerosis.

He suggests the following formulæ:

R.—Inf. sec. cornu. . . . . ℥ss.
Æther, sulphur. . . . . ♏ 45.
Acid, hydrochlor. . . . . ♏ 15.
Aquæ . . . . . ℥iss.—M.
Sig. Teaspoonful every two or three hours.

Also

Ergotin. . . . . gr. 30 to 60.
Acet, digital. . . . . ♏.75.
Aquæ . . . . . ℥iss.—M.
Sig. Teaspoonful as indicated.

In pill form.

Ergotin. . . . . gr. 45.
Pulv. fol. digital. . . . . gr. 30
Pulv. et. ext. gentian. . . . q. s.
Ad. pil. 50 in num.
Sig. Dose, two or three pills.

Also

Infus. fol. digital. . . . ♏ 23.
Ergotin. . . . . gr. 30.
Aquæ. . . . . ℥iss.—M.
Sig. Teaspoonful every two hours if needed.

POINTS IN THE DIAGNOSIS OF CONSTITUTIONAL ENFEEBLEMENT AS A GUIDE TO THE REJECTION OF RECRUITS.—DUPONCHEL, Major and Surgeon in the French army, has found (*a*) that depression of the apex

of the heart below its normal level does not necessarily imply organic disease. It is frequently the result of defective development, and the hypertrophy so often occurring in these patients at adolescence.

(*b*) Prolonged expiration over the apices, especially the right, is not a sign of tuberculosis when unaccompanied by other characteristic signs.

(*c*) Isolated, or taken together, these signs are of value when combined with measurements of the body as indicating defective constitution which may justify the rejection of recruits.—*Archives de Médecine et de Pharmacie Militaires*, September, 1887.

A Capillary Catheter for Cases of Stricture and Retention.—Dr. Cousins describes the following instrument, used in aspirating a distended bladder, in the *British Medical Journal* of September 17, 1887:

During the last two years I have made an extensive trial of the capillary catheter, and I have used it with great satisfaction in many troublesome cases of stricture retention. Many of my friends have also communicated to me their successes, so that I am now able, from an extended experience, to recommend a trial of the method at the very onset of the treatment. The operation is painless, and generally requires no anæsthetic. The little instrument is perfectly flexible, and can be used with far more ease and safety than the small gum elastic or fine silver catheters which are usually employed by surgeons.

The capillary catheter is a compound contrivance, consisting of a filiform bougie and a fine catheter, very carefully prepared with woven web and gum-elastic, and possessing great flexibility and toughness, together with a smooth and highly polished surface. The combination is about eighteen inches in length, and it can be used for pneumatic aspiration by slipping over it an India rubber tube connected with a glass bottle, fitted with a two-way cork and a hand-ball air-exhauster.

The operation is readily performed in the following manner: After injecting the urethra with warm oil, and covering the patient with blankets, the penis is drawn forward with the left hand, and the catheter gently passed down to the stricture. As soon as its progress is arrested, it must be withdrawn two or three inches, rotated between the thumb and finger, and again twisted down upon the obstruction. During the repetition of these manipulations it often readily slips into the bladder; at the same time, its free and easy movement in the urethra, together with the sensations experienced by the patient, clearly indicate to the surgeon that the stricture has been overcome, and the catheter coaxed to move in the right direction. The discharge of a little urine now takes place, and the distended bladder is soon relieved, and the urethral spasm subsides. The urine now escapes in successive jets through the catheter, and this flow can be accelerated by fixing to its end the aspirating bottle and hand-ball exhauster.

The "Tin Dressing" for Leg Ulcers.—Dr. Watson, of Boston, describes a dressing devised by him as follows, in the *Boston Medical and Surgical Journal* of September 29, 1886: There is one principle in the treatment of chronic ulcers of the leg which he thought hastened the healing process materially. The analogy was seen in the freezing of a sheet of water. If the water were smooth the skimming of its surface with ice went on more rapidly than if it were thrown into an uneven surface by the wind. In the same way if the surface of the ulcer were made flat and smooth, the epithelium would extend across it more rapidly than if, like the rough water, its surface were occupied by granulations, and the open surface were above or below the level of the surrounding skin, as in the exuberant or indolent ulcer respectively. It had, therefore, been his practice in such cases as required it to secure this condition by the application of a shield of sheet-tin on top of the ulcer to bring the surface even with the surrounding tissues. The dressing was known at the City Hospital as the "Tin dressing," and it method of application was as follows: The ulcer and surrounding surface were soaked in corrosive sublimate, 1 part to 4000, and thoroughly cleaned; a bit of protective was then placed upon the surface of the ulcer, covering a little more surface than the ulcer actually occupied, protective or some substance having a perfectly smooth surface was used in order that the new epithelium, which shot in from the edges over night, so to speak, should not be pulled off by adhering, as it did to cheesecloth or compress or anything having a meshwork-woven surface. The tin made to fit the surface on which it was to lie is then placed on the protective, and the whole as well as the surrounding tissues covered with a dry corrosive sublimate gauze dressing, which was held in place by an evenly applied bandage extending from toes to knee.

Ulcers which had been lagging for days beforehand would often take a rapid start under this dressing.

A Hæmostatic Mixture.—Pavesi has prepared the following, which is especially useful in gynecological operations; it is efficient and unirritating:

Acid sulpho-carbolic . . .	25 parts.
Alcohol rectificat.	25 "
Acid benzoic	5 "
Acid tannic	5 "
Glycerin	125 "
Aquæ rosæ	200 "

For local use.

Sulpho-carbolic acid is made by mixing one part of sulphuric acid and a half part of carbolic acid, and heating a few moments over a water bath. The benzoic acid is dissolved in glycerine and alcohol, and the tannic acid in alcohol.—*Gazette de Gynécologie*, August 1, 1887.

Cocaine Poisoning.—Schnyder reports the case of a druggist who for the relief of headache took three-quarters of a grain of cocaine and repeated it in three-quarters of an hour. Anæsthesia of the extremities and labored respiration followed, for which he took twenty drops of tinct. nucis vomicæ. Half an hour afterward spasms; cold extremities; motionless, somewhat dilated pupils; a pulse of 150, with weakened heart action and delirium supervened. Strong coffee and warmth, with stimulant inhalations, somewhat restored him; respiration became more free and the pulse became 120. For severe pains in the head cold applications and mustard leaves over the chest were applied. In four hours after taking the drug the pulse had become 80, but the patient

could not sleep.—*Corr. Blatt f. Schweizer Aerzte*, No. 15, 1887.

THE TREATMENT OF THE CERVIX UTERI WITH NITRATE OF LEAD.—CHÉRON has employed this substance as follows:

Plumbi nitrat.	1 part.
Lycopodii	2 parts.

The parts are first cleansed by cotton and glycerine, and the powder insufflated upon the diseased surface. —*Revue de Therapeutique*, August 1, 1887.

A NEW METHOD OF INHALING NITRATE OF SILVER FOR DISEASES OF THE AIR PASSAGES.—The *Journal of Laryngology* for September, 1887, thus concludes its investigations of this mode of treatment, which has been extensively used in Sweden and Denmark.

On reviewing the advantages and disadvantages of the method of inhaling nitrate of silver, as introduced and practised by Scandinavian investigators, its great use in the treatment of chronic bronchitis and of emphysema seems so evident, and its drawbacks so slight, if but caution is observed, that it deserves a fair trial by other practitioners. As a treatment for diseases of the upper air passages, we hardly think it has any advantage over the methods previously known.

For those who should adopt the inhalations on the principles above described, we recommend the following plan as the most simple and practical. In the middle of a small room is placed, on a low table, a small Berlin crucible or evaporating pan, containing one part of nitrate of silver and three parts of ammoniac nitrate, and under the cup is placed a spirit lamp, which heats it very slowly. The patients, who are sitting around the table, need not protect their faces, but linen or white clothing should be covered. Each inhalation ought not to last longer than thirty to forty-five minutes, and the treatment should not be extended over too lengthy a period.

CHYLOUS CYST OF THE MESENTERY.—BRAMANN reports in the *Archiv f. klin. Chirurgie*, Bd. 35, an interesting case which occurred in Von Bergmann's clinic at Berlin, in which laparotomy was performed for a cyst, as large as a child's head, in the mesentery of the small intestine, which contained a clear chylous fluid. The cyst probably resulted from the occlusion and dilatation of the thoracic duct or some other lymph channel. The cyst was opened, emptied, and its edges stitched to the abdominal wall; its total excision was impossible on account of the danger of intestinal gangrene from the severed mesentery.

ACETPHENETIDIN, A NEW ANTIPYRETIC.—KOBLER concludes from his study of this drug that it is an efficient antipyretic, the use of which is not followed by inconvenient symptoms. It is given in doses of eight, nine, or ten grains; one such dose being more useful than smaller, repeated doses.—*Wiener medicinische Wochenschrift*, No. 26 u. 27, 1887.

ANTISEPTIC CIGARETTES. — DR. MACNAUGHTON JONES describes in the *British Medical Journal*, of September 3, 1887, the following antiseptic cigarettes, which he has used successfully in diseases of the pharynx and nares: 1. Containing eucalyptus and iodoform disguised with vanillin. 2. Eucalyptus with iodo-salicylic acid. 3. Coltsfoot with eucalyptus and iodoform disguised with vanillin. 4. Tobacco, eucalyptus and iodoform disguised with coffee. Each cigarette contains one grain of the active ingredient. I may mention that the iodo-salicylic acid has not the unpleasant odor of iodoform and other iodine compounds, while it is quite as effective on the lower forms of life; under combustion, iodine is evolved. All the cigarettes will be found pleasant to smoke, and the odor of the iodoform well disguised, whilst its presence in the nasopharynx for some time after the cigarette is used may be detected by its taste. Those made with tobacco, eucalyptus, iodoform, and coffee are particularly agreeable, and the odor is thoroughly disguised. So, indeed, is it with those made with vanillin and coumarin, yielding an aromatic vapor which is pleasant rather than otherwise.

A USEFUL APPLICATION FOR PRURITUS OF THE VULVA.—VERRIER advises the following lotion, which may be used by saturated tampons in obstinate cases:

Acid. carbolic. solut. . . .	1 part.
Morphiæ acetat.	½ "
Acid. hydrocyanic. dil. . . .	6 parts.
Glycerin	20 "
Aquæ	240 "

—*Gazette de Gynécologie*, August 1, 1887.

PNEUMOTOMY.—GUERMONPREZ, of Lille, reported recently to the Paris Academy of Medicine the case of a patient who had suffered for four years with persistent vomiting, for which three operations had been done: 1. The exploratory incision of the pleura. 2. Two months afterward the removal of portions of two of the ribs. 3. Multiple puncture of the lung, and a superficial pneumotomy; eight months later a deep pneumotomy was made, followed by intrapulmonary injections to liberate inaccessible and retained secretions.

From this, and allied cases, the conclusions are drawn that 1st. Exploratory incision of the pleura is not a dangerous operation. 2d. When the fetid odor of matter vomited causes a diagnosis of a suppurative centre, the incision of the parenchyma must be deep enough to reach this centre, even if it be carried through healthy tissues. 3d. If two foci which communicate with difficulty are found, they may be stimulated to healing by injections of warm, stimulating materials, which will facilitate their evacuation by the incision through the thoracic wall. 4th. When performed under proper conditions, pneumotomy is a justifiable operation, whose results should be good.—*Gazette Hebdomadaire*, September 2, 1887.

CONCLUSIONS REGARDING THE VALUE OF INOCULATION AGAINST ANTHRAX.—At the International Congress of Hygiene, recently held at Vienna, the statistics of 260,000 sheep and 29,000 cattle which had been inoculated in France in five years time, were reported, and a thorough discussion of Pasteur's method followed. The conclusion reached by Koch and others was that the utility of the method was not yet proven, and the personal report of Pasteur, whose ill-health had prevented his presence, was desired to appreciate properly the results of his treatment for anthrax.—*Deutsche medicinische Wochenschrift*, September 8, 1887.

Chemical Tests for Bacilli. — The diagnostic value of Koch's cholera bacillus having been considerably impaired by the proved existence of other microorganisms of like morphological characters, the discovery by Pohl, Brieger, and others, of a chemical reaction alleged to be peculiar to cultures of the comma bacillus was welcomed as an additional test of importance. This reaction consists in the development of a red color (*cholera-roth*) on the addition of hydrochloric acid to the cultures, and, as Brieger has shown, the color depends upon the presence of a ptomaine containing derivatives of indol. We now learn from the experiments of Ali-Cohen, of the Hygienic Institute of Groningen (*Fortschritte der Medicin*, No. 17), that the reaction is not peculiar to the comma bacillus, and that it may be obtained by the use of any mineral acid that contains the impurity of nitrous acid, for the pure acids do not produce it. The indol derivative is produced by Koch's bacillus somewhat more rapidly than it is by other morphologically identical forms; but then there are bacteria not morphologically allied to the comma bacillus which can produce this substance quite as readily. The discovery of the *cholera-roth* is thus shorn of its diagnostic value, and reliance must still be placed upon bacteriological methods for differentiating the cholera organism.—*Lancet*, September 17, 1887.

The Treatment of Lupus.—Kaposi, of Vienna, considers no remedy specific against lupus; excision of diseased tissues he regards as most often successful. His favorite applications are

Zinc. chlorid.,	
Antimon. chlorid.	āā ʒ 2½.
Irid. Florent. pulv.	gr. 75.
Acid. hydrochloric. con.	ɱ 75.

This paste may be left in place twenty-four hours. Kaposi also employs Hebra's arsenical paste:

Arsen. alb.	gr. 15.
Hydrarg. sulph. rubri	gr. 45.
Ung. emoll.	ʒ 6.

This paste is generally allowed to remain in contact with the tissues twenty-four hours.

Pyrogallic acid may be used, in combination with ung. emol., one to ten. This is left twenty-four hours in contact with diseased tissue. Also

Iodini pur.	gr. 75.
Tinct. iodin.	ɱ. 74.
Glycerin.	ʒ 2½.

may be applied. In surgical instruments Kaposi prefers Vidal's spoon-curette.—*Allg. Wien. Med. Zeitung*, Nos. 24 and 26, 1887.

The Causes of Malignant Tumors. — Rappin concludes a series of studies upon this subject as follows:

1. There exist in carcinomata, sarcomata, and some of the benign tumors micrococci whose presence may be demonstrated by coloring fluids.

2. Cultures made of the tissues of these tumors produce a diplococcus which persists unchanged.

3. In its morphology this diplococcus resembles the bacteria of suppuration; inoculation of pure cultures of this bacteria in animals produces effects similar to the tissues from which the germs were taken.

4. Particles of normal tissues, when taken with all possible precautions against contamination, when brought in contact with appropriate nutritive media, give birth to bacteria.

5. From a therapeutic stand-point interstitial antiseptic injections are indicated; and also the determination, if possible, of the cause of these growths, and its antidote.—*Gazette Médicale de Nantes*, September 9, 1887.

Tubercle Bacilli and Flies.—In a communication made to the Académie des Sciences by MM. Spillman and Haushalter, and recorded in *La Semaine Médicale*, the question of the spread of the tubercle bacillus by means of the common house-fly is considered. The authors state that they have seen flies enter the spittoons containing the sputum of phthisical patients: they were then caught and placed in a bell jar. On the following day several of these were dead. Examination of the abdominal contents and the excrement of these flies on the inside of the jar showed the presence of many tubercle bacilli. The authors point out the wide dissemination of the disease which may take place in this way, and recommend as a preventive the employment of covers with a small opening.—*Lancet*, September 10, 1887.

The Treatment of Erysipelas Complicating Surgical Affections.—Among the numerous applications used in the local treatment of surgical erysipelas, Rothe advises an antiseptic liquid as follows:

Acid. carbolic.	gr. 7½.
Alcohol (50 per cent.)	gtt. 15.
Essent. terebinth.	ʒ 3¾.
Tinct. iodin.	gtt. 15.
Glycerin.	ʒ 3¾.

Fraipont and Van Winiwarter immerse the affected part for ten or fifteen minutes in a bath of warm bichloride of mercury solution, 1 to 2000. The part is then wrapped in iodoform gauze, and enveloped with a bandage material moistened in Burow's fluid, which, as prepared by Billroth, is

Alum	1 part.
Plumbi acetat	5 parts.
Aquæ	100 "

An impervious protective is placed over all.

On the following morning the epidermis will be found macerated; superficial diseased tissues will come away, and the part may be cleansed with material dipped in sublimate solution 1 to 2000, and then dressed antiseptically.—*Revue Générale de Clinique et de Thérapeutique*, September 15, 1887.

Salix Niger and Strophanthus in Genito-urinary Disease.—Mr. Fenwick, of the London Hospital, has found, in testing a number of new drugs, that those mentioned above are useful as follows:

Salix Niger (Black Willow).—A sexual sedative of decided value; useful in ovarian hyperæsthesia, also in prostatorrhœa, spermatorrhœa, excessive seminal emissions, and enforced continence. In the latter disorders

its action is good, but inferior to potassium bromide. This is, however, somewhat counterbalanced by its non-depressant qualities. Dose, ½ dr. to 1 dr. Finding it of value in those wearisome cases of urethral neuralgias, following gonorrhœa, I began to substitute soda salicylate for it. I was impressed by the relief this latter afforded. In cases of urethral pain in the adult, I first eliminate stone, stricture, urethral granulations, and over-acid urine, and then prescribe soda salicylate 7.5 gr. to 3ss in a gratifying result.

Strophanthus.—Kombé.—I believe there is a distinct future before caffeine, digitaline, and strophanthus as adjuvants to operations on the vesico-urethral tract. We have sometimes to deal with partial or complete temporary suppression, and sometimes with rigors after operative interference or even instrumentation. Caffeine seems indicated to avert the former; strophanthus the latter. Again, if we have reason to anticipate sudden flooding of the renal vessels and consequent urinary fever as the result of an operation, then digitaline, from its power of controlling the renal circulation, is indicated. Our treatment, however, on these lines must go *pari passu* with our oncometric knowledge of drugs which affect the kidney circulation or the abdominal blood pressure. I believe strophanthus has power, worthy of further investigation, in controlling rigors. I employed it on the theoretical grounds that it increases cardiac power and general blood pressure. Five in-patients suffering from violent rigors after instrumentation we treated with the tincture in doses of 5 m. after catheterization. In no in-stance were rigors induced.—*Lancet*, September 24, 1887.

A Rare Cyst; Extirpation; Recovery.—Weil is quoted by the *Centralblatt fur Chirurgie* of September 24, 1887, in his report of a congenital cystic hygroma of the right supraclavicular region, occurring in a child eleven months old, which was successfully extirpated. The cyst was multilocular, part containing blood, and part lymph; it lay close to the jugular and subclavian veins, but did not communicate with them.

Gunther and von Koch have reported blood cysts communicating with the jugular vein, but the cyst in the present instance was unique.

Recent Formulæ for Salol.—Nicot, Vuillet, and other French observers, have found the following formulæ useful:

Saccharl. lactis	4 parts.
Salol	1 part.

The ordinary dose of salol is fifteen grains in this combination.

Salol may be made into tablets after the following formula:

Gummi tragacanth.	gr. 15.
Gummi arab.	gr. 45.
Aquæ	ʒ 2½.
Salol	ʒ 6¼.
Saccharl. alb.	ʒ 15
Essent. citron.	gtt. 5.

The dose of salol mentioned (fifteen grains) will be obtained by dividing this mixture into twenty-five lozenges or tablets.

Equal parts of salol and powdered starch have been used with advantage, applied to ulcerations of the cervix uteri and vagina.

Salol may be combined with collodion, as follows:

Salol,	
Ether	āā 4 parts.
Dissolve, and add	
Flexible collodion	30 parts.

An oleate of salol has been found useful for troubles of the external portions of the eye. A pomade, salol ʒj to ʒvijss of vaseline, may be employed.

For burns:

Ol. oliv.	6 parts.
Salol	1 part.
Aquæ calcis	6 parts.

In suppositories:

Salol	ʒ 2½.
Ceræ alb.	gr. 53.
Ol. theobrom.	ʒ 10.

For ten suppositories.—*Revue Générale de Clinique et de Thérapeutique*, September 22, 1887.

Oatmeal and Lard for Burns.—Dr. Greene reports in the *British Medical Journal* of September 24 1887, his use of these simple but efficient remedies, as follows:

I have for some time been in the habit of using for all degrees of these injuries equal parts of fresh lard (that is, free from salt) and oaten flour made into a paste, which, when spread on a cloth (old calico), or, preferably, a piece of lint, I direct to be applied or rolled round the affected part or limb, and allowed to remain on for twenty-four hours, after which a fresh application is made, and so on every twenty-four or forty-eight hours, as the exigencies of the case demand. In every instance I was well pleased with the progress of cases subjected to this treatment, several of which had been ineffectually treated by other methods. The advantages which I claim for this application are: (1) its freedom from odor, (2) its soothing properties and antiseptic action, (3) its superior healing powers, and, lastly, its cheapness and the ease with which it can be procured (in most houses) on the shortest notice. This latter advantage is of no small importance, taking into consideration the sudden and frequent occurrence of injuries of this nature in everyday domestic life.

Atropia and Strychnia for Sea Sickness.—The following prescription is taken from the *Revue Scientifique* of September 24, 1887, as having been originally published by a naval surgeon in *La Semaine Medicale*:

R.—Atropiæ sulph.,	
Strychniæ sulph.	aa gr. ½.
Aquæ menth. piper. . . .	ʒ 10.

Sig. Dose, 15 minims, hypodermatically; may be repeated in two hours.

For a child two years old, one-sixth of this dose may be given. Caffeine, in 5 grain doses, or combined with atrophia and cocaine, may also be used to advantage.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE. . . . . $5.00.

SINGLE COPIES. . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, OCTOBER 15, 1887.

THE HEALTH OF THE CROWN PRINCE.

IN view of the alarming reports as to the recurrence of the growth in the Crown Prince's larynx, and of its undoubted cancerous nature, which during the week have appeared in the daily press, the following cable just received from Sir Morell Mackenzie by THE MEDICAL NEWS is of interest:

"The Crown Prince is free from recurrence of the laryngeal growth. A chronic inflammation remains, with a disposition to subacute catarrh on slight exposure, or after much talking."

In the light of this authoritative statement there exists no reason to alter the view already expressed as to the non-cancerous nature of the growth. The Prince, however, seems to have suffered from an attack of acute inflammation of the windpipe, and in case of recurrence, to which he appears liable, this might lead to changes in the deeper tissues. Should stricture ensue the complication would be serious, despite malignancy.

THE CHOLERA AT NEW YORK QUARANTINE.

THE cholera brought from the city of Naples to the port of New York by the steamer "Alesia" on the 23d of September and, on that date, transferred, with the steerage immigrants and their effects, to Hoffman and Swinburne Islands, still prevails there with apparently unabated virulence. As yet, no cases have occurred on the mainland, but the danger with which the arrival of the "Alesia" confronted our chief metropolis and maritime port is as threatening to-day as on the 23d of September.

The unexpected continuance of cholera among the quarantined immigrants, so long after the enforcement of measures which had been devised for its prompt suppression, and the increasing public anxiety lest the disease in some way pass the barriers which have been erected against it and invade the mainland, would seem to call for an inquiry as to whether all has been done by the authorities that present knowledge and experience require to be done in order, beyond peradventure, to secure a speedy arrest of the disease among the immigrants and protect the country from the disasters of an epidemic. The standard by which we must gauge the measures which have been enforced in the present emergency, should be sufficiently extensive to cover at least all the known avenues of attack.

Measures of prevention, to give the greatest possible guarantee of success in extinguishing an incipient epidemic of cholera, should, in the first place, be based upon the most exact knowledge we possess of the cause, mode of attack, and manner of spread of the disease; and, in the second place, these measures should be intelligently, thoroughly, and rigidly enforced.

What are the considerations involved in the first category? Probably nine-tenths of intelligent and experienced physicians all over the world, even including those of India, have for years admitted that there is most convincing proof that the active cause of the disease is a specific, material, living entity, of extremely minute size, endowed with the power of self-propagation, and of exceedingly rapid multiplication in enormous numbers; that among animals it naturally attacks man alone, assailing him only by way of the intestinal canal; that the evacuations from the bowels contain the active cause of the disease, and that when this agent in any manner—as through drinking water, milk, food, or the handling or washing of contaminated personal effects, etc.—reaches the intestines of another susceptible person, the disease may be thereby transmitted from the sick to the healthy; that the active agent exists in the dejecta of the lightest and almost imperceptible no less than in the severest and most deadly forms of the disease, and is known to be transportable from place to place through the movements of man and his personal effects.

Proceeding from this basis, logical deduction and common experience alike demonstrate the absolute necessity and efficiency of such measures of prevention as the following:

a. Speedy recognition and isolation of the sick; their proper treatment; absolute and rapid destruction of the infectious agent of the disease not only in the dejecta and vomit, but also in clothing, bedding, and in or upon whatever else it finds a resting place.

b. The convalescents should remain isolated from the healthy so long as their stools possibly contain any of the infecting agent; before mingling again

with the well they should be immersed in a disinfecting bath, and afterward be clothed from the skin outward with perfectly clean vestments, which cannot possibly contain any of the infectious material.

c. The dead should be well wrapped in cloth thoroughly saturated in a solution of corrosive sublimate, 1 to 500, and without delay, cortège, or lengthy ceremonials, buried near the place of death in a deep grave remote as possible from water which may, under any circumstances, be used for drinking, washing, culinary, or other domestic purposes. (Cremation, of course, is by far the safest method of disposing of cholera cadavers.)

d. Those handling the sick or the dead should be careful to disinfect their hands and soiled clothing at once, and especially before touching articles of food, drinking, or culinary vessels.

e. In the case of maritime quarantine, the well should be disembarked and placed under observation in quarters spacious enough to avoid crowding, and so well appointed and furnished that none will suffer real hardships.

f. Once having reached the station, those under observation should be separated in groups of not more than twelve to twenty-four, and the various groups should under no pretext intermingle; the quarters for each group should afford stationary lavatories and water-closets in perfect working condition, adequate to the needs of the individuals constituting the group, and supplied with proper means of disinfection; there should be a bed raised above the floor, proper coverings, and a chair for each member of the group, each person being required to use only his own bed; there should be a common table of sufficient size to seat around it all of the members of the group, who should be served their meals from a central kitchen, and with table-furniture belonging to the station and cleaned by the common kitchen scullions.

g. Drinking water, free from possible contamination and of the best quality, should be distributed in the quarters of each group, as it is needed, and *in such a manner that it is received in drinking cups only*: there should be no water buckets or other large vessels in which handkerchiefs, small vestments, children's diapers, etc., can be washed by the members of any group.

h. Immediately after being separated into groups in their respective quarters, every person under observation should be obliged to strip and get into a bath—a disinfecting one is preferable; and afterward be clothed with fresh, clean vestments from the skin outward; every article of clothing previously worn should be taken away and properly disinfected.

i. Then all of the personal effects should be at once removed to a separate building, washed, if possible, and thoroughly disinfected, or, if necessary, destroyed; after disinfection they should be temporarily returned to the members of groups, when occasion requires a further change of clothing.

k. Under no circumstances whatever should washing of clothing by those under observation be permitted; all used clothing should be first thoroughly disinfected (by boiling when possible) and then should be cleansed, the disinfection and washing being done by a sufficiently trained and absolutely reliable corps of employés supplied with adequate appliances.

l. All of those under observation should be mustered in their own quarters and be subjected to a close medical inspection, while on their feet, at least twice every day, in order to discover and isolate as soon as possible new cases which may develop, and, of course, the clothing and bedding of these new cases should be treated without delay in the manner already mentioned; in the meantime a watch should be set over the water-closet, for the purpose of discovering cases of diarrhœa, and when discovered, such cases should be temporarily separated from the rest, they should receive judicious medical attention at once, and precautions should be taken as if they were undoubted, but mild cases of cholera.

m. The quarters should be kept thoroughly clean, and every surface upon which infectious material could possibly be deposited, including the floors, should be washed with a strong disinfectant twice daily and oftener when necessary; evacuations from the bowels should be passed into a strong disinfectant, the hopper of the closet should be then flushed and finally drenched with a quantity of the same disinfectant.

n. For the proper attention to the sick there should be two or more competent and experienced physicians, assisted by a sufficient corps of intelligent and efficient nurses, with hours of duty so arranged that a physician with a sufficient number of nurses be in constant attendance in the wards of the hospital.

o. For the prompt recognition and separation of new cases, their temporary medical attention, the proper treatment of discovered cases of diarrhœa or cholerine, and of other maladies, and the immediate correction of every insanitary practice or condition by constant, vigilant, and intelligent supervision, there should be at least two or more competent and experienced physicians with hours of service so arranged that a physician is on duty night and day among those under observation; and he should have subject to his orders, at any and every moment, a sufficient and efficient corps of nurses and laborers to carry out properly and promptly his directions.

p. In order to prevent the intermingling of the various groups, to enforce obedience, and order,

and to make it absolutely impossible for the quarantined and their personal effects to have any communication with the exterior, a well organized and sufficiently large police corps should patrol the borders of the stations and the buildings, day and night.

q. Any group among whom there has developed no new case of cholera or of choleraic diarrhœa during the preceding eight or ten days may be regarded as harmless and be allowed to leave quarantine after each one is finally immersed in a disinfecting bath, and reclothed with clean garments from the skin outward; the garments removed being destroyed or thoroughly disinfected and cleaned as above indicated.

As yet no reference has been made to the crew, ship, and cargo. What has been said of the treatment of those under observation applies to every one of the ship's inhabitants. The observation, isolation, and cleansing of the crew and their effects could safely be performed aboard ship, if necessary. The ship should be thoroughly cleansed and disinfected, particular attention being given to the quarters of the immigrants and crew.

By the adoption and quick enforcement of all the above-indicated measures of prevention, New York and the country at large, without doubt, would, at the present time, be safe from the spread of cholera beyond quarantine, and, moreover, the disease would probably not even spread among the immigrants under observation.

But, how closely do the preventive measures enforced at the New York quarantine during this critical period come up to the standard we have cited? We regret that our duty to the public requires us to declare that they fall far short of it, and that, from what we can learn, they should be characterized as in many respects dangerously lax.

We have reason to believe that there is no constant medical attention and supervision at either Swinburne or Hoffman Island, and that the force provided for guarding the approaches to these stations is quite insufficient to guarantee absolute isolation from the mainland. We are informed that the washing of clothing is promiscuous, takes place around the open mouths of sunken cisterns, and that the water in the latter is accessible to the immigrants, if, in disobedience of orders, they chose to drink it.

We do not pretend to say where the responsibility for this state of affairs rests, but in view of the almost uncontrollable tendency of cholera to spread at times, it seems that there is much to be improved in the management and laws of quarantine, even in the Port of New York, which has heretofore, in this country, been regarded as a model. It is to be hoped that the report of the Committee appointed by the College of Physicians of Philadelphia, to investigate our quarantine safeguards, will have some effect not only in causing a prompt lessening of the danger which at present threatens the country through the Port of New York, but will ultimately contribute greatly to a general reform in our management of quarantine.

AMYL HYDRATE.

We have already called attention to the use of this comparatively new drug for the production of sleep and to quiet nervousness; the first reference made to it in these columns being taken from the *Therapeutische Monatshefte* for July, 1887. In the same journal for September, 1887, is a second paper by Dr. Scharschmidt, even more full in its accounts than the first, which records experiments not only as to its hypnotic powers, but also as to the time required for its absorption, its effect on the pulse and the general system. The drug can be given in the form of a clyster, or by the stomach in cognac or red wine and sugar.

The same writer also gives the results of its use in one thousand and fifty-one cases, for the production of sleep.

In eight hundred and sixty-nine cases the results are classed as good, in one hundred and thirty-eight they were medium, and in the remainder no effect was noted. The doses given ranged from 23 grains to 75 grains, the larger proportion receiving from to 45 to 60 grains.

The medical school of McGill University opened its classes on Monday, October 3d, with an introductory lecture by Sir James Grant, M.D., K.C.M.G. The eloquent lecturer dwelt on the importance of a good preliminary education before entering upon the study of medicine, and drew attention to the clinical advantages afforded to students in the McGill medical school. He also spoke of the importance of a knowledge of sanitary science, and the relation of disease to locality, and food supply. After giving some sound advice to the students, and especially to those now for the first time attending the medical classes, he thanked the faculty for affording him this opportunity of addressing the students.

In the evening Sir James Grant was given a complimentary dinner at the St. James's Club by the McGill medical faculty in recognition of the honor of knighthood recently conferred upon him by Her Majesty. Sir James is the first medical man in Canada who has been knighted.

Sir Robert Ball, Astronomer Royal of Ireland, recently gave a very eloquent and instructive lecture to the students of the University, the subject being the "Earth and the Moon." He explained how the moon caused the tides and how the days were continually growing longer, owing to the diminished

speed with which the earth revolves. This diminution, however, only amounts to a fraction of a second in a thousand years, so it need not trouble the present generation greatly.

THE U. S. Marine-Hospital Service reports yellow fever as prevailing at Tampa, Florida, and twenty cases and four deaths were noted up to October 7th. On October 10th six new cases and one death were reported.

THE epidemic of scarlet fever in London continues to spread, and there are now 1900 cases in the hospitals.

THE death of Dr. James A. Gray, managing editor of the *Atlanta Medical and Surgical Journal*, is announced.

SPECIAL ARTICLE.

THE YELLOW FEVER EPIDEMIC AT TAMPA.

So far as can be judged from the testimony presented, the disease now prevailing at Tampa seems to be yellow fever, and the panic that prevails in that portion of Florida is not altogether without justification. The positive statements of Dr. Wall, the Health Officer, whose long residence at Tampa, and whose experience in cases of yellow fever fairly entitle him to judge, should weigh much more than the dicta of interested laymen, each more anxious to prevent the stampede, and consequent commercial losses, than to tell the truth. The fatal progress of the disease tells its own story, and prevents adhesion to the theory that the disease is dengue and not yellow fever.

For the arrest of the progress of the disease, and the prevention of its spread, the experience of the last decade has conclusively established the utility of the measures of *isolation* and *segregation*, in conjunction with those public measures always needful in times of epidemic, namely, *municipal cleanliness, careful quarantine*, and *special hospitals*.

We have repeatedly seen examples in the United States of the calamitous results of the neglect to isolate the first cases, and, indeed, to the neglect of this precaution alone, we may attribute some of our most disastrous epidemics. Isolation means something more than the separation of the individual, while ill from the fever. It also includes the surveillance of all fomites, the attendants upon the sick, and really includes the disinfection of the premises, for no patient while suffering from a contagious disease can be said to be properly isolated unless the atmosphere about him be rendered practically aseptic, and contact with transportable fomites absolutely prevented. The immediate removal of the yellow fever patients from Jasper Rand's wharf at the foot of Palafox Street, in Pensacola, on the night of the 22d of August, 1883, probably prevented an epidemic in that city in that year; for, although the disease was then prevalent at the Navy Yard, from which the city was separated by a rigid *cordon sanitaire*, and the local conditions were undoubtedly favorable to the development and spread of the disease, no further cases were reported.

The occurrence of several cases at Tampa, in portions of the city remote from each other, at this time, prevents the carrying out of this measure.

The fears of the populace and, as well, the experience of the past, act as powerful incentives to segregate the well from the sick; and thus the material for the propagation and development of any epidemic is sensibly reduced, and yellow fever is one epidemic disease easily managed in this way, when the people cheerfully obey the sanitary authorities.

In order that the well may scatter themselves far from the original centre of infection, with safety to those living at the place of refuge, those now usual measures of land quarantine are absolutely essential. At the line of the *cordon sanitaire*, the refuge camp is established, and care taken that no fomites are carried beyond.

It is because of a lack of confidence in the efficiency of the guards, that the *cordon sanitaire* has so unjustly been derided; but there are guards the world over that do not guard, nevertheless, policemen cannot be dispensed with because of the possible unfaithfulness of a few. But it is certain that American quarantine guards are among the most faithful of mankind. The courage and devotion of the guards under Murray and Spohn, during the Brownsville (Texas) epidemic of 1882, and the faithful watchfulness of the Pensacola guardsmen under Captain Guttman, are plain proofs that an extended guard line can be maintained for long periods, successfully. Every effort, however, should be made to diminish the number of people subject to its operation, by hastening the formation of camps of refuge, as soon as isolation of the cases is no longer practicable.

Conjointly with these measures, municipal hygienic rules should be rigidly enforced, and care taken that when the refugees return, they shall return to a clean and regenerated city. If it were possible to destroy by fire every textile fabric in the sick room, it would be justifiable on sanitary grounds, although the milder measure of soaking them in disinfecting solutions, seems to have successfully prevented the spread of cholera in Paris at the time of its recent invasion.

In regard to special fever hospitals, there can be no question that they serve a useful and humane purpose; the patients can be more easily and cheaply provided for, the difficulty of obtaining nurses is obviated, the skill of an experienced resident physician may be secured, and modern hygiene may easily prevent such a hospital from becoming in itself a centre of infection.

JOHN B. HAMILTON.

WASHINGTON, October 12, 1887.

REVIEWS.

Students' Guide to Diseases of the Eye. By Edward Nettleship, F.R.C.S., Ophthalmic Surgeon to St. Thomas's Hospital, etc. With a chapter on Examination for Color Perception. By William Thomson, M.D., Professor of Ophthalmology in Jefferson Medical College. Royal 12mo. pp. 475, with 165 illustrations. Philadelphia: Lea Brothers & Co., 1887.

It is with books, as with men, that some age faster than others. The early symptoms of senility include, a cessation of increase in bulk; defective assimilation of new materials, causing them to appear as foot-notes, and interjected paragraphs; imperfect elimination of outgrown theories, and over-worked woodcuts; and a general rigidity of the plates, preventing the normal infusion of new ideas into the body of text. In the work before us such symptoms are conspicuously absent, and if Mr. Nettleship's book be not immortal, it at least presents that semblance of immortality which healthy, vigorous life always exhibits.

For the seven years since it first appeared, it has to show more than one hundred pages of new matter; which reflect, not only the progress of ophthalmic science and art, but, as well, the growth and maturing of the author's mind. For not only has new matter been added, but the original text has been truly revised, paragraphs of minor importance stricken out, imperfect articles rewritten, and whole chapters rearranged, so that the book, instead of becoming overloaded with undigested accretions, has improved in arrangement and unity as much as it has increased in bulk. Even of the eighty-nine cuts that appeared in the first edition, twenty per cent. have been replaced by new ones better illustrating the subject. Among the cuts that are entirely new we notice as of especial practical interest one giving seven illustrations of various deformities of the teeth from inherited syphilis and other causes.

Part third, dealing with "diseases of the eye in relation to general diseases" has shared fully in the recent additions, and should be of interest to every general practitioner, as giving the eye-symptoms and eye-complications of those general affections he has constantly to deal with. And the appendix, giving now some eleven pages of formulæ with remarks as to their use, cannot fail to strike the "practical" physician very favorably.

We notice among these formulæ, four grains to the fluid-ounce set down as the proper strength for the solution of homatropine; and the same proportion given for the solution of eserine. In the case of the former, its mydriatic power will be imperfectly developed, a twelve-grain solution, or even stronger, being on all accounts preferable; while the latter, if "used in mydriasis and paralysis of accommodation, whether caused by atropine or by nerve lesions," will be liable to cause, in many cases intense neuralgic pain from cramp of the ciliary muscle. In view of this, the subsequent remark, "a weaker solution (gr. j to ℥j) is often better borne," might well have been italicized.

Among the useful additions made in the present edition, we notice a table giving the shortening of the eye-ball in various degrees of hyperopia and its lengthening in myopia. In the effort to give only round numbers, however, it has been made needlessly inaccurate. Thus, H. of 2 Dioptres is said to represent a shortening of 0.5 mm., and H. of 3 Dioptres of 1 mm. But in spite of these slight imperfections, to one who knew what an excellent manual Nettleship's Guide already was, it must be a surprise to see how much he has been able to improve it. Never before has it so well deserved the high reputation it has won.

SOCIETY PROCEEDINGS.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, October 3, 1887.

The Vice-President, S.W. Gross, M.D., in the Chair.

Dr. Thomas G. Morton made some remarks on two cases of

EXCISION OF THE KNEE-JOINT

which presented some novelties. In the case of a boy, eight years of age, with strumous synovitis of the knee, he made an incision in the median line, intending to split the patella and draw it to either side, and then excise the joint and stitch it together. On cutting through the patella, however, he found that it was the seat of necrosis. He continued the incision in the median line and dissected out the patella. This was the first time that he had operated in this way, and he found that it was an exceedingly nice form of operation.

The second operation was for destructive synovitis of the knee occurring in a man, twenty-two years of age, who had worked until two days before his admission to the hospital, when he had a temperature of 101°, which continued for the next five days. In this case there was a sinus about two inches above the patella and to its inner side. This was opened sufficiently to admit the finger, and the joint was found involved, the suppuration being moderate in amount. The incision was then continued downward, and he was able to displace the patella with its ligament, and the tendon of the quadriceps muscle to the outer side. There was not the slightest trouble in making the excision of the joint. The patella was slightly eroded. He shaved off this portion, and also a corresponding portion of the femur and brought the two bones in contact. At the time o operation the temperature was 101.5°, has steadily decreased and has remained at normal since. The operation was done September 23d, and the dressing has not yet been removed.

In another case if he did not split the patella he would, as in the last case, draw the patella to one side.

For fixation he drills the tibia in three places, and the femur in a corresponding manner, and then ties them together with what is known as "twenty-eight day catgut." In only one instance has he known any portion of the catgut to come away. There has been no suppuration in any case where ordinary antisepsis has been employed.

There is one practical point that might be referred to, and that is, that, in drilling these bones, an ordinary bradawl answers every purpose. He never allows the instrument to perforate the articular surfaces, but makes

the opening just above them. With regard to the further treatment of the joint, he uses a slightly angular posterior splint placed along the outer side of the limb, binding them together with a roller bandage. He has had the best results, and it is rare that he has to dress any case before the second week.

Dr. Charles B. Nancrede related a case of

LUMBAR COLOTOMY

which presents certain points of interest with reference to prognosis, diagnosis, and treatment, and with reference to certain operative measures. The history of the case is briefly as follows: The man stated that while in the army he had dysentery, and that since that time he thought that the passage was small. There was probably then a stricture of large calibre. Seven or eight years ago he discovered an anal fistula, which was operated on successfully. Over two years ago another fistula formed, for which he was operated on, and, so far as can be ascertained, the stricture was detected at this time and also operated upon, for, after his recovery from the operation, he began to pass flatus and feces through the urethra. The stricture had evidently been cut so deeply that either from the depth of the incision or the subsequent ulceration, an opening had formed into the bladder. One year ago he was operated on for the extension and deep infiltration of the tissues of the fundament. He was at first benefited by the operation, but again relapsed, passing considerable quantities of feces through the urethra, and on several occasions had attacks of partial obstruction of the bowels resulting in fecal vomiting. His suffering gradually became very severe. When he came under observation the question which presented itself was, Is this a carcinoma or an ordinary fibrous or cicatricial stricture resulting from the old attack of dysentery? He recommended that left lumbar colotomy be performed, with the hope that the passage of the feces into the bladder would be obviated, and that if the stricture were not carcinomatous there might be some amelioration of the local condition. He performed the operation, and at the end of seventeen days the patient ceased to pass water by the rectum, and the indurated fundament had softened down wonderfully, and the so-called cancerous ulceration is beginning to heal at the edges. He did not believe this a case of cancer.

A word with reference to the operative measure. Usually when we get down to the colon it can be readily brought to the surface and recognized. In this case it was absolutely impossible to be sure what was present. The transversalis fascia was as dense as he had often seen the fascia lata of the thigh. The kidney fat was very deep, and the bowel was fully the distance of a forefinger below the surface of the skin. He then resorted to what he had seen recommended, but had never found it necessary to use—that is, inflation of the bowel. At once the colon came up into the wound, and there was not the slightest difficulty in recognizing and opening it. He did not see why this procedure might not be used with advantage in many cases of colotomy. In this case, although the colon was not distended, the man passed during the next ten days fully half a bucketful of feces.

Dr. Morton recalled an interesting case of lumbar colotomy in which, after making his incision, he reached a tissue which he could not diagnosticate. He punctured it and found a large cyst of the kidney. This was certainly as large as a goose's egg. After the cyst was evacuated the bowel rose up, and there was no difficulty. Not long ago a lady came to me with stricture of the rectum. Digital examination showed a dense stricture involving the whole circumference of the bowel, about one and a half inches within the anus. The ordinary uterine sound passed through it with difficulty. There had been no passage for a long time except of the most liquid character. It was a question between lumbar colotomy and excision of the entire stricture. He had little doubt that it was a syphilitic stricture, although he had no positive proof that it was of this nature. He determined to attempt removal of the stricture, with the patient's permission, to perform lumbar colotomy if he could not get above the stricture. He found that the entire stricture could be removed, and he did so, bringing the healthy bowel down and stitching it to the external surface. He had received a letter from this patient stating that she is absolutely well, and that she is able to have large passages without the slightest pain.

Dr. John B. Roberts said that there is one question about stricture of the rectum on which he should like to have an authoritative opinion. This was forcibly brought to mind by the death of a patient on whom he had operated for stricture of the rectum, and he has known of several similar cases with the same result. The case to which he referred was one of long-standing rectal disease, with symptoms of stricture for eighteen years. The patient had at first been told that it was carcinoma but, as she did not die, the diagnosis was evidently incorrect, and he was asked to see the case in consultation. The woman was exceedingly nervous. On examination, he found a dense annular stricture one and a half inches within the anus. Under ether, he made an incision, and dilated the stricture with his finger. He then introduced a large bougie, and, although he could introduce it with ease, he found that, unless he carried the base far back toward the sacrum, it always caught. On further examination, he found another obstruction high up. It felt like a hard tumor, and did not seem to be a cicatricial band like that already divided. He made a nick in this, and the bougie could then be passed without trouble. The next day he found that there had been a great deal of pain, and that the patient had insisted on sitting up in bed. There had been some bleeding, which had been checked by packing the rectum with ice. When he saw her the bleeding had stopped. That evening she insisted on getting out of bed and sitting on the commode, and had a large hemorrhage, followed by a second, from which she promptly died.

At the autopsy there was a large quantity of blood in the pelvis. There was no sign of any tumor, or of any obstruction. It may be that the second obstruction which he felt was due to a bend in the bowel, resulting from the old adhesions, and that above this the bowel was dilated and its walls thin. He should like to know the experience of other members of the Academy with this condition. In another case, in which an old lady complained of obstruction of the rectum, he passed a bougie and found nothing wrong. There were some hemorrhoids, on which he operated. This patient died

of peritonitis in a few days. He recalled a case in the practice of another surgeon, where an ordinary stricture was dilated, and the patient died of peritonitis.

Dr. Charles B. Nancrede asked if it is ever a good plan to use a bougie immediately after nicking a stricture? The death in stricture, where the fatal result is not due to exhaustion, results from the feces and discharges lying in contact with the upper portion of the bowel until they induce ulceration, perforation, and peritonitis, or they induce peritonitis as a result of the extension of inflammation from within outward. He thought that after nicking a stricture it is dangerous to trust to anything but the finger. This at once recognizes when a dangerous locality is approached. With a bougie one may get into an ulcerated, irregular portion of the bowel, where an amount of pressure not recognizable by the hand will produce perforation.

There is another point to which he would like to call attention, and that is, in stricture of the rectum, if we do not cut all the way back, there will be left a surface where there can be no drainage, and there is a strong probability that septicæmia will result. In operating on a stricture, it is better to cut back to the sacrum and coccyx, and then the diseased structure can be attacked without danger.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 6, 1887.

The President, A. Jacobi, M.D., in the Chair.

Dr. P. Albert Morrow read a paper on

THE MODERN METHOD OF TREATING SYPHILIS.

He said that the treatment of syphilis in this century differed from that of the fifteenth century in the modification of the method, and in detail rather than in essential nature. If stability be recognized as a true test of the value of a mode of treatment, the treatment of syphilis by mercury, having the stamp of professional approval after four centuries, might be regarded as of special value. But its mode of administration had been greatly changed; we had learned its limitations. We now regarded any treatment which seriously disturbed physiological functions as pernicious. Instead of overwhelming the syphilitic diathesis with metallic masses, the treatment had been extended, so to speak, to correspond with the natural life of the malady.

Dr. Morrow then took up the question of the use of mercury hypodermatically. This was not merely a different method of administering the drug, but, if the claims of its enthusiastic advocates were well founded, it overturned the general belief in the necessity for the long continued use of the drug, and the large quantity required.

Dr. Morrow's personal experience with the hypodermatic use of mercury was limited, but during the summer he had observed its employment in a large number of cases in the Paris hospitals. Some made use of the soluble, others of the insoluble salts. He gave the experience of Lewin, Jullien, of Lyons, Martineau, Balzer, DuCastel, Besnier, and others. The treatment by the soluble salts involved the introduction of a quantity of bichloride of mercury or its equivalent in other forms of one-eighth to one-sixth of a grain a day for thirty days; requiring, according to Lewin, about twenty-five centigrammes (nearly four grains) to effect a cure. By the insoluble salts the treatment required the introduction of ten centigrammes (one and a half grains) of calomel or the yellow oxide of mercury, and a repetition of this on an average four times, at intervals of from eight to fifteen days. The accidents from the hypodermatic method had become reduced very greatly. Jullien had not had an accident in several thousand cases. Dr. Morrow's paper concluded as follows:

In endeavoring to appreciate the therapeutic worth of the modern method of treating syphilis, we are confronted by a mass of confusing clinical statistics, as well as a crowd of contradictory statements on the part of the experimenters, some bearing testimony to its superior efficacy, others depreciating its value, and condemning it as obnoxious and impracticable. A careful weighing of this clinical testimony, balanced by my own observation and experience, justifies the following conclusions: The hypodermatic use of mercury, in simplicity, convenience, scientific accuracy, rapidity of action, and the development of a maximum effect from a minimum quantity of the drug, constitutes a decided improvement of the ordinary modes of its introduction into the system. The hypodermatic method is not so liable to cause salivation, gastro-intestinal disorders, and other toxic symptoms of hydrargyrism. There is a remarkable unanimity of opinion among observers as to its efficacy in suppressing the active manifestations of the secondary stage, and hastening their involution. The claims that the subcutaneous introduction of mercury increases its potentiality, and widens the range of its specific action, enabling it not only to subdue refractory secondary lesions which resist ordinary treatment, but also the tertiary lesions of syphilis, may be considered as yet *sub judice*. The claim that it endows mercury with a greater permanency of effect, preventing relapses, and preserving the patient from manifestations of the diathesis for a long time, is not proven. The more pretentious claim that the hypodermatic introduction of twenty-five centigrammes (four grains) of the bichloride, or forty centigrammes (six grains) of calomel, *cures* syphilis, must be rejected as extravagant and absurd. The irritant action of mercury introduced hypodermatically, manifest in the production of pain and local accidents, renders its general employment in the systematic treatment of syphilis impracticable. The proper position of the hypodermatic method in the therapeutics of syphilis is in the category of adjuvants. Its employment is indicated when the necessities of the case demand a rapid and intense mercurialization. In certain emergencies —when the integrity of an important organ is threatened, for example—its prompt and energetic action renders it superior to other modes of mercurialization. In exceptional cases—marital syphilis, for example—when the exigencies of the situation demand secrecy in treatment with the speediest possible suppression of the symptoms, this method is to be recommended. It constitutes a most excellent reserve treatment in cases where the gastro-intestinal irritability is so marked as to forbid the introduction of mercury by the stomach. In cases of tertiary syphilis, where iodine idiosyncrasy

is so marked that the iodide of potassium cannot be employed, hypodermatic injections of mercury should be substituted. While my own impression is that the hypodermatic method will never supersede the classic modes of employing mercury, I regard it as a decided acquisition to our therapeutic resources against syphilis —too valuable to be ignored, or practically disregarded, as has been the case in this country.

Drs. Bronson, R. W. Taylor, F. R. Sturgis, L. D. Bulkley, and the President, discussed the paper. Most of them had begun the use of the injections about 1869–70, at a time when the irritant effects of the injections were such as to cause them to cease the practice. Dr. Taylor had continued the method, using the different salts in special cases since, and he said that the treatment was applicable only under special conditions, corresponding in general to those contained in Dr. Morrow's concluding remarks. The President had certainly used bichloride with advantage in hereditary syphilis with severe and early symptoms. Dr. Bulkley thought the method was called for. Dr. Morrow closed the discussion, and said the object of his paper was to give the present status of this way of introducing mercury into the system.

NEWS ITEMS.

THE CHOLERA AT NEW YORK.—Health Officer William H. Smith, M.D., of the Port of New York, furnishes the following statement, under date of the 5th instant:

The steamship "Alesia," from Marseilles, August 29, and Naples, September 3, with most of her cargo taken at Marseilles—at Naples she received her cargo by lighters —arrived at this quarantine and was inspected the morning of September 23.

The report of the surgeon showed that there had been eight deaths on board, six of which were unquestionably cholera. "All the cases reported were fatal. Four cases were found in hospital sick with the disease, and four cases were discovered while inspecting the passengers. I may here refer to the fact that the bill of health from the consul at Naples declared that "there had been many cases of cholera at Naples and vicinity for the last five weeks. The exact number could not be ascertained. The mortality of those attacked is 70 per cent." (Consular bill of health. The well passengers were removed the same day to Hoffman Island for observation, and the sick to Swinburne Island Hospital. The number of cases on board on arrival was eight; twenty cases have developed among the passengers since they have been under observation to this date; five of those removed from the vessel have died and three recovered. Of those that have developed while in quarantine, nine have died, four have recovered, five are convalescent, and the remaining two are now seriously ill. The disease has been very virulent and rapid in its fatality in a majority of the cases; in several instances patients that were well at the inspection in the afternoon were nearly or quite pulseless within twelve hours. At this date there has been no development of cases among the immigrants for the past two days.

The steamer was twice washed with scalding water from the boilers through the hose in every accessible part, and immediately after this washed in every part with a solution of corrosive sublimate, two parts to one thousand. The hatches had been closed and sealed, and covered with tarpaulin before the passengers were taken on board, except three cabin passengers, taken at Marseilles. All the immigrants were removed to Hoffman island. Immediately subsequent to the washings with the solution of mercuric chloride, after breaking out the cargo to the bottom of the hold, one hundred pounds of sulphur were burned in the hold, the hatches of the spar-deck being closed for ten or twelve hours. The disinfection by the solution before mentioned was the next day repeated, every accessible portion of the vessel being washed with it by brooms or sponges, followed by the combustion of one hundred and fifty pounds of sulphur, the hatches being again closed until the following morning. Every textile fabric—carpets, mats, the dunnage and clothing of the crew—were immersed in boiling water for a considerable time by the introduction of steam through hose attached to the boilers. Finally, all exposed portions of the steamer, except the saloons, including the forecastle, were repainted.

The steamer was detained in the lower bay fourteen days. The well passengers were removed to Hoffman Island for observation, and the sick to Swinburne Island Hospital the day of their arrival at quarantine. The cleansing and disinfecting of the baggage of the immigrants commenced immediately thereafter. A large tank that can be securely closed, having a perforated pipe, and extending from the bottom to the under side of the lid, and connecting with a large boiler used for heating the buildings, is used in part for the disinfection. Two rooms, fifteen by twenty feet each, made as close as possible, are used to disinfect by the combustion of sulphur. Each piece of baggage and every article of clothing have been subjected to sulphurous acid gas thus produced for several hours, in the ratio of three pounds to each one thousand cubic feet of air-space. The disinfection by moist steam heat has been at the same time constantly in progress—the clothing is subjected to this process for at least three hours. Barrels of a solution of bichloride of mercury are placed in the closets and used to wash them after the dejecta of each person has been removed by the flush from the tanks above the hopper of the closet. Every day the floors of the large buildings, each 50 by about 150 feet, are washed with a solution of the same article. To-day the subjection of each and every article of baggage has been again commenced, and will be continued until all articles have been again disinfected by the means mentioned.

For two days past no new cases have developed. It is well to state that the first cases on the "Alesia" developed the ninth day after the steamer left Naples. It is as yet an open question whether the cases that have developed on Hoffman Island arose from infection contracted from the same source that gave rise to the deaths on board the steamer, or from sources that were transferred to Hoffman Island with the passengers. There is every reason to believe at this writing that the infection among the immigrants is destroyed, except, possibly, that its development may be exceptionally long delayed in cases which may occur.

THE CHOLERA.—The *British Medical Journal* of September 24, 1887, contains the following notes upon the cholera:

The hopeful signs of a cessation of the cholera epidemic, which seemed to be evident a fortnight ago, have, unfortunately, not been maintained; for, during the past week, the disease has broken out with renewed violence at Messina, in Sicily. As many as 156 cases and 44 deaths are reported to have occurred there on September 20. This recrudescence is reported to be associated in the local mind with the arrival in the port of a vessel from India; but the only foundation for such an opinion appears to be the fact that, while unloading, some of her crew fell ill and died. The disease maintains its foothold in Catania, Palermo, Tripani, and other Sicilian towns. In the neighborhood of Naples, the disease has also shown a tendency to increase, especially around Castellamare. In Malta, the disease continues to cause several deaths daily. Up to September 22, 389 cases and 248 deaths had already occurred on the island.

BACTERIOLOGY IN SPAIN.—A bacteriological laboratory has been established at Barcelona. Dr. Iaime Ferran, whose name will no doubt be remembered in connection with the so-called preventive inoculations of cholera two or three years ago, has been appointed Director of the institution, with Dr. Inocente Pauli as chief assistant. The laboratory owes its establishment in a great measure to the initiative of Don Pablo Despax, a rich merchant of Barcelona, whose first intention was to found an institute for the treatment of hydrophobia, on the model of M. Pasteur's. On the matter being brought before the municipal authorities, however, they determined to establish a fully equipped bacteriological laboratory. The buildings, which are now completed, are in the gardens of the Asilo de los Pobres; they contain rooms for microphotography, for histological and bacteriological researches, and for inoculations, together with all the necessary instruments and appliances. Other rooms are fitted up as museums, and there is also a library. Antirabic inoculations will be carried out by Dr. Ferran and a staff of assistants, in strict conformity with M. Pasteur's methods.—*British Medical Journal*, October 1, 1887.

WHOOPING COUGH LEGALLY CONSIDERED CONTAGIOUS.—The Attorney-General of Michigan, in response to an inquiry from the State Board of Health, has included whooping cough in the diseases declared "dangerous to the public health," and physicians will hereafter be legally bound to report it among contagious and infectious diseases.

MEANS ADVISED BY THE INTERNATIONAL CONGRESS OF HYGIENE, AT VIENNA, FOR CHECKING FOOD ADULTERATION.—CARO, of Madrid, HILGER, of Erlangen, and VAN HAMEL ROOS, of Amsterdam, in the discussion of the means which could be adopted by all nations for the prevention of food adulteration, advised the foundation of an International Commission, three members from each country, to take measures for suppressing fraud in foods; this Commission to control regularly the sale of foods, being in constant coöperation with scientific authorities in hygiene and medicine in their several countries. This Commission is also to establish stations for the municipal examination of food, completely and uniformly organized and equipped. Uniform methods of examination and criterions of judgment are to be adopted, and international legislation, as uniform as possible, is urged. The technique of the examinations to be made is described, and the apparatus to be employed.—*Revue International des Falsifications des Denrées Alimentaires*, September 15, 1887.

VIENNA VACATION COURSES.—These courses, inaugurated during the recent vacation season in Vienna, were much less frequented than was expected, the chief attendants having been foreigners.

MEDICAL TEACHING AT OXFORD.—Oxford University has recently erected and equipped buildings devoted to the study of anatomy and physiology, with histology. The future student of medicine can now ground himself thoroughly in these branches, and in chemistry, at Oxford, before entering a college of medicine.

CONTAGION FROM LIBRARY BOOKS.—The sanitary authorities of Hawick, Eng., have requested, and the public library board requires, that those who take books from the library shall sign a statement that no infectious disease exists in their houses; that they will return the books and give notice if any infectious disease appears.—*Sanitary Inspector*, September, 1887.

A CURIOUS ADULTERATION OF MACE.—A very strange adulteration of mace has been lately observed in Amsterdam. Pulverized biscuit had been mixed with mace in a very large proportion. This adulterated spice was sold in several shops, and, looking at the enormous difference of price, a nice profit must have been yielded. Unfortunately, the mixture was not seized in the presence of witnesses, and the justice could not interfere.—*Revue Nationale Scientifique et Populaire des Falsifications des Denrées Alimentaires*, September 15, 1887.

COLOR-BLINDNESS AMONG THE RAILWAY OFFICIALS OF GERMANY.—An extensive investigation into the prevalence of color-blindness amongst German railway officials has afforded some interesting results. The inquiry, which has lasted severa years—the latest data having been obtained on July 1, 1886—was extended to seventy-nine railways. Of 104,743 persons tested from April 1, 1882, to July 1, 1886, 850, or 0.81 per cent., were found to be color-blind. Of 239,726 persons tested up to July of last year, 1934, or 0 81 per cent., were color-blind, while in 145,556 officials and other servants employed on the seventy-nine railways on July 1, 1886, 100 were entirely and 441 partially color-blind, a percentage of 0.37. The methods of testing were chiefly the Stilling method (by means of color-plates) and the Holmgren method (by means of colored woollen threads); but the Cohn, Schmidt, and Rimpler methods were also adopted. In 16,201 cases the test was repeated, and 305 times only did the results differ from former results. The officials of German railways who are color-blind have been given duties, in the discharge of which their incapacity can have no ill results, so that there is no

danger of their continued employment in dangerous posts.—*British Medical Journal*, September 3, 1887.

ON BALDNESS.—DR. AUSTIN FLINT sends to the *Popular Science Monthly* for October, 1887, an article written in 1853 by his father, which we quote as follows:

I send an extract from this article which appeared as an editorial in the *Buffalo Medical Journal*, March, 1853, No. 10, page 651, and was entitled "Hats and Baldness": . . . . The most characteristic trait of the hat is the tightness with which it encircles the head. Herein consists, in our opinion, its agency in the loss of hair. The stove-pipe hat must needs encircle the head tightly, in order to be secure in its position in spite of wind and other disturbing forces. To appreciate the degree of compression, one has only to note the indentation on the forehead after a tightly fitting hat has been worn for some time. Everybody knows how commonly this is to be observed. The head is, in fact, pretty firmly ligated while the hat is worn. Now, what must be the effect of this on the circulation? Plainly, the effect is to interrupt the circulation in the scalp above the circle on which the compression is made. It is precisely like tying a cord around the head, sufficiently to diminish, if not stop, for a time, the flow of blood through the temporal and other arteries by which blood is distributed to the superior portion of the scalp. The hair follicles, as is well known, are very vascular. Their functions require this vascularity, and an adequate, constant supply of oxygenated blood. If this supply be diminished, the growth and nutrition of the hairs are proportionally affected, and, finally, the *pulp* inclosed in the follicle withers and dies, as does any other part when deprived of the *pabulum vitæ*. This effect occurs on the crown, because interruption of the circulation in arteries is always felt most in the parts to which the terminal branches are distributed.

"Such is our explanation of the fact that baldness is so frequently observed in the young and middle-aged men of the present generation. The remedy is to repudiate the present fashion of hats. Let some inventive genius devise a substitute for the unseemly, as well as hair-destructive, article which is now the *mode*, and we are firmly convinced that toupees will become objects of curiosity rather than utility, and the bald pate will again be venerated as the distinguishing trait of old age." . .

A COMMISSION TO REGULATE THE PRODUCTION AND USE OF ALCOHOL.—The French are about to appoint a commission under the presidency of Léon Say, composed of senators, deputies, the Dean of the Faculty of Medicine, and practical chemists, to legislate regarding alcohol and the hygiene of beverages.

AN INTERNATIONAL JOURNAL IN THE INTEREST OF PURE FOODS has been recently established. It is edited by VAN HAMEL ROOS, of Amsterdam, and has upon its staff collaborators from the civilized countries of the world. The American contributor is Dr. Tucker, of Albany. The journal is published in French, German, and English. It will be published six times yearly, each issue containing from 150 to 180 large pages. At the recent meeting of the International Congress of Hygiene, at Vienna, the journal was declared the official organ of the Congress.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM OCTOBER 4 TO OCTOBER 10, 1887.

HALL, WILLIAM R., *Captain and Assistant Surgeon.*—Ordered from David's Island to Fort Custer, Montana.—*S. O. 232, A. G. O.*, October 5, 1887.

PRICE, C. E., *Captain and Assistant Surgeon.*—Ordered from Fort Custer to Fort DuChesne, Utah Territory.—*S. O. 232, A. G. O.*, October 5, 1887.

SUTER, WILLIAM N., *First Lieutenant and Assistant Surgeon.*—Ordered from Washington Barracks to Fort McKinney, Wyoming Territory.—*S. O. 232, A. G. O.*, October 5, 1887.

WEISEL, D., *Captain and Assistant Surgeon.*—Ordered from Fort McKinney to Fort Sill, Indian Territory.—*S. O. 232, A. G. O.*, October 5, 1887.

HORTON, S. M., *Major and Surgeon.*—Ordered from Fort Riley to Fort Adams, Rhode Island.—*S. O. 232, A. G. O.*, October 5, 1887.

BACHE, D., *Major and Surgeon.*—Ordered from Fort Adams to Fort Riley, Kansas.—*S. O. 232, A. G. O.*, October 5, 1887.

KIMBALL, J. P., *Major and Surgeon.*—Ordered from West Point to Fort Elliott, Texas.—*S. O. 232, A. G. O.*, October 5, 1887.

NEWTON, R. C., *Captain and Assistant Surgeon.*—Ordered from Fort Elliott to David's Island, New York Harbor.—*S. O. 232, A. G. O.*, October 5, 1887.

HEIZMANN, C. L., *Major and Surgeon.*—Ordered from Fort Ontario to West Point, New York.—*S. O. 232, A. G. O.*, October 5, 1887.

CASTER, E. C., *Captain and Assistant Surgeon.*—Leave of absence further extended fifteen days.—*S. O. 231, A. G. O.*, October 4, 1887.

CABELL, J. M., *First Lieutenant and Assistant Surgeon.*—Will be relieved from duty at Fort Omaha. Assigned to temporary duty with Battalion of the Sixth Infantry in the field.—*S. O. 98, Department of the Platte*, October 1, 1887.

BORDEN, W. C., *First Lieutenant and Assistant Surgeon.*—Will be relieved by officer commanding troops, upon arrival of Assistant Surgeon Cabell, and will return to his station, at Fort Douglas, Utah.—*S. O. 98, Department of the Platte*, October 1, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING OCTOBER 8, 1887.

MARTIN, WILLIAM, *Assistant Surgeon.*—Detached from the Hospital, at Norfolk, and granted sixty days' leave.

BATES, N. L., *Medical Inspector.*—Detached from the Naval Dispensary, and ordered to the Examining and Retiring Boards.

PRICE, A. F., *Surgeon.* Ordered to the Naval Dispensary, at Washington, D. C.

WAGGENER, J. R., *Surgeon.*—Ordered to the Receiving Ship "Minnesota."

FITZSIMMONS, PAUL, *Surgeon.*—Detached from the "Minnesota," and ordered to the "Marion," October 15th.

VEEDER, LOUIS W., *Assistant Surgeon.*—Detached from the Receiving Ship "Vermont," and ordered to the "Marion," October 15th.

RUSH, W. H., *Passed Assistant Surgeon.*—Detached from the Coast Survey Steamer "Blake," and ordered to the Navy Yard, New York.

BERRYHILL, T. A., *Assistant Surgeon.*—Detached from the "Minnesota," and ordered to the "Blake."

DRENNAN, M. C., *Surgeon.* Detached from the Naval Academy, and wait orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, FOR THE WEEK ENDING OCTOBER 8, 1887.

IRWIN, FAIRFAX, *Passed Assistant Surgeon.*—Granted leave of absence for twenty-five days, October 5, 1887.

GUITERAS, JOHN, *Passed Assistant Surgeon.*—Granted leave of absence for seven days, September 28, 1887.

NORMAN, SEATON, *Assistant Surgeon.*—Upon expiration of leave of absence, to rejoin station, at New York, October 4, 1887.

ORIGINAL LECTURES.

ON THE GENERAL ETIOLOGY AND SYMPTOMS OF CHOREA.

BASED ON THE RECORDS OF 410 CASES AT THE INFIRMARY FOR NERVOUS DISEASES, PHILADELPHIA.

Two lectures delivered at the Infirmary during the Summer Session.

BY WILLIAM OSLER, M.D.,

PROFESSOR OF CLINICAL MEDICINE IN THE UNIVERSITY OF PENNSYLVANIA.

LECTURE II.

SYMPTOMS.

FEW affections have more clearly defined features than chorea. The involuntary and irregular contractions of various muscle groups give objective characters recognizable at a glance.

On careful inquiry we find very constantly initial symptoms of some moment. The child displays an unwonted restlessness, is unable to concentrate attention, or to sit still, a condition well expressed by the term "fidgets" so often used by mothers in describing the onset of the disease. The mental state is correspondingly irritable, and the child may become emotional, crying on the slightest provocation, and often displaying groundless fears. Night terrors are noted in a number of cases. Very commonly the temper suffers, and from a docile, quiet child, the poor victim becomes cross and unmanageable. Punishments inflicted at this stage by thoughtless parents or teachers aggravate the mischief, or even precipitate the attack. The appetite may fail, and anæmia not infrequently develops. After a week or two, the onset of the disease is shown by a marked increase in the restlessness, and by the occurrence of sudden involuntary movements. These may be noticed first at the table when the child spills a tumbler of water by a sudden jerk, or upsets a plate. In this stage, too, there may be pains in the limbs, more frequently the legs, and in the joints. Persistent headache is a not uncommon symptom.

For convenience we may recognize three grades of cases: *mild*, in which the affection of the muscles is slight, the speech not seriously involved, and the general health not much disturbed. *Severe*, in which the movements are general, the power of speech is lost, and the patient is unable to get about or help himself; and the *chorea insaniens*,[1] or maniacal chorea, characterized by profound cerebral disturbance.

The following cases illustrate these forms:

Ida A., æt. seven, was admitted to hospital April 24th, with her third attack of chorea. Early in January, 1885, she had an attack of acute rheumatism; was in bed four weeks. Mother also has rheumatism. One month after convalescence the chorea began, and for several months she twitched, chiefly on the right side. January 29, 1886, she had a second attack, and she attended at the clinic for three months. At this time there was no rheumatism, and the heart sounds were clear. About the end of March of this year, her mother noticed that she was extremely nervous and irritable, and on the 30th she had irregular jerky movements of both hands and of the shoulders, with an occasional facial grimace. On April 20th she returned very much worse; the movements of arms constant, speech not affected. She was admitted to hospital, put to bed, ordered Fowler's solution, ♏ v t. i. d., galvanism to the spine, and massage of the limbs daily. To be kept quiet and undisturbed. There was no heart murmur. She improved rapidly, and at the end of a week the movements had almost ceased. On May 7th she was discharged well.

This mild, ordinary case represents the common type of the disease as we have it at our clinics. It is interesting to note the occurrence of rheumatism, the absence of any heart murmur, and the recurrence in the spring.

An illustration of severe chorea is the following case:

Ella A. (sister of preceding), æt. nine. Has not had rheumatism. Has been nervous at school. Failed in some lessons. Was frightened at a lecture at the Wagner Institute, and three months ago was much upset by seeing a child injured and bleeding. The twitching first noticed in right arm. When brought to clinic, December 30th, she presented the appearance of a rosy, plump child. The condition was as follows: Choreic movements are universal; the hands and feet jerk about in a most violent manner, the movements usually beginning in the left side, and extending to the right. They number thirty to thirty-two in a minute, and are so strong that the most powerful restraint fails to repress them entirely. The hands will be drawn from the lap violently upward, striking the chest, or they will rise suddenly and fall heavily on the knees. When she is seated on a chair the feet will be lifted from the floor and come down suddenly with a loud stamp. The face is in constant movement; speech is almost impossible, and she presents a truly pitiable condition. So violent are the movements that she has frequently injured and bruised herself, and has several times inadvertently struck her mother. She is intelligent, sleeps well, even soundly; the movements ceasing completely. It was impossible to examine the heart on account of the extreme jactitation. She took Fowler's solution up to ♏ xv t. i. d. with benefit; but the case was protracted, and, though the violent movements subsided, it was several months before they disappeared.

We have four or five of these extreme cases every year; often they are carried into the clinic in some instances covered with bruises on the exposed and prominent portions of the body.

[1] Bernt: Monographia Choreæ Sancti Viti, Prague, 1810. Gee: St. Bartholomew's Hospital Reports, 1886.

There does not appear from the records to have been a case of the extreme maniacal chorea, c insaniens, under t current of the hospital, so I here give the notes of one which I saw with Dr. George Ross, in Montreal.

Emma M., a strong girl, æt. eighteen, was admitted to the General Hospital, October 17th. She was a waitress at a hotel, and when carrying a tray was badly frightened by two men who were fighting, and dropped her dishes. A severe reprimand only increased her fright. The next day she packed her trunk and went home, a distance of thirty miles, but met her father on the way, who insisted that she should return to Montreal. He says that her hands and arms were in constant motion from the way back her father got drunk, and threatened to go to jail if she did not keep quiet. Five days after this she was admitted. Arms and legs were in constant motion, jerking about in all directions; the face was spared. She was rational, but could scarcely speak. On the night of the 19th she had no sleep, raved and talked all the time; movements incessant. On the 20th, 21st, and 22d, this condition persisted, as rather grew worse, the temperature ranged from 101° to 103°, the tongue was dry and cracked, and she became much emaciated. On the night of the 22d the temperature rose to 105°, and she died exhausted five days after admission, and ten days from the onset of the symptoms. The tongue showed a coat of soft, warty vegetations on the anterior portion of the mucal segments.

There are many points of interest in the *symptomatology* of chorea which may be considered more in detail. Mitchell has pointed out in his lectures that there are differences in the character of the irregular movements, thus in one group, comprising the greater number of cases, there is "awkwardness and incoordination of voluntary movement, followed soon or late by automatic or involuntary spasms of various parts." In a second group the disease does not get beyond the stage of incoordination, and irregular movements only occur during willed actions. In a third group there are "constant, automatic, irregular, clonic spasms, usually of the hands, but during volitional acts these entirely vanish and the most complicated acts are well performed without obvious incoordination."

The various muscle groups are not equally affected in chorea, but there are usually special regions to which it is confined or from which, as starting-points, it spreads to other parts of the body. In a majority of the cases the hands are first involved, then the face, and subsequently the legs. The movements may be confined to one side, hemichorea, during the entire attack or for some weeks before the other side is invaded. It begins most often in the right side; thus, there were 126 cases in which the movements were at first dextral, starting usually in the hand, and only 80 instances in which the left side was first involved. The movements rarely start in the legs; in only 6 instances is it noted in the records. In about a dozen cases it is said to have been general from the first, but early symptoms are readily overlooked. In 126 cases the movements became general. The muscles of the trunk and face are, as a rule, bilaterally affected; we rarely see the one shoulder group involved without the other, and the facial grimaces are not often confined to one side.

In nearly one-fourth of the cases speech was affected. When slight this may be only an embarrassment or hesitancy and the child utters the words plainly. In other instances speech is an incoherent jumble, the tongue and lips move and sounds are uttered, but it is impossible to catch the words. Sometimes a few words are spluttered out in an explosive way. In very severe cases the child will make no attempt to speak. The inability is in articulation rather than phonation, the lips and tongue are more concerned than the intrinsic laryngeal muscles, or those of the expiratory group. In one case with marked spasm of the inspiratory muscles and involvement of the larynx, as shown by the whistling inspiration, the speech was not at all involved. In rare instances a difficulty in articulation is the first symptom noticed (Case 343[1]).

In Case 202 there were marked sighing and sobbing due to choreic spasm of the inspiratory muscles. Case 181 had paroxysms of panting and hard expiration. In several instances odd sounds were noted; thus, in Case 86 there were sounds in the throat like a sob, which continued day and night. Case 101 had a "peculiar noise in the throat," and Case 183 made a grunting noise while eating.

As a rule, the movements cease during sleep. In three cases they are stated to have persisted. In one of these, a child of four years, the movements may have been the irregular twitching seen during sleep in nervous children. In Case 121 the movements are said to have been first observed in sleep. In Case 119 *b*, a severe attack, the statement of the persistence during sleep is very specific.

Muscular weakness is a prominent symptom of chorea, and may result in a condition of paresis or even paralysis. It may be hemiplegic, paraplegic, or more frequently monoplegic. Of 28 cases in which there was a *physical test* of marked loss of power, the lesion was distributed as follows: legs, 6 cases; right hemiplegia, 4; left arm, 10; right arm, 6; arms and legs, 1; arms, 1. Very rarely does the loss of power reach the grade of complete paralysis, but the child may be unable to lift the arm to the head, the shoulder may droop, the grasp may be feeble or there is wrist drop. It is important to remember that there may be extreme paresis with slight incoordination and few spontaneous movements. To such case Todd gave the name of paralytic chorea. The weakness of the arm is shown by the enfeebled grip, of the leg by a dragging or by a decided limp. In his original description Sydenham speaks of the "unsteady movement of one of the legs, which the patient *drags*." The paralytic symptoms may precede or come in the course of the attack, more rarely follow it. In Case 89, a girl, aged sixteen, with subacute rheumatism, had a sudden loss of power in right arm and leg, with loss of voice, but retention of consciousness. The attack lasted only half an hour and was followed by pain in the limbs and choreic movements. The case was under observation for two months and made a good recovery. In the majority of the cases the paresis come on during the attack, was slight, and passed away with the disappearance of the chorea. Occasionally a local paralysis or weakness remains, as in Case 229, a lad of ten, who had a severe general chorea in September, 1880, during which the

[1] Loc. cit., p. 198.

limbs were paralyzed. He recovered gradually but when he returned in September, 1883, in a second attack, there was talipes of the left foot the result of the paralysis in former attacks. In Case 21, a wrist-drop remained for two years, the result of a palsy which came on with chorea of right arm. Case 91 illustrates a difficulty in determining whether a patient has ordinary chorea or is the subject of post-paralytic spasms. Girl, aged five, when two years old had congestion of the brain followed by hemiplegia which disappeared in a few weeks. Since the attack there have been more or less general choreic movements, which at the age of five were slight, though distinct. With arsenic they disappeared in three months. The history suggests a post-paralytic case, but the complete recovery is unlike the usual sequence in this condition. Gowers[1] and Ollivier[2] have written fully on the subject of paralytic chorea, and our experience tallies very closely with theirs. It is not often of serious import and usually disappears.

Do the choreic spasms extend to the muscles of organic life? So far as our experience goes, the great gastro-intestinal muscle is never affected; certainly there are no symptoms which can be referred to irregular contractions of the coats of the stomach or bowel. Abdominal pain is not often a complaint; constipation, however, is not uncommon. The sphincter ani remains uninvolved. So, also, the bladder acts normally in the most extreme cases. There are a few instances of incontinence of urine, but not more than we might expect in the records of 400 children. Spasm of the bronchial muscles, inducing asthmatic attack, is not met with even in those cases in which the respiratory muscles are involved. By some writers the irregularity and rapidity of the heart's action, and the mitral systolic murmur have been regarded as due to disturbed rhythm in the ventricular contractions, and to choreic spasm of the papillary muscles; but this is a mere conjecture, and the symptoms are explicable in a more reasonable way.

Sensory troubles occupy a less important part in the history of chorea. Pain in the muscles or nerves of the affected limbs is not common. In children it is sometimes difficult to get an accurate idea of the seat of the pain. There are instances, usually of hemichorea, in which pain, without arthritic complication, is a very marked symptom. Mitchell has spoken of these cases as *painful* choreas. Numbness, tingling, and pricking sensations are mentioned five or six times in the records. Anæsthesia of the affected side, which has been noted by several writers, has not been observed. Tender points, on which the French writers have laid so much stress, have not been frequently observed. In the printed schedule of our chorea books there is a special question relating to this subject, and in the great majority of the cases it is followed by a negative statement. In a few instances there were sensitive regions over the cervical, dorsal, or lumbar spines. It is the experience at our clinics that these tender points, either dorsal or along the course of the nerves, are very uncommon. Marie[3] has compared them to the hysterogenic points in hysteria, and has also found ovarian tenderness in a number of cases, always on the same side as the chorea.

[3] Progrès Médical, 1886.

Headache is a frequent, and in some cases a persistent, symptom. It may precede the attack.

Psychical disturbance is rarely absent in chorea, though fortunately, in the majority of cases, slight in degree. On the moral side we have irritability of temper, often a strange perverseness, and emotional outbreaks. A frequent complaint of the mother is "that the character of the child is completely changed." The memory becomes enfeebled, and the aptitude for study is lost. This impairment of the intellect may be progressive, and terminate in positive dementia. Usually we can "read the mind's complexion in the face," and can see, as the case progresses, the clouds obscure a bright, clear countenance, leaving it dull, heavy, and expressionless. There may be hallucinations of sight or of hearing. The patient may do odd, meaningless acts. Thus, Case 150, a girl of twenty-one, with a second attack, would hide away her clothes, and, on one occasion, wandered off for two days alone. More serious still are the cases, usually young adults, with mania, the *chorea insaniens* of Bernt. A large proportion of the fatal cases come in this class. The delirium is of an active, noisy character, and there are instances on record in which the chorea has been overlooked, and the patients sent to an asylum. Usually, but not necessarily, the motor disturbance in these cases is of an aggravated character. So impressed have some observers been with the predominance of the psychical trouble in chorea that they have regarded the motor disorder as an epiphenomenon of secondary importance.

Epileptiform seizures may occur, and there are records of five cases with convulsive attacks, or periods of sudden unconsciousness. Case 110 had a severe convulsion during the course of the disease. In Case 410, the child, æt. nine, has had for five years epileptic attacks, not numerous, only three or four a year. She is now, May 4, 1887, in her second severe attack of chorea.

In Cases 202, 232, and 248, there were attacks of loss of consciousness, possibly epileptic. Gowers has called attention to the relation of chorea to convulsive seizures,[1] and has reported ten cases. The infirmary experience does not indicate a common association of the two affections.

A relationship with *hysteria* is much more frequent, and there are a dozen cases, all in girls from fourteen to twenty-seven years of age, which presented marked hysterical symptoms, while many others had minor manifestations. With one exception the movements in these cases were those of ordinary chorea, and the symptoms of hysteria were subsidiary. In case 239, a girl aged nineteen, was affected with "jerking spasms" in legs and arms, which came on suddenly. She had had hysterical spells, and had been troubled with constant eructations of gas. The movements of the arms and shoulders became very rhythmic, and the head was moved from side to side.

The condition of the *reflexes* has been studied by Sinkler in 50 cases,[2] with the following results; in 26, the knee-jerk was normal; in 15 it was diminished in degree; and in 9 it could not be obtained.

Trophic lesions are not common in chorea, unless we regard, as some would have us do, the joint troubles as arthropathies occurring in the course of a cerebro-spinal

[1] British Med. Journ., 1878. [2] Loc. cit., p. 448.

disease. Under this head, however, we may very properly consider the skin affections, of which the records mention 11 cases. In five of these the rash was erythematous or papular, and unquestionably due to arsenic. In Case 332, a boy of seven, there was a pigmentary change in the right cheek after a course of Fowler's solution for six weeks. It is highly probable that the rash was due to arsenic. Similar cases are reported by "Oscar Chamille," and Stewart.[3] There were two cases of herpes zoster. In case 2, a girl of seven, the vesicles came out on the right side about three weeks after beginning to take arsenic. In Case 318, a girl of eleven, the herpes was on the left side in the lumbar region, and appeared about seven weeks after beginning the arsenic treatment.

Case 15, girl aged eighteen; no manifestations of rheumatism; had been taking arsenic for ten days when an erythema resembling erythema nodosum appeared, and remained for some days. In Case 312, girl aged eight, with pains in wrists at time of attacks, but no swelling. There were black and blue raised spots on the face. They were not painful, and came out in crops. They did not disappear on pressure, and resembled a purpuric eruption. Apparently the rash was not due to the arsenic, as in one attack, at least, it appeared before the administration. In Case 347, child aged eight, had first attack of chorea in 1885; second attack in 1888, preceded by acute rheumatism; knees and ankles swollen, and they were large, swollen, purple blotches on the legs and arms.

In these last instances we have probably illustrations of purpura rheumatica, which not infrequently occurs in children, in acute paroxysms, with very slight rheumatic trouble. They assume mild forms of the peliosis rheumatica (Schonlein).

Several [illegible] of the cases were treated by the arsenic so commonly used, but it is probable that none of them took the remedies in sufficient quantity to produce curative effects in the disease itself. [illegible] Roberts has observed a case of purpura, and [illegible] has reported several cases of erythema.

Cases of complete paresis are unusual in our records. In Case 10, where the [illegible] occurred on the 3d day, when, as occasionally happens, the endocarditis has ceased to exert any influence on the choreic symptoms. There may be the most extensive and violent movements, with normal temperature, and a great increase of the pulse rapidity throughout. Post-febrile chorea is [illegible] study of the disease [illegible] from different causes. In [illegible] practice it is rare to see [illegible] chorea. H. A. Hare[4] has called attention to the fact that in post-febrile the temperature of the affected side may be elevated.

The general symptoms of the disease shall be separately considered, and it need only be mentioned here that in [illegible] the pulse was [illegible] in Case 10 it was [illegible] during the attack.

[illegible]

[illegible]

The *duration* of an attack of chorea is extremely variable. From eight to ten weeks may be stated to be an average time for attacks of moderate severity. In mild cases, recovery may take place in two or three weeks. Not infrequently, however, cases drag on at the clinic for three or four months. The term *acute* chorea is applicable to those rare cases of extreme severity, with or without mania, which may terminate in a week or two. On the other hand, there are cases which drag on month after month and become truly chronic, lasting even for years. They are of sufficient interest to receive a separate consideration.

The liability to *recurrence* is an important fact in the history of chorea and has been carefully noted in the records. The 410 cases represent 683 separate attacks. In 240 cases there was a single attack; in 110, two; in 35, three; in 10, four; in 12, five; and in 3, six.[5] Case 23 is a good illustration of recurrence. Mary R., aged eight, came to the clinic March 23, 1877. The attack had begun in the autumn of the previous year and had continued. She improved rapidly under treatment, and the movements ceased. Toward the end of June the symptoms returned, and this is noted as a second attack, though probably it was only a relapse. The third attack was in August, 1880. The fourth in the spring of 1881. The fifth in January, 1882, and in February, 1883, she returned with a sixth attack. There was no rheumatism and the heart was not affected.

The notes give no clew to the conditions which render recurrence liable. Of the 60 cases in which there were three or more attacks, there was a history of rheumatism in 11, a proportion very much higher than in the cases with only one or two attacks. Mitchell has called attention to the vernal recurrence of chorea, and we have had many instances in which year after year, in March, April, or May, the patients would come back for treatment. Autumnal recurrence is certainly less common. It is the custom at our clinics to warn the patients of this tendency and to give instructions with a view to prevention, and even to order a course of arsenic in the early spring. Sydenham had observed this point, for he says that as "the disease is liable to return again, I think it well for the patient to be purged about the same time, or a little earlier, the following year."[1]

Certain cases of chorea display peculiarities sufficiently marked to warrant special consideration.

Choreic Tremor.—There are seven cases in our records in which tremor persisted for a period of years.

Case 37.—Martha K., aged seven. For five years has had choreic movements—sudden, abrupt, and decided, sometimes in the face, sometimes in the extremities. Menstruation began at fifteen years of age. No heart murmur, but she was anæmic. The movements were a good deal under control. After attendance for two months without benefit she disappeared from observation.

Case 40.—Lizzie, aged five. When two years old had convulsions, of the brain followed by hemiplegia, which disappeared in a few weeks. From this time she has been more or less choreic. When seen August 8, 1879 the movements were general but slight; none in face. Under the use of liq. potass. arsenitis, m ii t.i.d. she

[1] Loc. cit., p. 20

improved, and on December 31, 1881, the movements had ceased and the child seemed quite well.

Case 186.—Lizzie K., æt. twenty-one. No history of rheumatism. When thirteen years old had the first attack, which was general and affected the speech. After lasting, without intermission, for three years the movements ceased, and she returned December 1, 1882, with a second attack which had already lasted three months. There is no note of her return to clinic.

Case 246, already referred to as of congenital origin. —Jennie W., æt. nineteen. Good family history. Mother was frightened by seeing a marked case of chorea some time before the child was born. Movements began at birth and have continued. When seen February 3, 1884, movements general; muscles of face, arms, and legs in constant motion, mouth motions particularly affected. Muscles were well developed. She could knit and dress herself. Has been going to school; learns easily, intelligence fair.

Case 230.—Wilbur H., æt. twelve. No neurosis in family. As an infant, could not hold up the head or move the legs. At three or four months the choreic movements of the hands were noticed. When seen first, October 1, 1883, there were general, but slight, irregular movements. In May, 1887, the condition remained the same; there were slight jerky motions in extremities and head. Intelligence defective.

Case 335.—Mary M., æt. twelve. Mother very nervous and uncle had "spasms." For three years has had movements in face, head, and arms; speech never involved. On September 21, 1885, when first seen, the head was chiefly involved. The jerky movements of the right hand occurred when at rest, not when in use. She was treated for some months without much improvement. On the 7th of May, 1887, she returned to the clinic. The chorea had gradually disappeared, and, although nervous, she seemed very well.

Case 348.—Alfonso G., æt. twenty-one; baker. A sister had chorea, and died of heart disease in 1872. Was well until August, 1884, when he began to have jerking movements in head, arms, and legs. Speech somewhat affected. When first seen, June 1, 1885, there were spasmodic contractions of all the muscles of the face, neck, trunk, and arms; legs not affected. The inspiratory muscles were involved, and at times a high-pitched whistling inspiration occurred, as if the constrictors of the larynx were involved. He has been under observation and treatment for two years, and has somewhat improved. The movements of the arms have ceased, and the thoracic muscles are not much affected, but those of the head and neck are still involved. His general condition has remained excellent, and there has not been at any time mental disturbance.

The two congenital cases should go in a separate category, as possible instances of symptomatic chorea dependent upon widely diffused cerebral changes, but they illustrate clinically the most extreme form of chronic chorea.

In Case 91 the movements followed temporary hemiplegia, and might possibly be regarded as symptomatic; but as they were general and finally disappeared, it is not likely that they were the result of the lesion which induced the hemiplegia.

The other cases are peculiar only in the protracted course of the disease. It is encouraging to note the recovery, after three years' duration, in Cases 186 and 335.

Habit chorea.—This convenient term has been applied by Mitchell to certain local choreic movements, usually of the face, met with very frequently in children from the ages of seven to fourteen years. The orbicularis oculi, the corrugator supercilii, and the facial group are commonly affected, and the child repeats a series of grimaces. Occasionally it is limited to a single muscle. Motion of any sort aggravates the movement. In many instances it is at first nothing more than a trick which the child has caught, and can restrain, but constant repetition makes a habit which finally becomes uncontrollable and may persist throughout life. There may be movements of the shoulders and arms, and a case beginning as a local chorea may lapse into the pronounced general form. There are often associated movements of a curious character. Thus a lad with blepharospasm would, when walking, suddenly stop and put his feet together, or rotate the head. A lad at present in attendance has, in addition to slight facial chorea and a shrugging movement of the shoulders, the following curious trick: he will suddenly put the index-finger of the right hand between his teeth and bite it hard, while, at the same time, the pad of the second finger violently compresses the tip of the nose. The skin over the distal joint of the finger is raised in hard callosities, due to the constant biting; and the nose has become flattened. He is a sensible lad, and when asked why he does such a silly thing, answers, "I cannot help it—I feel I must," and in goes the finger as he speaks. Such habits have close affinities with the more infantile tricks of thumb-sucking, head-nodding, rocking, etc., and they are not without interest in connection with certain imperative conceptions of adult life.

Chorea of pregnancy.—In two cases of the 410, the attacks were in pregnant women.

Case 277.—A woman, æt. twenty, who had had repeated attacks of chorea, applied at the clinic October 15, 1884. She was married early in May. Began to have movements of limbs August 15th. At time of visit, both sides were involved and there was decided affection of speech. She had morning sickness, the menses had stopped, the breasts were enlarging, the papillæ prominent, and she was believed to be pregnant. She attended at the clinic for four weeks, and improved very much. The mental condition was good.

Case 236.—Mrs. B., æt. twenty-two, applied at the clinic November 16, 1883. Had an attack when nine years of age, and has been nervous ever since. Is pregnant. Attack began about September 15th, and has recently got worse. The right side chiefly involved; speech much affected; no mental symptoms. She remained under treatment for a few weeks, improved slightly, but did not return.

A third case was admitted to hospital in the spring of 1876. The notes have been mislaid, and I am indebted to Dr. Neff for the following memoranda. She was aged about thirty, a servant at the Colonnade Hotel. Had had chorea as a child. In the fourth or fifth month of pregnancy she accidentally broke a fifty-dollar demijohn of brandy and received a severe shock. Soon after, chorea developed and she was brought to the hospital. The attack was very severe, and after two

months she was transferred to the maternity department of the Philadelphia Hospital, where she died.

A fourth case is at present under treatment at Dr. Sinkler's clinic. Woman, æt. twenty-one, married three months. Menses have stopped, and she is believed to be pregnant. Nine years ago she had chorea—a most obstinate attack—which persisted for five years without intermission. She had a second attack, which lasted two months. The present one began shortly after her marriage, and is, possibly, not directly dependent upon pregnancy. It is, so far, not a serious attack.

The chorea of pregnancy is often severe, and the mental symptoms may be of the most aggravated kind; very many of the cases of chorea insaniens come in this category. Primiparæ are most frequently affected, and, as in the cases recorded above, previous chorea seems to play an important determining rôle. The mortality is high, ranging from twelve to thirty per cent. Two recent French monographs by Hervé[1] and Gayard[2] have reviewed the entire subject, but not added materially to our knowledge of the conditions under which it occurs.

ORIGINAL ARTICLES.

THE RELATIONS OF CHRONIC PHARYNGITIS TO INTRANASAL AND AURAL INFLAMMATION.

By RALPH W. SEISS, M.D.,

ADJUNCT PROFESSOR OF OTOLOGY AND INSTRUCTOR IN PATHOLOGY AND MICROSCOPY IN THE PHILADELPHIA POLYCLINIC.

For years past it has been the habit of almost all systematic writers to divide chronic pharyngitis into several varieties: simple, follicular, granular, and atrophic pharyngeal inflammation being the usual divisions adopted. The causes of the disease given by various authors are almost innumerable: the strumous, gouty, and rheumatic diatheses, heredity, overuse of the voice, and the abuse of tobacco, are enumerated by Morell Mackenzie as the especial factors; frequent attacks of acute sore throat are considered by many writers to be a necessary cause of this disease. A few writers, notably Seiler and Bosworth, state that nasal catarrh and consequent mouth breathing are very important factors in the disease, but the almost universal tendency among laryngologists seems to be to consider inflammation of the pharynx as belonging to at least three separate diseases, each with its especial etiology and clinical history.

For some years I have taught at the Philadelphia Polyclinic and elsewhere that chronic pharyngitis, when not syphilitic, or tubercular, or perhaps gastric in character, is always dependent on intranasal disease, and have been in the habit of correctly foretelling the pharyngeal condition present by an examination of the anterior nares. I consider all the various "varieties" of chronic sore throat to be simply stages of one progressive inflammatory disease, which is in turn almost invariably dependent on the stage of intranasal inflammation present in the case. My experience has led me to believe that overuse or improper use of the voice or gastric disturbances are rarely if ever the sole cause of grave chronic inflammation of the pharynx; of course, the already existing disease may be aggravated by them, but if the nasal passages be normal the pharynx will almost invariably be found in a similar condition.

In cases of simple chronic rhinitis the pharynx will be found to be in a condition of chronic hyperæmia, with the mucous membrane and underlying tissues somewhat swollen and infiltrated; the swelling being due to the proliferation of small cells in the sub-epithelial tissues. A few varicose and dilated bloodvessels show prominently on the mucous-streaked surface, although in this variety hypersecretion is not marked. It is rarely that any discomfort is experienced by the patient at this stage; "morning sore throat" is occasionally complained of, and there may be a trifling cough. If the simple rhinitis progresses, developing into the first stage of true hypertrophic catarrh, a new set of pathological phenomena appear in the pharynx; a chronic *lymphadenitis* is set up, the lymph follicles become enlarged, hard, and markedly hyperæmic, and now on inspection the well known conditions of "follicular pharyngitis" will be found. The mucous membrane presents much the same appearance as in the preceding form, but shows greater thickening, the vessels are more dilated and tortuous, and studding the posterior pharyngeal wall are seen numerous oval tumors of varying size, averaging half a centimetre in diameter, deep red in color, and each surrounded by an area of congestion. This condition may obtain for years without gross change, and I think, authors to the contrary, very rarely, at least in this climate, causing serious discomfort or any very prominent symptoms. Certainly the grave systemic disturbances which many writers have described as belonging to follicular sore throat must be exceedingly rare, since no disease is more common, and I have found the condition especially prevalent among physicians themselves, and the affection is frequently found among athletes and rowing men in the most robust health.

In patients in whom the nasal disease progresses through the second stage of hypertrophic rhinitis well marked changes take place in the pharynx. The contents of the enlarged lymph follicles soften, break down, and are absorbed, or more rarely they burst, and a small superficial ulcer results. Changes also take place in the proper glandular structures, the epithelium multiplies, the glands becoming choked with epithelial elements, and subsequent atrophy follows. This stage of chronic pharyngitis is the form most commonly seen in Philadelphia; the appearances are a swollen and infiltrated condition of the mucous membrane as in earlier stages, but varied by areas of atrophy from the pressure of newly formed tissue. The surface is studded with the often *cystic* remnants of follicles, or by the scars or minute ulcers left by their softening. The bloodvessels are large, numerous, and tortuous. Symptoms consisting of cough, "morning sore throat," dryness, hoarseness, and general discomfort

[1] De l'Ictère pendant la Grossesse. Paris, 1854.

[2] Contribution à l'étude de la coqueluche des Femmes enceintes. Paris, 1884.

in the pharyngeal region nearly always accompany this stage of the inflammatory process.

This *stage of breaking down* grows worse and worse as the nasal disease progresses into the third or sclerotic type of hypertrophic rhinitis. The sub-epithelial connective tissue becomes filled with small cells, which form a fibrillated structure, and the pressure exercised by this new growth induces atrophic changes, which occurring irregularly give a rough and nodular contour to the pharyngeal wall.

The succeeding well-defined form is the "nodular" or "granular" variety of pharyngitis—the posterior wall is *light colored and yellow* in appearance, and (from the destruction of follicles, the irregular atrophy of glands, and deposit of new connective-tissue) its surface is nodulated and granular. This stage gives yet more marked symptoms of impaired function and is usually progressive. Ultimately, as the result of very advanced nasal sclerotic changes or true atrophic nasal catarrh, we find complete destruction of all the glandular and follicular elements of the pharynx; the posterior wall consists of a simple membrane of new-formed fibrous tissue resting upon the bodies of the vertebræ, and the appearances of true *pharyngitis sicca* obtain; viz., extensive "absorption" or atrophy, the pharynx has a cup-shaped appearance, and its cavity is greatly enlarged, the pharyngeal wall is dry, puckered, red, and shining, and usually deeply congested from crust irritation. The symptoms of this stage of pharyngeal inflammation are usually marked and grave; the patient complains of hacking cough, of the accumulation of dry crusts within the pharynx, pain and discomfort, and the larynx will be found to show a deeply congested and often abraded mucous membrane on examination, and laryngeal cough is the rule.

Although occurring but rarely, there are occasional exceptions to the regular sequence of chronic pharyngitis to nasal catarrh; frequently recurring attacks of acute sore throat may spur on the pharyngitis so that it undergoes more rapid changes for the worse than the rhinitis present; and in dyspeptics the course of chronic sore throat is more rapid than in patients in whom the digestive tract is in a normal condition. Patients who work in a dust or chemical-laden atmosphere, and who are compelled by nasal lesions to breathe mostly through the mouth, show very rapid progressive pathological changes in the throat. The sequence, is, however, so well marked and reliable that but few errors need be made in diagnosing the stage of chronic pharyngitis present from an examination of the anterior nares.

Why the pharyngeal condition so closely follows the various stages of intranasal inflammation is not easy to determine; four causes are at work: extention of the inflammatory disease by continuity; irritation and septic influences from the flowing of abnormal nasal mucus over the pharyngeal tissues; mouth-breathing from nasal stenosis; and irritation from hawking, coughing, and forcibly blowing the nose to get rid of abnormal secretions. Their importance is in the order of their enumeration.

It is, of course, not intended here to deny that some or all of the many causes of chronic pharyngitis enumerated by authors may not have important etiological relations to the disease; a cause not often recognized is the use of various "hot" condiments and sauces, which cause a most marked pharyngeal hyperæmia in many individuals, with consequent infiltration of small cells. The use of undiluted alcohol is also a prominent causative factor in many cases. I have certainly seen fewer cases of chronic sore throat due to a vicious use of the voice, than to badly chosen treatment received for a trifling pharyngeal inflammation at the hands of physicians.

The remote results of advanced pharyngeal inflammation, associated as it is with grave intranasal lesions, are not infrequently of serious import. Nearly all cases of the atrophic type complain of "chest fretting," and a slight degree of chronic bronchitis is frequently found; great susceptibility to acute attacks of bronchitis and "winter cough," is the rule. Whatever be the relations of the same, it is also certain that a large proportion of patients with atrophied pharyngeal tissues are anæmic, dyspeptic, and generally below par. Great impairment of voice is an almost necessary result, and various local hysterical phenomena are very common.

Otologists usually consider inflammation of the lower pharynx as standing in an important etiological relation to chronic catarrhal deafness, and usually place considerable weight on the results of an examination of the lower pharynx in prognosis. While this is certainly the case, it is probable that could a grave chronic pharyngitis exist while the nares and the region of the pharyngeal tonsil remained fairly normal, no aural symptoms would obtain, inflammation of the lower pharynx tending neither to obstruct the orifices of the Eustachian tubes nor to extend to them by continuity. If great sclerosis has occurred in the lower pharynx, it is safe to argue that a similar condition exists in the lower portion of the Eustachian tubes, and, perhaps, even extending into the middle ear, but this is due to the inflammation of the pharyngeal vault, and not to the secondary disease of the lower throat. The upper pharynx belongs pathologically to the nasal region and is not under discussion here.

The *local treatment* of chronic pharyngitis, except in the earliest stages, is very unsatisfactory; applications made directly to the pharyngeal mucous membrane are nearly worthless, except to relieve symptoms, and possibly, if long continued to arrest the disease. Atrophied glands, degenerated lymph follicles, new-formed connective tissue, cannot be replaced by any treatment known or likely to be discovered. Treatment must be directed to the nasal cavities to be of avail; if the rhinitis be cured—so far as destruction of tissue permits—the pharyngitis will improve and the symptoms cease. Painting the pharynx with mineral and vegetable astringents, iodine, etc., if gently and thoroughly carried out, will often markedly relieve symptoms, and is still largely used at the Philadelphia Polyclinic. In the early stages of the disease a spray of potassium bromide (10 to 20 grains to the ounce) is of value; in more advanced cases I use applications

of tincture of sanguinaria or galanga properly diluted with glycerine; in yet more advanced stages *liqueur de Villate* diluted with water, or one or other of the thymol solutions suggested by me are most useful. Various other well known solutions have been found valuable in selected cases; a 10 grain solution of crystal *hydrastin* has been used by us with benefit in "nodular" pharyngitis. In all cases better results will be obtained if the entire pharyngeal region be sprayed clean with some alkaline and antiseptic solution; formulas of which for use in private practice may be made very elegant and agreeable. The faradic current used two or three times a week, the positive pole being placed directly on the pharyngeal mucous membrane, and the negative over the larynx or angle of the jaw, is of the greatest value. It requires care and judgment in its manipulation, or quite as much harm as good may result.

Operative procedures have not proved satisfactory in my hands; the destruction of enlarged follicles by chemicals or electro-cautery only appears to hurry on the dreaded atrophic changes, except where individual follicles have undergone cystic changes, when their careful obliteration is expedient. Obliteration of varicose veins occasionally relieves symptoms, various local hysterical phenomena having been cured by some writers by this treatment. If properly done, it is safe and of value, although I have never seen cause to ascribe much symptomatic importance to the dilated vessels, regarding them as a necessary result of the general condition. When softened lymph follicles are found they may be incised and the resulting raw surface touched with ordinary tincture of iodine; less atrophy and scarring take place when so treated than if allowed to run their course undisturbed.

Internal treatment should be directed more to the nasal lesions than in hopes of directly affecting the pharynx. Strychnia and chloride of ammonium have proved the most useful drugs in my hands; the former is usually given in combination with phosphoric acid; various other medicines are doubtless of great use in selected cases. Outdoor exercise and "training" under a competent instructor are of enormous value in this, as in all diseases of the respiratory tract.

Although a *cure* of advanced chronic pharyngitis cannot be hoped for, by prolonged and well-directed treatment all symptoms may be relieved, the disease arrested, and if the patient is seen and treated from time to time no further trouble need be apprehended. In all cases the whole body must be interrogated for remote causes, violent pharyngeal symptoms being not seldom dependent on lesions of the digestive or genito-urinary tracts, a cure of which is imperative before the throat symptoms can be relieved. The well known hygienic methods of "strengthening" the throat should never be forgotten or neglected after convalescence is established.

In treating any case of pharyngeal or laryngeal inflammation the positive causative relation of the nasal lesions must not be overlooked, and in direct relation to the success attained by intranasal therapeutics will be the improvement in the *chronic pharyngitis*.

A NEW HEART TONIC, STROPHANTHINE.

By THOMAS J. MAYS, M.D.,

Professor (adjunct) of Diseases of the Chest in the Philadelphia Polyclinic.

Strophanthine is obtained from the seeds of *Strophanthus hispidus*, which, according to "Just's *Botanic Annual*, is an exogenous creeper, belonging to the Apocyneæ, climbing the highest trees, and which is indigenous to the valley and mountain forests of equatorial Africa. The seeds are ground and formed into a paste by the natives of Africa, and this preparation they employ to poison their arrow-points. The poisonous property, which undoubtedly resides in the strophanthine, is very active, and is thus used for the purpose of procuring food, and as a means of defence against enemies.

The strophanthine which is manufactured by Merck, and which we employed, is a white crystalline powder which melts at about 365° F., and evaporates without leaving a residue. It has a feebly acid reaction, and is very soluble in water. Its general physiological action, as worked out by Dr. Fraser, of Edinburgh, is that of a muscle-poison, with a special affinity for the cardiac muscle. In small and appropriate doses it has a most decided beneficial action on the heart. It readily subdues an excited pulse, and does not seem to give rise to the cumulative effects, or to the digestive troubles which follow the administration of digitalis. Its action is principally confined to the heart, and even the bloodvessels are said to be uninfluenced by it. We have administered this agent in a number of cardiac affections, and, so far as our experience goes, believe it to be a very valuable therapeutic measure, as the history of the three following cases will demonstrate.

Case I.—Mrs. A., aged seventeen, consulted us July 21, 1887, for a pain in the back, palpitation of the heart, and pain over cardiac area, and for this we prescribed quinia, iron, and ammonia. On the 3d of August she returned no better, dyspnœa, cardiac pain, and palpitation continued, pulse 120. Treatment: Strophanthine $\frac{1}{100}$th grain every three hours. 4th. Pulse 112. Same dose every two hours. 5th. Pulse 104. Much better. Same dose every hour and a half hours. 6th. Very much improved, $\frac{1}{48}$th of a grain every three hours. Dyspnœa gone and feels very well. Pulse 80. This was the first case in which we gave the drug, and it is very evident that we began with doses which were too minute.

Case II.—*Subclavian aneurism.* J. B., aged forty, laborer. Was first seen July 19, 1887, when he complained of cough, expectoration, much dyspnœa and poor appetite, and frequent pains shooting down left arm, for about one year. Had chancre twelve years ago. *Physical signs:* Dulness on percussion below clavicle from sternum to shoulder-joint. Loud systolic bruit and a very perceptible thrill imparted to the finger over same region. Bruit propagated over the whole cardiac area and into the axilla but

not into the carotid, and its maximum intensity existed at junction of first left intercostal space with sternum. There was marked weakness of left radial pulse. Gave him four grains of iodide of potash every four hours. August 22d. No better. Trinitrine one drop of one per cent. solution three times a day. Sept. 4th. Cough, pain, and dyspnœa very much worse. $\frac{1}{75}$th of a grain of sulphate of atropia and two drops of tincture of aconite root every three hours. Sept. 6th. No better. $\frac{1}{64}$th of a grain of strophanthine every three hours. 8th. Better. Appetite improved, dyspnœa and pain less. 13th. Better. Same treatment. 16th. Very much better, same treatment.

Case III.—*Aortic regurgitation.* W., aged thirty-five, married, first came under observation August 19, 1887, when she was suffering from cough, whitish, tough expectoration, dyspnœa so marked that she was unable to lie down. Had hæmoptysis nine months ago, œdema of lower extremities, and was losing flesh. Had rheumatism. Aortic diastolic murmur, mucous râles at bases of both lungs. Administered quinia, iron, and ammonia. August 22d. No better. Five drops of digitalis tincture every three hours. 24th. Somewhat better, but unable to lie down, $\frac{1}{64}$th grain of strophanthine every four hours. 15th. Much better. Dyspnœa improved and she is now able to lie down at night without difficulty. 26th. Still improving. Œdema in lower extremities has disappeared. Same treatment. Oct. 1st. With the exception of some rheumatic pain in her arm she feels comparatively well.

1829 Spruce Street, Oct. 1, 1887.

AN APPARATUS FOR THE QUANTITATIVE ESTIMATION OF SUGAR IN THE URINE.

By S. P. KRAMER, M.D.,
of Cincinnati.

The fermentation test for sugar in the urine has long been considered the most certain and reliable test; it is the one to which recourse is had when others fail.

If, then, we could secure for the quantitative estimation of sugar an apparatus at once accurate, simple, reliable, and inexpensive, we would then have a saccharometer useful to, and attainable by any practitioner.

The apparatus devised by Dr. Max Einhorn,[1] consists of the fermentation tube described by Salkowski and Leube.[2] It consists of a bent-glass tube, the long arm of which is graduated, of about five cubic centimetres capacity. The short arm ends in a bulb, which acts as a reservoir to retain all the overflow. The test is made in the following manner: A gramme of fresh commercial compressed yeast is thoroughly shaken up with ten cubic centimetres of suspected urine. This is poured into the reservoir, and the long arm and bend of the tube are filled by inclining the apparatus and allowing the urine to flow in and displace the contained air, the pressure of the atmospheric air retaining the urine in the long arm. The apparatus is allowed to remain undisturbed at the ordinary temperature of the room (70° F.), for a period of twenty to twenty-four hours. The sugar, if there be any present, will then have fermented, having been converted into carbonic acid gas and alcohol. Part of the carbonic acid gas passes up into the graduated long arm, and part escapes into the outside air. Now, by a number of experiments, Dr. Einhorn has determined the volume of gas corresponding to a given percentage of sugar in the urine, and the tube is graduated by the results of these experiments. But with more than one per cent. of sugar the entire long arm of the tube is filled with gas, and all the urine is forced into the reservoir, giving off its carbon dioxide to the outside air; so that we cannot ascertain if the urine contain more than one per cent. of sugar. To obviate this, it is necessary to dilute the urine sufficiently to bring the amount of gas evolved within the capacity of the instrument. After the reaction has been completed the amount registered on the graduation is multiplied the same number of times as the urine was diluted.

While the apparatus is exceedingly simple, it admits of several sources of error.

In the first place, since the instrument is graded by the results of a number of experiments and not by an exact chemical calculation, the graduation itself must be in some degree deficient. Then under different degrees of temperature and pressure, the volume of gas in the tube and that given off, varies so that the error due to variations in temperature and pressure is multiplied; the amount of gas absorbed by the urine also varies under different conditions of temperature and pressure. Then there are the inconvenience and inaccuracy resulting from diluting the urine; and moreover, since nearly all diabetic urine contains more than one per cent. of sugar, the urine must be diluted in nearly all cases, and any error either in the graduation or volume of the gas is multiplied the same number of times as the urine was diluted.

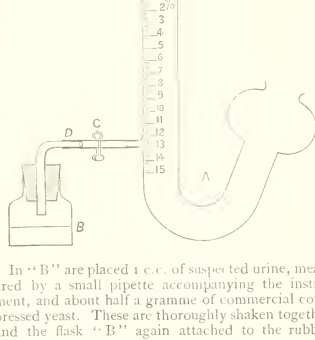
The following apparatus seems to answer all the requirements, both as to simplicity and accuracy. The aim has been to collect and measure all the gas evolved, while the instrument is graduated by exact chemical calculation.

The apparatus (see figure) consists of a bent tube "A," the long arm of which is graduated, while the short arm ends in a bulb. From the side of the long arm there is projecting a nipple. To this is attached air-tight, by means of rubber and glass tubing, the fermenting flask "B." Fitting over the rubber tubing is a brass clamp "C." The test is made in the following manner: To about 50 c.c. of water are added a little bicarbonate of soda and nitric acid. Effervescence takes place, carbonic acid gas being given off, and saturating the water with carbon dioxide. This is allowed to remain undisturbed until effervescence has ceased. The clamp "C" of the apparatus is then closed, and the flask "B" removed by separating the glass and rubber tubing at "D."

The long arm and bend of the tube "A" are filled with the water previously saturated with carbonic acid gas. This is done by pouring the water into

[1] Medical Record, p. 91, 1887.
[2] Salkowski and Leube, "Die Lehre vom Harn," p. 223.

the reservoir, inclining the tube, thus allowing the water to run in and displace the contained air.



In "B" are placed 1 c.c. of suspected urine, measured by a small pipette accompanying the instrument, and about half a gramme of commercial compressed yeast. These are thoroughly shaken together and the flask "B" again attached to the rubber tubing at "D."

The clamp "C" is opened, and the apparatus is allowed to remain undisturbed at the ordinary temperature of the room, for a period of twenty to twenty-four hours.

By this time the sugar, if the urine contain any, will have fermented. The carbonic acid gas passes up and is collected in the long arm of the tube, where the percentage of sugar may be read off on the graduation.

The instrument is graduated in the following way: From the equation: $2C_6H_{12}O_6 = 2C_2H_6O + 2CO_2$, we determine by means of their molecular weights, that one part by weight of glucose yields 0.4889 part by weight of carbon dioxide at 0°C and 760 mm. of atmospheric pressure. Then the number of cubic centimetres of carbon dioxide, obtained from 1 c.c. of urine containing one per cent. of sugar, equals $0.4889 + \frac{a}{100}$, in which "a" is the weight of 1 c.c. of urine, and "B" is the weight of 1 c.c. of carbonic acid gas at the given temperature and pressure.

The instrument is graded by the result of this calculation, so that it is mathematically correct.

Correction is made for the amount of carbon dioxide absorbed by the 1 c.c. of urine; also for the amount of carbonic acid gas produced by the yeast itself, independent of the sugar. Correction is also made for the amount of sugar not converted into alcohol and carbonic acid gas. The instrument is graded to 70° F., and slight variations from this will make a difference scarcely appreciable. The difference in pressure in the two arms of the tube is disregarded: since, in an instrument so small (8 inches) the error resulting therefrom would be so minute as to have no significance.

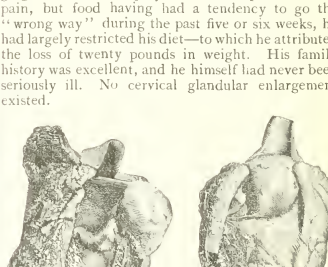
That the apparatus is simple and inexpensive, may be judged from the preceding; that it is accurate is shown by the record of thirteen experiments with a solution containing a known quantity of sugar, which yielded on the production of carbon dioxide an average error of 0.026 per cent., which is so minute as to have no clinical importance whatsoever.

A CASE OF ROUND-CELLED SARCOMA OF THE LARYNX.

By LOUIS JURIST, M.D.,
LECTURER ON LARYNGOLOGY, JEFFERSON MEDICAL COLLEGE; FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

On the 29th of August, 1884, Mr. E. D. T., white, aged sixty-five, was referred to me by Dr. Sibbald, of Wissahickon, to determine the cause of an attack of dyspnœa, which had come on the day previous.

On inquiry, Mr. T. stated that his shortness of breath, although of two months duration, had only become severe enough, on the day previous, to lead him to seek medical advice. There was moderate inspiratory and expiratory stridor. His voice, although perfectly clear, was hesitatingly formed and muffled. During the past two years, he had had occasional attacks of sore throat, for which domestic gargles had been employed. He complained of no pain, but food having had a tendency to go the "wrong way" during the past five or six weeks, he had largely restricted his diet—to which he attributed the loss of twenty pounds in weight. His family history was excellent, and he himself had never been seriously ill. No cervical glandular enlargement existed.



Laryngoscopic examination, made without difficulty, pictured a smooth, globular, non-ulcerated growth of grayish tint and dense consistence, about the size of a horse chestnut, springing from the left ventricular band. The amount of breathing space is fairly well shown in the woodcuts. The manipulation, he insisted, gave him great relief.

The danger of suffocation was carefully explained to his sons, and the proposition was made that he should at once enter the Jefferson Medical College Hospital, to have a preliminary tracheotomy performed; this was declined.

The following morning, while at another institution, I was hurriedly summoned to the hospital by a member of his family, who stated that his breathing was much worse, and begged me to operate at once. Shortly before we reached him, he fell unconscious, during a suffocative spasm, in the waiting-room of the hospital, and in spite of an immediate tracheotomy by one of the attending surgeons, Dr. J. W. Hearn, could not be resuscitated.

Only a partial post-mortem was permitted. The larynx and trachea removed. Microscopical examination showed the tumor to be a round-celled sarcoma.

The history, macroscopical appearances, the absence of ulceration, of glandular involvement, correspond entirely with the description of these growths in the latest work on the subject (Butlin, H. T., *Malignant Diseases of the Larynx*) and have an important bearing on the treatment. Keeping before us the inevitable termination of extensive mechanical obstruction of the larynx, from whatever cause arising, and subscribing to the statement that "the evidence at present seems to prove that sarcoma of the larynx neither affects the lymphatic glands, nor produces secondary growths, and that its malignant properties are limited to infiltration of adjoining parts;" laryngectomy, either partial or complete, is clearly indicated.

If, as Butlin claims, "even the worst cases of sarcoma are scarcely to be looked upon as hopeless," the issue in this case is the more deplorable.

To avoid confusion, it may be stated that this is the case referred to in the *International Encyclopedia of Surgery*, vol. v. p. 736.

839 North Broad St.

GENERAL CONCLUSIONS, DERIVED FROM THE STUDY OF THE EYES OF ONE THOUSAND INSANE PATIENTS.

By LOUIS J. LAUFENBACH, M.D., Ph.D.,
ASSISTANT SURGEON OF THE PENNSYLVANIA EYE AND EAR INFIRMARY, PHILADELPHIA.

The conclusions expressed in the present paper are derived from the examination and study of more than a thousand cases of insanity, observed either in private practice, or at the Philadelphia and Norristown hospitals. This work has extended over a period of more than four years, and consisted of a thorough eye examination, the ophthalmoscope being employed by the direct method whenever possible, the eye being examined usually with and without dilatation of the pupil; vision for form was taken in all cases; in addition, the ear and pharynx were examined, as it was thought that these examinations might serve as a corroboration to those of the eye. The work was undertaken with the thought that if a sufficient number of patients were examined, it might serve to shed some light upon the pathology of insanity, and it was hoped that, even in a therapeutic aspect, it might prove not unprofitable.

Of course, in the short paper here presented, many points of minor importance evolved during the investigation are omitted, the effort being to indicate the general results obtained, only well-marked characteristics being here presented.

Vision for form, in all conditions of insanity, is practically normal, when we allow for refractive errors, opacities in the refracting media, and unhealthy conditions of the background. Of course, all things being equal, for instance, vision in dementia is not as good as in acute mania, because, as we shall find, in dementia we are dealing with a general degenerative condition, as expressed in the eye by more or less atrophy of the nerve, whereas, in acute mania we usually have present a condition of exaltation, represented by an increased blood-supply in the eye. Then, again, in imbecility, we do not expect to obtain the same vision as we would in other cases, as the want of education, and the frequent impossibility thereof, is a factor to be taken into consideration. In conclusion, we may say that vision for form in the insane is the same as in the mentally normal with similar eye conditions.

The visual fields are very often reduced in consequence of the optic nerve degeneration so frequently found in cases of insanity; this reduction of the field's area differs not in variety or extent from what we would expect to find in similar nerve degeneration in the sane.

The pupils are far more frequently unequal and irregular in outline than in the sane; they are, also, more frequently sluggish, the irides slowly responding; particularly is this the case with the light reflex, the accommodation reflex being more frequently normal. These pupillary variations are more frequent, both in severe acute attacks, as well as in very old chronic cases. In the former we have slowly responding pupils, inclined to dilatation, while in the latter class they are more often unequal and irregular in outline.

Insufficiency of the recti muscles was found to be more frequent in imbeciles and idiots than in the mentally sound, but in the other classes of insane patients this fact was not observed.

Corneal, scleral, lens, and vitreous troubles are met with in about their ordinary frequency.

Choroidal inflammations are very uncommon, except in cases of general paresis.

Choroidal congestion is more common than among the sane; it is often found in connection with retinal hyperæmia, but not unfrequently it is found alone.

In studying the condition of the optic nerve and retina, it will be found best to take up in a connected manner the various forms of insanity. In fact, after studying the eye-conditions among insane patients, one cannot help feeling that there is a very intimate relationship existing between the various forms of insanity; one is led to believe that the three divisions—melancholia, mania, and dementia—are but different stages or phases of the same condition.

We shall find it best to first give the results obtained in cases of acute melancholia, as undoubtedly this is the commencement stage of many, if not all, cases which are found under the classes of melancholia, mania, and dementia.

On examining the eyes of a case of acute melancholia, we find that the fundus almost invariably shows us a condition of retinal hyperæmia, or of congestion; if taken early enough, it is but hyper-

æmia: the vessels, both arteries and veins, are larger than normal; they are often tortuous, with slight increase in the size of the lymph channels; the general appearance of the retina is more red than usual, and the nerve is slightly pinkish. If the case goes on into one of acute mania, we have a more marked increase in the blood-supply, we have a condition of congestion; the vessels are larger, the retina becomes darker in color, while the macula lutea loses its brilliancy, inclining to become a dull red. If the case is sufficiently severe, this condition of things continues increasing in severity, and soon we have retinal effusion, with a decidedly pink nerve. If the case becomes better, the congestion lessens, the effusion gradually disappears, and as the case gets well, the eyes gradually assume their normal condition.

Not infrequently we have, early in a case of acute mania, a condition of atrophy presenting itself; or, again, a swelling of the nerve, with obliteration of its edges (a slight papillitis), resulting in atrophy. These cases are not inclined to recover; they are apt to go into a chronic condition, and are almost invariably incurable. It may be that in the case of acute mania the congestion and effusion remain, becoming no worse, nor yet better. If it continues, we have, sooner or later, an atrophy of the optic nerve resulting. Patients who have had one or more attacks of acute mania, almost invariably present a condition of nerve atrophy in addition to an increased blood-supply. A case of acute mania, becoming one of chronic mania, gradually shows more and more atrophy of the nerve, while the congestion gradually subsides, the effusion being absorbed, the vessels becoming less tortuous, and decreasing in calibre. As the case of chronic mania merges into dementia, we have still more marked atrophy, and now we begin to find that the blood-supply is not only not increased, but that it rapidly diminishes, until, at length, it is less than normal; frequently the vessels in long-standing cases of dementia are very few and very small. When the condition of chronic dementia is fully pronounced, we have a very decided atrophy of the nerve-structure, and a very marked diminution, both in the number and size of the retinal vessels.

There is a distinct and separate class of cases of acute mania which are classed as cases of delusional mania, in which there is almost invariably some heart defect, and we find only a slight degree of hyperæmia of the retina, or else we find the retina perfectly normal. These cases often last for a very long time, year after year the same mental condition is present, they show no progressive eye change. They are not inclined to get well, nor to pass over into dementia, but die usually in their disturbed mental state, from heart disease.

If a case of acute melancholia is becoming better, we find a gradual diminution of the retinal hyperæmia or congestion, the fundus of the eye clears up, and when the patient has recovered, there usually no vestige left in the eye. Cases of acute melancholia which are but very slowly progressive, in which year in and year out there is but little change in the mental condition, show but little or no change in the retinal circulation. Usually there is present a hyperæmia which continues on the same plane. The case may continue year after year, and may go on into dementia later on, when we shall begin to notice the atrophic tendency; if, however, there is a tendency to recovery, we find the eye presenting a subsidence of its abnormal condition, the blood-supply is lessened, the vessels are smaller, and less tortuous.

There is, however, a series of cases of melancholia which from their onset are very mild in character, and remain so throughout, becoming well in a greater or less length of time. These cases very rarely have any eye-change; but, when present, it is of the nature of a very slight retinal hyperæmia, which clears up as the case recovers.

As before indicated, we have in general paresis the majority of the cases of choroidal inflammation. The greater number of cases examined, which have been classed as paralytics, were found to present some syphilitic lesion of the eye.

In imbecility and in idiocy we have bloodvessels whose calibre is greater than normal, the vessels being numerous and tortuous, and the blood-supply is invariably greater than the normal; in addition to this we usually have large optic disks, but they are not of normal color, and seem to present an increased amount of fibrous tissue, showing a poor nerve condition. The macula lutea is usually of a dull red color.

In epilepsy we have present the same conditions, with far less frequency of large optic disks, as in imbecility and idiocy, but it is not so invariable. In addition, we have in epilepsy a more decided tendency to nerve degeneration, and also have an increase in the size of the perivascular lymph channels, and, in many cases, we have retinal effusions occurring.

N. W. COR SIXTH AND GREEN STREETS, PHILADELPHIA.

MEDICAL PROGRESS.

CONTAGION AND DISINFECTION.—At the recent meeting of the Society of Prussian medical officials, PETRI, of Berlin, urged that the successful practice of disinfection required a knowledge of the germ to be attacked, and the agency directed against it. As Koch has shown that anthrax is the most virulent of known germs, it may be used as a test. First of available disinfectants he placed carbolic acid in five per cent. solution; two per cent. solution is inert. Sublimate is too poisonous, too easily decomposed, but is useful in disinfecting the unbroken integument. In the schedule of disinfectants of the Berlin Disinfection Ordinance, February, 1887, it is omitted. Laplace has shown that the addition to both carbolic acid and corrosive sublimate solutions of one-half per cent. hydrochloric acid increases their efficacy; a two per cent. carbolic acid solution, with this addition, kills anthrax. In disinfection to destroy the cholera bacillus whitewashing walls with lime was especially recommended. Esmarch has also shown that spores can be removed from walls by rubbing them with stale bread, which should be burned at once.

KOCH, of Berlin, stated that his observations that five

per cent. solution of carbolic acid destroyed anthrax had been confirmed by others. Guttmann's experiments, to the contrary, are not explicit enough nor plainly described. Koch had studied anthrax especially because it was, when he began his work, the best known of infectious germs; he had, therefore, made it a test object, and the germs since discovered give every evidence of a feebler virulence than anthrax. Successful disinfection consists in combating each disease in the special manner required by its individual germ.

In the discussion which followed Schulz advised the addition of potassium soft soaps as an auxiliary means of disinfection to the substances now employed in the Berlin Ordinance.

Philipp, of Berlin, had used Guttmann and Merk's method of disinfection with spray of corrosive sublimate without injury to any one employed in the work.—*Deutsche medicinische Wochenschrift*, Sept. 29, 1887.

Wounds of the Palmar Arches.—Thiriar, of Brussels, summarizes his views in a recent lecture, as follows: The safest and best plan is to ligature in the wound, if possible; if not, above it. In recent cases it can usually be done in the wound. Where it is necessary to tie higher up, it is of no use to tie the ulnar and radial; and if the wound is not very recent, and there has been time for a considerable amount of collateral circulation to have developed, even the brachial must be tied above the profunda. It is necessary to remember that the axillary artery sometimes gives off two brachial branches as high as the axilla itself. M. Thiriar examined a large number of arms in the dead-house when he was in charge of the post-mortems, and found this anomaly present in twelve per cent. of the cases. However, he has always succeeded in arresting hemorrhage in wounds of the palmar arches, even when the tissues were suppurating, by a modification of Sir J. Simpson's plan of acupressure. He uses needles curved to a semicircle, and, passing them under the artery, brings the edges of the wound together, and occludes the vessel by the application of a twisted suture, which there is no need to draw very tightly. He summarizes his advice thus: 1. Direct ligature. If impossible, 2. Twisted suture and acupressure. If unsuccesful, 3. Ligature of humeral in the middle, if the collateral circulation has not had time to develop; above the profunda, if it has. 4. Employment of compression, direct or indirect, forced flexion, forcipressure, styptics, etc., only as temporary expedients.—*Lancet*, October 1, 1887.

Ethereal Tincture of Phosphorus in the Asphyxia of Pneumonia in Children.—Dr. Faria, of Brazil, is quoted by the *Revue Générale de Clinique et de Thérapeutique* of September 22, 1887, as prescribing an ethereal tincture of phosphorus in the asphyxia which occurs in the cases of children suffering from pneumonia. His prescription is as follows:

Aquæ cinnamom.	℥ 25.
Tinct. ethereal. phosphor. . . .	gtt. 8.
Spirit. ætheris	℥ 5.

Sig. Half teaspoonful to spoonful hourly as needed.

The Conveyance of Tuberculous Infection by Expired Air.—Cadéac and Malet are quoted as follows by the *Wiener medizinische Presse* of September 18, 1887:

Their experiments consisted in allowing rabbits to inspire air expired by phthisical patients daily for several hours. Infection did not result. When, however, an irritating substance, like bromine vapor, had caused inflammation of the bronchial mucous membrane before the inhalations, infection resulted. Twelve rabbits and guinea-pigs were kept for two or three months in an atmosphere shared by nineteen tuberculous animals, but without any closer association; none of them was infected. If the non-tuberculous animals were brought into closer relations with the tuberculous, infection resulted. The air expired by tuberculous animals was condensed, and the water resulting was injected into animals. These experiments gave no positive result. The conclusion, however, was reached that secretions and excretions of the phthisical are infectious when they become dried, and, as dust, inspired or taken into the mouth by the common use of food and drinking utensils.

Brouardel on Typhoid Fever.—At the recent Hygienic Congress at Vienna, Brouardel read a paper on the causation of typhoid fever, whose summary is as follows:

He would now seek to show what science had done; and, as an illustration, he selected typhoid instead of cholera, for in the long run it was the most fatal of the two diseases. At Geneva the International Congress was still undecided. Some said that typhoid arose from the fermentation of organic matter; others that a specific germ alone sufficed, without any decomposition of organic matter. The Congress could not agree whether the fever was contagious or only spread by water or the absorption as food, of some other contaminated substance. In 1884 an effort was made to utilize the current of the Rhone as a motive power. A lock was constructed, and this caused some of the drinking water supply to flow backward toward the mouth of a sewer. Some months previously this sewer received the dejections from two or three isolated cases of typhoid fever. In a few days after the contamination of the water supply a serious epidemic broke out in Geneva, and there were no less than 500 cases. Last year at Clermont Ferrand and Mont Ferrand there were 300 cases of typhoid due to water contamination, while such places as Chamavière and Royat, though close by, escaped, their water being derived from a different source. In Paris, whenever the supply of the pure water from the Vannes or the Dhuys fell short, and the waters of the Seine, the Ourcq, or the Marne were used instead, the hospitals were filled with patients suffering from typhoid fever, precisely three weeks after such alteration in the character of the water supply. Studying the question from the bacteriological point of view, Dr. Brouardel showed that the multiplicity of microbes rendered this investigation very difficult. After five years it was found that a few drops of carbolic acid in a culture broth had the property of killing all these microbes with the exception of the special microbe of typhoid fever. This latter developed so slowly that it escaped the action of the acid. In the examination of the waters the same process was used: and now it was possible to say definitely that such or such a substance contained the real

germ of typhoid. At the same time he was not prepared to say that typhoid could never arise merely from foul air. In a family of mine, living on identically the same food, the sons alone contracted typhoid fever. It was found that under his room window there was an open soil pipe. In another family precisely the same incident occurred, and this among his own patients, and quite recently. Nevertheless water was the more general cause of the disease. He concluded by urging that it was more easy to cover water than to protect open rivers or canals from contamination. Water ought to be brought to large towns in pipes or closed aqueducts. If we thus protected the health of the great centres, the rural districts would also largely benefit, as their epidemics were very often imported from towns.—*Lancet*, October 1, 1887.

INTRACRANIAL SARCOMA; REMOVAL; RECOVERY.—DURANTE, of Rome, reports the following case in the *Lancet* of October 1, 1887:

The course of the disease, the loss of memory and of the sense of smell, and the objective and subjective state of the patient led me to believe in the presence of a tumor within the cranium, the pressure of which affected the anterior lobe of the brain and paralyzed or destroyed the olfactory nerve. Moreover, the displacement of the globe of the eye led me to believe also that the tumor had penetrated the superior arch of the orbital cavity. Such being my diagnosis, I proposed to the patient an operation that would remove the offending object, explaining to her the gravity of the operation without reserve. She was brave, and she consented.

To reach the tumor it was necessary to make a large opening in the left frontal bone; so with an incision commencing from the inner angle of the left orbit upward nearly to the hair line as far as the temporal region, I raised all the soft tissue from the bone in a flap. The bone being exposed, with a sharp scalpel and hammer I removed a large portion of it, commencing at the superior orbital margin, inferiorly, and found that the internal parietes of the frontal sinus had been forced outwardly. The dura mater being now exposed, I examined it, and found that it had been perforated by the tumor just opposite the frontal eminence. With great care I now began to scoop out the tumor. As soon as a considerable portion of the tumor was removed, I detected that it did not adhere beyond the internal surface of the dura mater, and that therefore its enucleation was comparatively easy; and then removed it and carried with it all the adherent portions of the dura mater. The hemorrhage was slight and easily controlled by the hæmostatic, a tampon treated with sublimate. The tumor was lobular, of the size of an apple, and weighed seventy grammes (about two ounces). It occupied the anterior fossa at the base of the left cranium, extending to the right and upon the cribriform lamina, which it destroyed. Posteriorly it extended to the glenoid tubercles before the sella turcica. The left anterior cerebral lobe was greatly atrophied; the orbital arch was much depressed, but not perforated by the tumor as I had anticipated. Having stopped the bleeding completely, I now united the wound by first intention, leaving in the cavity occupied by the tumor a drainage-tube, which descended to the left nasal fossa through the opening made on the ethmoid by a prolongation of the neoplasm; then I closed the nasal cavity with an iodoform tampon. The operation lasted about an hour. The patient bore the chloroform very well, showing only the weakness following the use of an anæsthetic and attendant upon loss of blood. On the third day she had fairly recovered, and the wound was healing without suppuration. The drainage worked well, a large quantity of serum tinged with blood flowing through it. On the fourth day, however, the patient was overtaken by sudden prostration, was inclined to sleep, exceedingly disinclined to talk, and complained of mental confusion. I then discovered that the drain had stopped during the night, so I at once removed the tampon, replacing it, however, further down the nasal cavity. The effect was good; the serous fluid began to drip again. Not satisfied with this, I applied a gum-elastic "pump" to the external opening, and drew off about an ounce of liquid. The flow was thus reëstablished, and continued all the following day and night. On the renewal of the flow the alarming symptoms disappeared as if by magic. On the seventh day I removed the stitches and the drainage-tube, and on the fifteenth day the patient returned to her home, doing very well. She had lost that sensation of vacuity around her person which made her uncertain in her movements, but had not regained her memory or the sense of smell.

Three months after I presented my patient to the Chirurgical Society at its meeting in Perugia, in 1884. She was in a happy frame of mind, and willingly related her experience. She stated that now all her faculties and mental conditions were normal, and that she had even regained her sense of smell. This greatly surprised me, for I felt sure that I had destroyed the left olfactory in removing the tumor, which had destroyed the cribriform lamina of the ethmoid. Upon experimenting, however, with aromatic substances, we found that she could only smell with the right, and that the left was totally insensible, its olfactory having been destroyed either by the pressure of the tumor or by the operation itself. The part of the bone which had been removed was now partially reproduced, the cavity in the region of the operation had now disappeared, and the eye had regained almost entirely its normal position. The tumor, under the microscope, presented a multiform fibro-cellular structure of sarcoma.

It is now four years since that operation was performed, and my patient is in perfect health. My diagnosis and the operation, apparently so hazardous at the time, are therefore justified by the result. And, though such operations have generally failed, the success of mine should secure proper consideration at the hands of modern surgery.

A USEFUL APPLICATION FOR DIPHTHERIA.—SIMON applies the following, hourly through the day, with a camel's-hair pencil to the throat of a diphtheritic patient:

Acid. salicyl.	gr. 8.
Decoction of eucalyptus . . .	℥ 15.
Glycerine	℥ 7½.
Alcohol	℥ 3.

As the decoction of eucalyptus is not commonly used in America, the tincture or oil may be employed, in proportionate strength.—*Revue de Clinique et de Thérapeutique*, September 29, 1887.

The Protection of Water Supply.—Hueppe of Wiesbaden, advised the following measures, at the Congress of Hygiene, at Vienna:

1. Protection of springs by proper walls from surface water; they should be as far as possible removed from cesspools.

2. Inspection and proprietorship of sources of water supply by a central bureau.

3. Inspection of potable waters by this bureau, with the effort to procure water naturally filtered through proper soil, and from deep sources of origin.

4. The intelligent use of sand filtration. (Thiem's method was commended.)

5. Uninterrupted and vigorous use of proper "water works." Prevention, in every possible way, of water stagnation.—*Deutsche medicinische Wochenschrift*, September 22, 1887.

A Preparation for Burns on the Eyeball.—Mr. Flanagan, Pharmacist to the Massachusetts Eye and Ear Infirmary, recently compounded the following to meet the want of a surgeon in a case of burn of the eyeball:

Atropine (uncombined alkaloid)	.	0.10 part.
Cocaine " "	.	0.05 "
Oleic acid	.	1. "
Olive oil	.	9. "

The alkaloids are dissolved in the oleic acid by the use of a water bath, and the solution is then added to the olive oil, warmed. A preparation was tried in which chloroform was used in place of the oleic acid, but the mixture proved more irritating to the affected parts.—*Pharmaceutical Record*, September 20, 1887.

Cold Affusion in Lightning Stroke.—Dr. Hidalgo, of Mexico, brought before the Academy of Medicine of that city, at a recent meeting, the case of a man who was struck by lightning, and was at first thought to be dead, but who, after having had, at the suggestion of a passer-by, a large quantity of cold water thrown over him, began to show signs of vitality. He did not at first receive any medical treatment, so that the early history of the case had to be obtained from the relatives. After being brought home, water was still poured over him until he spoke for the first time, saying he was cold, and begging that this treatment might be stopped. He was then put to bed. During the night he did not sleep, but kept talking in a delirious manner, and complaining of pain, especially in the head. When asked what was the matter, he said at one time that he had something the matter with his chest, and at another that he had rheumatism all over, but he made no reference to the lightning.

Dr. Hidalgo saw him the next day, and found him in a semi-comatose state. The pulse was 75, full and compressible, the temperature normal, the respiration rather rapid. He was so deaf that he could only be made to open his eyes by shouting close to his ear. The pupils were contracted. He complained of pain all over, but especially in the head and arms. He had passed three badly smelling liquid stools during the night. He was neither hungry nor thirsty. The electric spark had entered the right parietal region, just behind the auricle. The scalp was burned over a surface of about four by five centimetres, and a spot of dried blood was seen on the upper part of the auricle. The right side of the neck was reddened as by a burn of the first degree; below this, as far as the umbilicus, the effects were equal to those of a burn of the second degree, of the width of about fifteen centimetres at most, but very irregular in its dimensions. The electric fluid had passed down the inner aspect of the right leg, producing a burn of the second degree. It had then passed down to the foot, where the burn was of the first degree, and the strip of skin affected much narrower than above. The hat, coat, and trousers were injured—as if torn—all along the course of the current, but they were not burnt in any part. The patient was treated with sedatives and some clysters, and in sixteen days was perfectly well.

Dr. Hidalgo supposes the pneumogastric was affected by the shock, which paralyzed the respiration, and subsequently the heart's action, similarly to the behavior of an overdose of chloroform. The indication, therefore, was to reëstablish the respiration, and this was admirably fulfilled by the cold affusion, which fortunately was administered quickly, before the paralysis of the heart had become absolute.—*Lancet*, October 1, 1887.

Stomatitis.—The following is the formula for a gargle, recommended by Monin in this affection:

Acid. boric.		
Acid. salicyl.	.	āā gr. 15.
Potass. chlorat.	.	ʒ 2.
Glycerin.	.	ʒ 12½.
Essent. myrrh.	.	gtt. 16.
Aquæ aurant. flor. . . .	.	ʒ 9¾.

Sig. Use as a gargle.—*L'Union Médicale*, September 24, 1887.

The Temperature of Food given to Invalids.—In the *Wiener Klinik* for September, 1887, Uffelmann, of Rostock, states the following conclusions of his observations upon the temperature of foods for the sick:

1. Cold food and drinks lessen body temperature; the lowered temperature is a genuine loss of heat.

2. The ingestion of cold substances lessens the irritability of the diseased stomach.

3. Cold substances ingested raise the tone of the stomach, increase intestinal peristalsis, promote the passage of stools, and, in dysentery, for example, cause an increase of pain.

4. Cold food and drink increase the liability to cough.

5. Warm foods raise bodily temperature slightly, and promote perspiration.

6. Hot foods and drink are more stimulating than cold.

7. When often given, hot foods lessen the tone of the digestive tract and the vessels of the abdomen.

The Comparative Value of Malt Extract and Beer.—Dr. Townsend, in the *Boston Medical and Surgical Journal* of October 13, 1887, summarizes his studies upon this question, as follows: The small amount of alcohol in the malt extract is due to the presence of the tincture of hops. A glass of beer and a tablespoonful of the malt are practically of the same nutritive value as far as the sugar is concerned, while the tablespoonful of malted wheat or Liebig's food contains one-third as much again of sugar; but the latter

two are superior to beer in nitrogenous substances, the malt containing more than three times as much, and the Liebig's food more than seven times as much; and they are also superior to beer in the inorganic salts, the malt having nearly four times as much, while the Liebig's food has nearly five times as much. Beer, of course, contains alcohol in addition. The superiority of the Liebig's food in nitrogenous substances and minerals makes it preferable to malt, if the diastatic power of the latter is to be disregarded, by taking it directly into the stomach.

By way of summary, it may be said that although malt by reason of its contained diastase is able to convert starch into sugar in a watery medium at the temperature of the body, it has no power over starch in the living stomach, owing to the presence of the gastric juice. Administered directly by the mouth, therefore, it is of use only on account of its contained nutriment, and is inferior in the amount of nitrogenous and inorganic principles to a food formed by the action of diastase on wheat—that is to say, to Liebig's food.

EPITHELIOMA OF THE EPIGLOTTIS; REMOVAL; RECOVERY.—DR. MYLES, clinical assistant to Sir Morell Mackenzie, describes the following case in the *New Orleans Medical and Surgical Journal* for October, 1887:

Mr. D., aged about fifty-four, consulted Dr. Mackenzie in the summer of 1886, suffering from a greatly relaxed uvula and general congestion of the throat. The larynx was perfectly healthy. Dr. Mackenzie amputated a portion of the uvula, and after a few weeks the throat became perfectly healthy.

In the middle of November, 1886, he began to suffer again and consulted his ordinary medical attendant. His attendant used a laryngoscope and found general congestion. In the spring of 1887, as he was still suffering with his throat and great dysphagia, he consulted several specialists, and a growth was discovered on the epiglottis. At the end of May Mr. D. returned to Dr. Mackenzie, who found the epiglottis invaded in every part, both surfaces and edges, by papillary formations. These growths did not merely project from the mucous membrane, but the epiglottis had entirely lost its contour, and appeared to have undergone papillomatous degeneration. A small piece of the epiglottis was removed, and microscopic examination failed to show any distinct cancerous element. The patient had become very much emaciated, and was decidedly weak; of course, the question arose whether constitutional debility was due to cancerous cachexia, or whether it resulted from diminished supply of food, caused from constant pain in swallowing.

Having seen many cases in which the epiglottis had been entirely destroyed without any inconvenience to the patient after cicatrization had taken place—Dr. Mackenzie determined to remove the entire epiglottis. Accordingly, on June 22d, after making several applications of cocaine, Dr. Mackenzie operated with his epiglottome. This instrument resembles a tonsillotome.

The epiglottome is eight and one-fourth inches in length, the curved portion passing downward being about three and a half inches in length. Near the proximate end is a strong wooden handle, fixed at an angle of about sixty degrees to the horizontal portion. The instrument in other respects is exactly like Dr. Mackenzie's ordinary tonsillotome, and, as in that instrument, the cutting blade is pushed forward by the thumb being forced through a metal ring.

The patient being placed in the ordinary laryngoscopic position, Dr. Mackenzie, guided by the laryngeal mirror, placed the loop of the instrument over the epiglottis, then laying aside the laryngeal mirror he seized the tongue himself and pressed the instrument home. From experiments which Dr. Mackenzie had previously made with a blunt instrument he had found, that if he allowed the patient to hold his tongue himself the instrument always slipped off. In fact it is necessary for the operator to press the instrument very firmly against the base of the tongue, whilst at the same time the tongue itself, in order to get a sufficient resistance to effect clean section, is dragged forward by the left hand of the operator and securely held. No pain was felt in the operation, but cocaine was again liberally applied to the base of the wound, and an hour after the operation, when the bleeding, which was very trivial, had ceased, one-fourth grain of morphia was applied to the cut surface.

The patient passed a good night, and the next day was able to swallow solids easily. Liquids passed into the larynx and gave rise to coughing. After the third day the patient was able to swallow as well as he did before the operation.

Since that time the patient has steadily improved, and in the latter part of July was able to swallow without any difficulty.

SACCHARIN FOR DIABETES.—FISCHER, of Berlin, has devised pastilles after the following formula:

Saccharini	gr. 45.
Natrii carbon. sicci.	gr. 30.
Manniti	3 12½.

For 100 pastilles.

One of these may be used to sweeten a cup of coffee, tea, or cocoa.—*Deutsche medizinische Wochenschrift*, September 29, 1887.

PARTURITION IN PRIMIPARÆ OLDER THAN THIRTY.—ECKHARDT has investigated 543 cases of births in primiparæ above thirty in Schröder's clinic, and concludes that parturition at this comparatively late period of life is caused by late coitus or disease of the woman or man. The rigidity of the tissues in these patients causes prolonged labors and wounds of the genitalia. Diseases and complications of pregnancy are more frequent with these patients than with other primiparæ. Placenta prævia; prolapse of the cord; contracted pelvis; breech presentation, face presentation, and twins are more frequent than in young primiparæ. The children of such women are smaller than those of younger women. Retained placenta and uterine atony are more frequent than in others. With women between thirty and forty male children predominate over female; with women over forty female children are in excess. It is comparatively rare to find children with hard, well ossified crania among old primiparæ.

Realizing the fallacy of laying too great stress on statistics, Eckhardt forms no theories on the results of his investigations.—*Centralblatt für Gynäkologie*, October 1, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,
PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, OCTOBER 22, 1887.

THE OSTEOGENIC FACTORS IN THE DEVELOPMENT AND REPAIR OF BONE.

UNDER the above caption, DR. WILLIAM MACEWEN, of Glasgow, presents an interesting and important contribution, in the October number of the *Annals of Surgery*. There are but few persons who are entitled to speak with so great authority in regard to surgical affections of the bones, and any communication from him in regard to their pathology and surgery is sure to attract attention. In the present article the observations are physiological, and in a measure experimental, and have a most important practical significance. Of late years it has been the custom to seek the elucidation of obscure problems in medicine or surgery, by experimentation upon animals, but in the present case the observations are of a clinical nature, and the experiments have been performed upon men. Although the article is not yet finished, we feel justified by its importance in calling attention to it.

It has long been held that bones grow in length from the epiphyses, and in thickness from the periosteum, and that the destruction or removal of the periosteum results in a necrosis of the subjacent layers of bone. The periosteum was, therefore, considered to be the main factor in the reproduction of bone; indeed, certain experiments have shown that the periosteum may be transplanted into a remote locality, and result in the formation of a plate of bone. As an illustration of the fact that the periosteum is a bone-forming membrane, we have the numerous instances where the long bones have necrosed as the result of injury or inflammation, and the continuity of the shaft has been restored by means of an involucrum formed by the detached periosteum, but not infrequently no such result follows; and the work of Dr. Macewen is intended to elucidate the fact that the periosteum plays a much less important rôle in the development and repair of bone than is generally believed.

The article consists chiefly of certain propositions which are dogmatically stated, and the proof of which is subjoined in a series of clinical observations. These propositions begin with simple statements which will be accepted almost without comment, and gradually lead up to observations of a more complex character. Proposition A states that when the periosteum has been mechanically detached from an extensive area of an adult healthy bone, and replaced after the lapse of some hours, union between the bone and the periosteum can take place without sloughing or observable augmentation following. This proposition requires but little argumentation for its proof; such cases are not infrequent, and the most important requisites are cleanliness, asepticism, and accurate apposition.

Proposition B deals with inflammatory separation of the periosteum, and states that after the withdrawal of inflammatory products, reunion between the periosteum and bone may take place without necrosis ensuing; showing that the temporary separation of the periosteum from the bone, even as a pathological result, is not necessarily attended by death of the bone

Proposition C holds that the periosteum covering a portion of bone may be completely destroyed or permanently removed, yet the denuded bone may not only retain its vitality, but may throw out cells which will cover it, and form a new periosteum. It is substantiated by a number of observations of the most convincing character.

Proposition D goes still further, and maintains that a portion of bone which has its continuity severed on all sides, and at the same time has had all its periosteum removed, is capable of living and growing. This is a very important observation, since it has a direct bearing upon fractures with comminution. The fragments should be kept disinfected, and reimplanted, and frequently a good result is obtained; in this way a cure is possible, of severe fractures, trephining operations, etc. The fragments should be quite small, from a quarter to an inch in diameter.

Proposition E goes still further, and is the most interesting conclusion of the article as far as it is yet published. It is that not only do detached portions of bone, deprived of the periosteum, live when reimplanted in their original position, but such portions are capable of living after transplantation. Parts of deeper layers of bone which had no periosteal connection have been transplanted, and have lived and grown. The proof of this statement is found

in a case of necrosis of the humerus, in which no regeneration of the bone occurred, the arm remaining perfectly helpless and useless. A space of two inches separated the two portions, and this was overcome by bone grafts from a cuneiform osteotomy, with the result of filling in the hiatus, and restoring the arm to a marked degree of usefulness. In this particular case the periosteum had been preserved, but without the production of a new bone, and the grafting was undertaken after the lapse of fifteen months, the patient having returned to have the limb amputated.

If it be possible to effect an artificial union by means of the insertion of bone grafts, and so overcome gaps in the bones, the art of conservative surgery has made a notable advance. How great a loss of substance may be repaired in this manner, and whether the grafts may be taken from animals, are points not touched upon in this article, but full of interest. There are certain affections which require that portions of the bones shall be removed, and it is to be hoped that at some future time a means will be found for remedying the defects which have been made. The recent removal of a portion of the inferior maxilla has served to impress these reflections upon us. Will it ever be possible, in such cases, to transplant a corresponding piece from another person or an animal, and in this way restore the continuity of the jaw-bone? or could a new bone be formed by the implantation of small bone grafts? In the light of Macewen's experiments this result may not be beyond the realms of expectation.

THE DYSPNŒA OF ASTHMA AND ITS TREATMENT.

The causation of the asthmatic paroxysm is still in dispute, and at least three theories have advocates, more or less zealous. The demonstration of the bronchial muscle gave a firm anatomical basis to the view that the attack was due to its spasmodic contraction. Wintrich and Bamberger hold that such a condition is inconceivable with the enlarged and hyper-resonant state of the lungs during the paroxysm, and they support a theory of tonic spasm of the diaphragm, either alone, or with the other muscles of respiration. A third view, that of Traube and Weber, attributes the attack to swelling and hyperæmia of the bronchial mucosa—through vasomotor agency—similar to that which occurs in the nasal mucous membrane in the early stage of catarrh. At present a majority of the observers are divided in opinion between the theory of spasm and that of hyperæmia with tumefaction.

In *The American Journal of the Medical Sciences* for October, 1887, Fraser, of Edinburgh, relates some interesting observations which support the spasm theory, and have a very practical bearing on the treatment of the attack. It occurred to him to study the auscultatory phenomena during the asthmatic paroxysm in order to ascertain if they could be modified by the action of any agent known to control the contractility of unstriped muscle. Now, it is well known that the most constant and striking physical signs accompany asthma, viz., the dry whistling râles (without any moist sounds) produced in the tubes, either by spasm of the muscle or swelling of the mucosa. If it could be shown that the administration of a remedy known to relax unstriped muscle was followed by a disappearance of the râles and relief of the dyspnœa, a strong point would be made in favor of the spasm theory. This Fraser has done, using the nitrites, whose capabilities of relaxing non-striped muscle in the case of arteries is well known. Eight observations are recorded in which either nitrite of amyl, nitrite of ethyl, nitrite of sodium, or nitroglycerine was given, and the chest carefully auscultated before and after every administration. In each instance, improvement more or less positive followed, and the dyspnœa and sounds disappeared simultaneously. From the well-recognized action of these bodies in reducing the contractility of non-striped muscle, it seems reasonable to attribute the relief to the relaxation of the spasm of the bronchial muscles.

The nitrite of amyl was given in solution, five minims in two drachms of water, or inhaled, ten minims on blotting paper at the bottom of a small glass tumbler. The nitrite of ethyl (nitrous ether) acts well in ten minim doses of a twenty-five per cent. alcoholic solution. Of the nitrite of sodium ten minims of a ten per cent. solution, and of the nitroglycerine five minims of a one per cent. solution were employed. The administration of nitrite of amyl in the asthma paroxysm has long been practised, but the accurate determination of the coincidence of the relief of the symptoms with the disappearance of the physical signs has not before been so closely followed. We believe a combination of the nitrite of amyl, given during the paroxysm, and the nitrite of sodium given continuously, will act more surely than either remedy alone, as the latter gives that permanence which we miss in the action of the nitrite of amyl.

Sir Morell Mackenzie, in an interview in the beginning of the week with a press reporter, reaffirmed the accuracy of his cablegram of last week to The Medical News. He said that the Crown Prince's condition was excellent, and that there was nothing to justify the alarming rumors current with reference to his health.

The fifteenth annual meeting of the American Public Health Association will be held at Memphis on November 8th, 9th, 10th, and 11th. The Executive Committee has selected the following important

topics for discussion: I. The pollution of water supplies; II. The disposal of refuse matters of cities; III. The disposal of refuse matters of villages, summer resorts, and isolated tenements; IV. Animal diseases dangerous to man. The President, Dr. George M. Sternberg, will make an address upon recent work in bacteriology, in connection with private and public hygiene. The Committee on Disinfectants will present a report embodying the researches and experimental work of the committee during the year.

In addition, there will be presented a number of papers upon other important topics, and the meeting gives promise of being of the highest interest.

It is understood that the railroad rates from all parts of the country will be one and one-third fare for the round trip, upon the certificate plan; that is, those attending will pay full fare going and one-third fare returning. A certificate must be obtained from the Chairman of the Local Committee of Arrangements, Dr. G. B. Thornton, of Memphis, Tennessee, which must be filled out by the ticket agent when the ticket for Memphis is purchased. This certificate is necessary to secure the reduced return rates.

At a recent meeting of the council of the College of Physicians and Surgeons of the Province of Quebec it was resolved to recommend the Legislature to pass a law requiring every one, no matter what his qualifications, to pass an examination before the College in all branches of medical study, before being allowed to practise. They also made large additions to the already very stringent preliminary examination in general education.

The *Journal of Morphology*, edited by C. O. Whitman, Director of the Lake Laboratory, Milwaukee, Wisconsin, is announced. It will be devoted to zoölogy, and the first number contains contributions from the leading zoölogists of America.

At the annual meeting of the Montreal Medico-Chirurgical Society, held on October 14th, the following officers were elected for the ensuing year:

President—Dr. James Perrigo.

Vice-Presidents—Dr. Wm. Gardner and Dr. James Guerin.

Secretary—Dr. R. F. Ruttan.

Treasurer—Dr. J. A. McDonald.

Librarian—Dr. T. D. Reed.

Dr. John B. Chapin, Medical Superintendent of the Pennsylvania Hospital for the Insane, has just been elected an honorary member of the Medico-Psychological Association of Great Britain and Ireland.

Dr. W. T. Councilman, of Johns Hopkins University, will read a paper before the Philadelphia Pathological Society, on October 27th, on "Further Investigations on the Malarial Germ of Laveran."

Baron Bernhard von Langenbeck, the "Nestor of German Surgeons," died of cerebral apoplexy at Wiesbaden on September 30, 1887, aged seventy-seven. He studied at Göttingen under his uncle, a famous anatomist and surgeon. In 1848 he was appointed Professor of Surgery at the University of Berlin, and Director of Surgery. He accompanied the German armies in the wars of 1864, 1866, and 1870, he was chief surgeon on the staff of the Emperor during the Franco-German war, and he was called to attend the Emperor after the assault of Nobiling. He was the instructor of the leading German surgeons of the present day. His contributions to medical literature date from 1836, when he wrote upon the anatomy of the retina. His best known works are those upon resections for gunshot wounds of the joints; and his name is also familiar in connection with the *Archiv für klinische Chirurgie*, which he edited ever since its establishment in 1860.

Mainly through his example conservative surgery obtained a sure footing in military practice. He was a bold and dexterous operator, and his remarkable results in the excision of joints are well known.

He was for many years President of the Congress of German Surgeons, and was only permitted to retire last year on account of his health and at his own earnest solicitation; he suffered from cataract, but was successfully operated upon last spring by Pagenstecher. His last appearance in public was at the Congress of Naturalists and Physicians at Wiesbaden, when, on September 19th, he opened the proceedings of the Section for Surgery with a few remarks. In his death German surgery loses her most distinguished exponent of his generation.

Dr. Henry Howard, one of the oldest members of the profession in Montreal, has recently passed away. He received his medical education in Dublin, and was a pupil of the celebrated oculist Dr. Jacobs. Dr. Howard came to this country in 1840, and was soon actively engaged in the practice of his profession as an oculist. His leanings, however, were always toward psychological science, and when an insane asylum was established at St. John, P. Q., Dr. Howard was appointed medical superintendent, and on the removal of the institution to Montreal and its great enlargement, he was appointed chief medical officer. Dr. Howard contributed many papers to the various journals on neurological and psychological science, and was a very prominent member of the Montreal Medico-Chirurgical Society, of which he was at one time President. He was a great

favorite with the profession, and was especially popular with the younger men, with whom he loved to discuss all of the more recent advancements in medical sciences. His opinions on crime and insanity were, perhaps, peculiar and somewhat in advance of his time, but he believed in them thoroughly, and was certain that in the near future, as methods of investigation became more accurate, they would receive confirmation. He liked to be called a "Physiological Psychologist." What was once said of Prof. Sharpey, might also be said of Dr. Howard—"He had not a single enemy" (in the profession), "and he numbered among his friends all those who had the advantage of being in his society."

REVIEWS.

RECENT WORKS ON NURSING.

THE NURSING AND CARE OF THE NERVOUS AND THE INSANE. By CHARLES K. MILLS, M.D., Professor of Diseases of the Mind and Nervous System in the Philadelphia Polyclinic, etc. 12mo. pp. 147. Philadelphia: J. B. Lippincott Co., 1887.

MATERNITY, INFANCY, AND CHILDHOOD. By JOHN M. KEATING, M.D., Visiting Obstetrician and Lecturer on Diseases of Women and Children, Philadelphia Hospital, etc. 12mo. pp. 221. Philadelphia: J. B. Lippincott Co., 1887.

OUTLINES FOR THE MANAGEMENT OF DIET. By EDWARD TUNIS BRUEN, M.D., Assistant Professor of Physical Diagnosis, University of Pennsylvania, etc. 12mo. pp. 138. Philadelphia: J. B. Lippincott Co., 1887.

THESE three volumes are the substance of lectures delivered by their authors to nurses, and belong, in reality, to the literature of nursing.

It is an encouraging fact that within a short time nursing has advanced to be a recognized branch of medicine, with several centres where training schools are educating nurses, and by whose instructors books like those in question are produced. These books are eminently fitted for those to whom they are addressed; non-professional attendants may profit by them, and the physician may find convenient knowledge at hand in them with which to refresh his memory for needed details.

Dr. Mills's volume enters a field but little cultivated. There exists no American book commonly known devoted to this subject; and the need of properly educated attendants for the nervous and insane has long been urgently realized. He gives useful points in the recognition of the common disturbances of the nervous system which are so often puzzling, even to a physician. His lucid and discriminating description of massage is greatly needed, in view of the abundance of poorly educated persons practising this mode of treatment. The applications of electricity which it is proper for a nurse to make are clearly described, and the apparatus in common use.

The care of the insane, as practised in the best asylums and the private practice of the author, is treated of in the concluding portion of the book. As supplying a want long felt, and as applying to the treatment of an especially difficult class of patients principles of training which have proved successful in other fields, Dr. Mills's book is valuable and welcome.

Dr. Keating's book is addressed to mothers quite as much as to nurses. It includes maternity and the care of the child until puberty in its scope; and treats fully of the many and varied details which comprise the existence of the young human being. The style of the book is popular, entertaining, and impressive; the treatment advised rational, and the book bears evidence of large experience and careful observation. The author's conservatism is exemplified in his advice to treat all cases of membranous croup as if diphtheria, and certainly nothing but good can come to the mildest case of croup if his instructions be carried out, while, if diphtheria be certainly present, much good will be accomplished before the disease has become established in its full severity.

To those called upon to meet the many and perplexing cares of the custody of children, Dr. Keating's book will be an efficient and happily explicit guide.

In his book upon Diet, Dr. Bruen has fortunately escaped writing a cook-book on the one hand, and a primer of physiology on the other. The author has succeeded, not only in subordinating science to the practical, but in applying science, and in a manner which will enlist the attention of all who read his book. The physiology of digestion and the liquids and solids required by the human organism, are treated of with discrimination, in the light of the recognized facts regarding digestion and assimilation. Infant feeding is carefully considered, and also the amount of food adapted to organisms of various types. The increase and diminution of flesh, and the diet adapted for the diseases most dependent upon a chronic vice of nutrition are described in a clear and interesting manner, the book forming a genuine addition to the numerous literature of nutrition.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting October 12, 1887.

DR. WILLIAM T. BULL read a paper on

GASTROTOMY FOR THE DIGITAL EXPLORATION OF THE ŒSOPHAGUS AND REMOVAL OF A FOREIGN BODY; RECOVERY.

The introduction of the finger into the pyloric orifice of the stomach for the exploration and dilatation of that orifice when constricted, has been successful in the hands of Loreta, who first attempted it, through a small incision in the stomach.

The cardiac orifice, and the stomach above it, have also been found to be accessible to instruments after a gastric fistula had been established; and dilating instruments have been introduced in that way from below upward in the course of treatment of stricture. But in

only one instance thus far recorded, has the effort been made to explore the œsophagus through the stomach. That was in a successful case, reported by Richardson, of Boston. In a man, who had a plate with false teeth impacted in the lower end of the œsophagus for ten months, he opened the stomach by a small incision, and attempted to reach the body in the œsophagus with the finger. This being unsuccessful, he enlarged the incision (to five inches) so as to admit the hand and forearm. The plate was detached by introducing the finger into the œsophagus, and drawing it first into and then out of, the stomach. A prompt recovery followed the operation.

The feasibility of this procedure was afterward demonstrated by Dr. Richardson[1] in a series of measurements and experiments on the cadaver. In twelve subjects he found that the distance from the centre of an incision, starting from the outer edge of the rectus muscle, and running five inches parallel to the costal cartilages, and one inch below them, to the œsophagal opening in the diaphragm, to be 7.55 inches. When the stomach was drawn as far as possible out of the abdominal wound, the hand and forearm were inserted into its cavity through an incision five inches in length, and the index and middle fingers could be passed two and one-half inches into the œsophagus. He found the distance from the teeth to the œsophagal opening in the average subject to be fifteen inches, and concluded that a body whose position when arrested in the œsophagus was not less than thirteen inches, could be reached from below by the hand introduced as described. Cheever's statement, that through the wound of œsophagotomy the finger could reach as low as the level of the arch of the aorta, was confirmed; and in four cadavera he was able, by passing one index finger through an œsophagotomy-wound downward, and the other upward from the stomach, to bring the two fingers into contact. Fortified by these observations, and the success of the case referred to, he urges with propriety the resort to gastrotomy for bodies impacted at a distance of no less than thirteen inches from the teeth, after other means have failed.

These valuable observations of Richardson's were fresh in my mind, when a boy presented himself, with a peach-stone impacted in his œsophagus, thirteen inches from the teeth. During forty-eight hours I made two efforts to dislodge it with instruments introduced through the mouth. I discarded œsophagotomy; the situation of the body, allowing six or seven inches for the distance from the teeth to the œsophagotomy wound, would leave as many inches of œsophagus through which to manipulate. One could accomplish no more than through the mouth. Deciding on gastrotomy, I considered the best method of performing this with the least injury to the parts, and was led to these reflections:

1. That large incisions in the abdominal wall and stomach, together with the manipulation of that organ outside of the abdominal cavity, and the introduction of the hand into it, ought to be avoided, if possible. They would be very dangerous in so young a subject.

2. That the exploration could be effected by the finger alone, introduced through a small wound, if the anterior wall of the stomach were invaginated, so as to fold itself about and behind the finger entering the œsophagus.

3. That the nearness of the œsophageal opening in the diaphragm to the vertebral column would make that structure an easy guide to the orifice, and, moreover, an incision in the median line would be nearer to that orifice than one parallel to the border of the ribs. This incision was in general preferable, and the hand or finger, manipulating through it, would be less encumbered by the overhanging ribs.

4. That the nature of the body (it being smooth and free from sharp corners) made it probable that it would be safe to push it up from below, or to draw it up, in case it was not easily dislodged downward into the stomach.

Case.—L. C., a colored boy, four years of age, and in good general health, was admitted to the New York Hospital, August 25, 1887. His mother stated that he had swallowed a peach-stone on August 20th, five days before his admission. On drinking immediately afterward the water was regurgitated, and from that moment he had been unable to retain any nourishment. He had lost much flesh, was weak, and complained of thirst and occasional nausea, but vomited only when he attempted to swallow. He had no pain. A physician had passed a probang, but could not reach the stomach. The bowels had moved once in five days, and the urine had been passed as usual.

I saw the boy immediately after his admission, and was struck by his anxious expression and feeble appearance. Though of spare habit, he was decidedly emaciated. He had no fever, and his pulse was a little more rapid than usual, and of small volume. He was given a glass of water, swallowed it, and immediately rejected it. No swelling of the neck could be seen or felt. An œsophageal bougie with an ivory bulb at the end was passed to a distance of thirteen inches from the incisor teeth, where it struck against a hard body. The sound made by a light impact could not be distinctly heard, but the sensation communicated to the finger was unmistakable. The examination was well borne by the patient, and I tried at once to dislodge the body with coin-catchers of different sizes. These only grazed its surface. Attempts to get beyond it with fine gum-elastic and whalebone bougies were equally unsuccessful; and after ten minutes' gentle manipulation the boy was put to bed. I ordered rectal enemata every six hours, containing three ounces of peptonized milk and an ounce of whiskey, and bits of ice by the mouth.

August 26. The rectal injections are well borne, and are continued. The manipulations of yesterday were repeated for fifteen minutes, but without result. An attempt to grasp the body with œsophageal forceps failed. I thought it dangerous to make further efforts, and advised gastrotomy, to which the parents consented.

29th. The operation was done with the assistance of the house-staff, and in the presence of Prof. Wm. H. Carmalt, of New Haven, and several other surgeons. It was just one week after the body had been impacted. After the ether-narcosis was complete, I passed an œsophageal bougie with an ivory-bulb tip and ascertained that the body was still in place, thirteen inches from the teeth. One or two gentle taps were made upon it with the bulb, in the hope that, with the relaxation caused by the ether, it might drop into the stomach.

[1] Boston Med. and Surg. Journal, December 16, 1886.

This, and a further cautious attempt to get beyond it with the evacuator and a slender bougie, were unsuccessful.

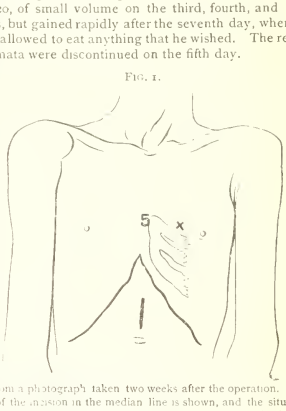
The abdominal cavity was opened by an incision three inches in length, extending from the level of the ninth costal cartilage to a point two inches above the umbilicus. The upper limit was determined by noting the point where the percussion dulness of the liver disappeared. This exposed a part of the anterior wall of the stomach and its greater curvature, about two and one-half inches from the pylorus, while the lower edge of the left lobe of the liver was seen in the upper angle. The index-finger, passed over the under surface of the diaphragm, could feel the motions of the heart, but detected no foreign body at the situation of the œsophageal opening. The stomach was empty. The pylorus was identified, and a part of the anterior wall was selected for incision; this was distant about three inches from the pylorus and midway from the greater and lesser curvatures, as estimated by the fact that the superficial vessels were least conspicuous there. I drew this part out of the abdominal wound and put two loops of silk through it, two inches apart in a vertical line, and made an incision one and a quarter inches long between them. This permitted the escape of a little gas and a few drops of brownish fluid. I fixed two more loops of silk into the edge of this wound, in order to control it thoroughly, and protecting the edges of the abdominal incision with flat sponges, passed my index-finger directly backward till the vertebral column was felt, then upward till it entered the œsophagus.

The finger stopped up the wound so that nothing could escape had there been fluid present, and this encouraged me to depress the abdominal wall and to crowd the finger as far up as possible. In this manipulation the anterior wall, with the loops of silk, followed the finger into the cavity and was folded on itself like the invaginated scrotum in examination of the inguinal canal. The body could not be felt till a bougie was passed and pressed greatly upon it from above. Then one of its flattened surfaces rested against the tip of the finger with a "collar" of mucous membrane below it. I made an effort to tip it with the finger-nail, so that its edge would present downward. I immediately passed along the finger a curved œsophageal forceps till it reached the body, and then drew out, by means of the loops of silk, the anterior wall, the finger following it, and still blocking the opening. One or two efforts to grasp the stone with this and a straight forceps, introduced in the same way, although it could be plainly felt with the tip of the blades, were unsuccessful.

Reintroducing the finger, a slender bougie was passed over it and projected from the mouth, a sponge, one-half inch in diameter and one and a half inches long, was tied to the lower extremity with strong silk, one end of which was left long. The sponge was pulled through, meeting with slight resistance, but the foreign body, while apparently dislodged, was not brought up. A larger sponge was then tied to the long end of the silk and was drawn through. This brought the stone into the mouth, where the finger met and extracted it. In these manipulations the anterior wall was held by the loops of silk two inches above the abdominal wall, while the loops in its edges, manipulated by my assistants, Dr. Lines and Dr. Adams, of the house staff, were useful in securing easy access to the interior of the stomach. A few drops of turbid brownish fluid escaped from time to time, but were absorbed by two sponges held on either side of the stomach wound. No blood was seen in the mucus surrounding the stone or the sponge, and I concluded that no injury had been done to the œsophageal mucous membrane. The gastric mucous membrane was sutured with eight catgut sutures, the peritoneal coat with ten or twelve Lembert sutures of fine carbolized silk. The punctures above and below the incision, occupied by the loops of silk, were each closed with a single Lembert suture, for I was in doubt whether they extended through all the coats or not. The abdominal incision was closed with a continuous peritoneal suture of catgut, and interrupted silk sutures through the other layers. The duration of the operation was one hour and a quarter, and at its close the general condition of the patient was satisfactory.

The dressing was of bichloride gauze, covered with absorbent cotton and a roller bandage. The boy made a rapid recovery without accident. The temperature was never above 99°, and there was no pain, nausea, or vomiting. He was quite weak, with a pulse of 110 to 120, of small volume on the third, fourth, and fifth days, but gained rapidly after the seventh day, when he was allowed to eat anything that he wished. The rectal enemata were discontinued on the fifth day.

FIG. 1.



From a photograph taken two weeks after the operation. The site of the incision in the median line is shown, and the situation of the impacted stone, indicated by X, at the level of fifth rib.

For the first twenty-four hours he received nothing by the mouth, during the second day brandy and water, and beef-tea at frequent intervals, on the third day ice cream and milk and tea, then soft boiled eggs and toast. His appetite was quite poor and he had no desire for food till watermelon was offered to him in addition to his other diet, on the fifth day. The wound healed entirely by primary union without any pus and there was no decided tenderness in its vicinity. He sat up on the tenth day, and walked alone freely as well as ever, a week later.

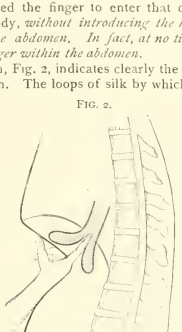
I submit the patient for your inspection, and have traced one or two lines on his dark skin to show the relative situation of the foreign body (opposite the level

of the upper border of the fifth rib), and of the incision in the *linea alba* (Fig. 1).

At the time of operation the abdominal wall, in consequence of his week's starvation, was thinner and softer than now, and could be more easily depressed, so as to lessen the distance in a straight line from the abdominal incision to the œsophageal opening at the cardiac orifice. This condition, and the moderate proportions of the boy, permitted the finger to enter that orifice and to reach the body, *without introducing the hand into the cavity of the abdomen. In fact, at no time was more than one finger within the abdomen.*

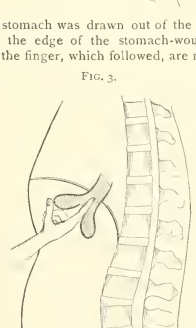
A diagram, Fig. 2, indicates clearly the nature of the manipulation. The loops of silk by which the anterior

Fig. 2.



wall of the stomach was drawn out of the cavity, and which held the edge of the stomach-wound, closely plugged by the finger, which followed, are not shown.

Fig. 3.



In the adult it would doubtless be necessary to introduce the hand into the abdominal cavity, in order to carry before the finger, or invaginate the anterior wall of the stomach. This proceeding is made clear by Fig. 3. I likewise present the peach-stone, and the sponge attached to the string which was drawn through the œsophagus. The stone is of average size, has a circumference of two and five-eighths inches, measures one inch in its long, and five-eighth of an inch in its short diameter, and is sharp only at one end.

In connection with this case, the following features seem to be worthy of attention:

1. The small wound in the stomach—one and a quarter inches—just sufficient to admit the index finger.

2. The invagination of the anterior wall of the stomach.

3. The use of the loops of thread, entrusted to assistants, by traction on which the edges of the wound in the stomach were kept close against the finger, so that it acted as a plug, and prevented the escape of any fluid.

4. The moderate manipulation of the stomach itself. At no time was it drawn more than two inches beyond the abdominal wall. This was at the time instruments were introduced; as soon as they reached the cavity, the wall, with finger and instruments, was at once thrust upward, and the œsophageal opening was reached by following the vertebræ and the middle line as a guide. The instrument being passed almost directly from the wound to the œsophagus did not wander about over the surface of the gastric mucous membrane.

Each of these features is in itself, a small "point," but they form, when combined, an important part of that sure and delicate technique which is essential to success in operations on the abdominal viscera. Furthermore, I think that the plan of not making any prolonged effort to draw the stone into the stomach was of great advantage. Aside from the fact that much time would have been spent, one would have directed one's efforts against the stone lodged in the part of the canal where it had rested for seven days, and where the mucous membrane might have been inflamed, softened, and ulcerated, and, therefore, easily perforated. In drawing it from below upward, one had the advantage of the larger calibre, and a sound mucous membrane, which neither the smooth body nor the soft sponge was likely to injure.

I have always regarded Dr. Richardson's contribution as an invaluable addition to our store of knowledge, and I hope that this Society may be of the opinion that in following his example I have helped to demonstrate that in gastrotomy we have an additional resource in the management of foreign bodies in the œsophagus. The comparative safety of the operation may be judged from tables of cases of gastrotomy for foreign bodies in the stomach recently reported by Bernays[1] and Richardson.[2] In twelve instances bodies have been removed from the stomach, which was uninjured and not adherent, and in two cases (including my own) from the œsophagus. All but two cases were successful.

These figures are more favorable than the statistics of œsophagotomy reported to the Society, last year, by Dr. Markoe;[3] these show 82 cases, of which 63 recovered and 19 died. The marked difference in the death-rate suggests to my mind the advisability, in cases where one is in doubt as to his ability to extract the body safely by œsophagotomy, of resorting promptly

[1] The Medical News, January, 1887.

[2] Boston Medical and Surgical Journal, December 16, 1886, page 573.

[3] The Medical News, May 1, 1886.

to operating the stomach. Such a doubt may arise from the difficulty in estimating the exact situation, from ignorance of the nature of the body, or from the circumstance that no instrument can be passed beyond it. It is certainly dangerous to use forceps which open in the œsophagus, when bodies completely occlude its lumen, and those which are flat and lie crosswise can only be caught by specially contrived instruments, or withdrawn by getting such an angular instrument as the coin-catcher beyond them. Pressure from below with a large bougie, or traction toward the mouth, would disengage any sort of body.

As a general rule, one can deal with all bodies impacted within the reach of the finger, manipulating in the œsophagotomy wound, that is six inches from the cricoid cartilage, according to Dr. Richardson, by the operation in the neck. Beyond this point gastrotomy would be necessary, and would probably be safe and efficient.

Dr. Stimson asked Dr. Bull if he had been able to determine why the body lodged just where it did.

Dr. Bull replied that the position of the body was determined by the presence of a concentric projection, or collar, of mucous membrane, which was situated about an inch and a half above the pyloric orifice; the body lodged just above this constriction.

Dr. Weir asked if the narrowest part of the œsophagus was not usually situated higher.

Dr. Bull said that it was, but that if a foreign body succeeded in passing the point opposite to the arch of the aorta it was usually arrested at the position described in this case.

Dr. Weir believed that the calibre of the œsophagus was larger than was generally represented, especially by French writers. He had passed bougies having a diameter of 21, 22, and, in one instance, 23 millimetres.

Dr. Stimson thought that, while the method employed by the reader had been in the highest degree judicious and successful, it seemed possible that it might sometimes be found difficult to push the foreign body upward as to push it downward—that is, under certain circumstances in which the impaction was due to the shape, rather than to the bulk of the body, to its length and peculiarity, rather than to its breadth. In the present case the stone could not be forced downward through the lower part of the œsophagus, although the finger, which was as thick as the stone, could be passed upward past. It was conceivable that, in pushing a large body upward, its upper end might diverge from the axis of the canal and catch in the mucous membrane in such a way that any effort to dislodge it from below, by pressure on its lower end, would only make its fixation more firm. In withdrawal by an instrument, which grasped the anterior end of the body, this difficulty was less likely to be encountered, although, of course, the use of the forceps had dangers of its own. Experience might show that the difficulty which I retrench the generalization of the method so successfully employed by Dr. Bull.

Dr. Sands thought that the dangers incurred by applying instruments from above were greater than the risk of stage gained.

Dr. Wyeth thought the mechanism of the sponge in the case reported was nearly perfect; by thoroughly distending the œsophagus it served to obliterate any projecting folds of mucous membrane. The pressure upward would naturally dislodge the large, smooth end of the peach-stone first, and thus facilitate the extraction.

Dr. Makkoe said that every surgeon who had had experience in searching for foreign bodies in the œsophagus had found that little could be accomplished. He had noted this especially after œsophagotomy. He could readily conceive how Dr. Bull failed to grasp the body with forceps. He might have feared to open them sufficiently wide through a dread of tearing the mucous membrane.

Dr. Bull thought that most foreign bodies of irregular shape, such as plates with teeth, could be removed from above by means of an instrument, such as a coin-catcher. There was some danger in these manipulations, but it might be offset to some extent by care and delicacy of touch on the part of the surgeon. A sharp body could not be safely pushed upward from below, while the removal of a smooth body from above by means of forceps was always more or less risky. He had about a year previously perforated the œsophagus while endeavoring to extract a horse-chestnut with forceps. If we accepted the belief that a small wound in the abdominal wall, and also in the stomach, could be made with a minimum of risk, why should we not perform gastrotomy at once? There was absolutely no reaction after the operation in the case reported.

Dr. Weir referred to a case reported in a foreign journal, in which a patient had swallowed fragments of wood and glass with suicidal intent. Gastrotomy was performed and the foreign bodies were removed. The patient subsequently repeated the act, and gastrotomy was performed a second time with success.

Dr. Bull asked Dr. Markoe regarding the feasibility of introducing the finger through an œsophagotomy wound as far down as the arch of the aorta. The latter replied that he had never been able to reach so far.

Dr. Wyeth said that he knew a country practitioner who being obliged to rely on his own resources, dislodged a pin from the œsophagus by feeding the patient with balls of corn-meal mush, containing pellets of fine cotton. The mush was digested, and the cotton remained in the stomach. The patient was then given an emetic, and vomited the cotton, in which was imbedded the pin.

Dr. Sands stated that a physician had once brought to him his child, who had swallowed a nail. At the father's suggestion the boy was placed on a diet of sweet potato, and soon after he had a copious evacuation, containing a mass of potato, in which was found the nail.

NEPHRECTOMY.

Dr. John Wyeth presented a tumor of the left kidney, which he had removed by the lumbar incision. The patient was a woman, who had suffered from urinary trouble for five years. She had at intervals of a few weeks or months an obscure pain in the left lumbar region, followed by hæmaturia. During the past three years she had been confined to her bed, and last May she was placed under his care through the courtesy of Dr. McWilliams, of this State. Upon examination a tumor of the left kidney was detected, which Dr. Wyeth thought was due to cystic degeneration of the

organ, resulting from calculous pyelitis. The patient was reported to have passed calculi, but none had ever been seen by her medical attendants.

Dr. Janeway saw her in consultation, and thought that the tumor was a neoplasm, although he declined to give a positive opinion as to its character. Nephrectomy was performed in May. The usual lumbar incision was made, and, as there was a space of only three inches between the last rib and the crest of the ilium, a transverse incision was made, the latter extending *to*, but not *through*, the peritoneum, which was folded back toward the median line. There was no hemorrhage of any consequence. The mass was easily separated and the pedicle was secured with an elastic ligature, which was applied entirely by the sense of touch. The vessels were then divided and ligated. The operation lasted two hours, and the patient died of shock fifteen hours later. There was no autopsy. The tumor measured about ten inches in circumference at its least prominent part, and was eight inches in length. A microscopical examination showed that the growth was a medullary carcinoma, which grew from the upper third of the organ.

Dr. Sands asked regarding the condition of the other kidney.

Dr. Wyeth said that it was inferred that it was healthy, as the patient passed a fair amount of urine (such as could not have come from the organ destroyed by disease), which contained only a trace of albumen and no casts. The sound kidney could be felt during the operation.

Dr. Bull suggested that it might have sprung from the suprarenal capsule.

Dr. Wyeth thought that a careful examination of the specimen would show the intimate relations of the tumor to the kidney itself.

Dr. Briddon called attention to the fact that the occurrence of hæmaturia would seem to prove that the kidney itself was affected.

Dr. Weir asked if laparotomy would not have been a safer and more rapid procedure.

Dr. Sands agreed with Dr. Weir's criticism. He thought that the anterior section would certainly give more room than the lumbar incision. In the case of a suppurating kidney, however, the objection might be raised that, if the former method were adopted, the pus might escape into the peritoneal cavity.

Dr. Briddon cited a case in which he had tried to remove a tumor, larger than the one exhibited, through a lumbar incision, and was obliged to abandon the attempt and to perform laparotomy; it was easily removed by the latter method. He suggested that it might not be a bad idea to make a lumbar, in addition to the abdominal, incision, since the former could be utilized for drainage.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, October 12, 1887.

The President, J. Solis-Cohen, M.D., in the Chair.

Dr. Carl Seiler read a paper on

CHRONIC RHINITIS AS AN ETIOLOGICAL FACTOR IN ACNE OF THE FACE.

For a number of years he had made the observation that acne vulgaris and acne rosacea coexisted frequently with chronic rhinitis, and particularly with the atrophic form of nasal catarrh, but it is only lately that he has come to the conclusion that this form of nasal disease is in many cases of acne the exciting cause. This conclusion may seem far-fetched and perhaps unreasonable at first glance, but he hopes to be able to show that there is undoubtedly a close connection between the two affections. For this purpose he gave a short history of a few of the cases which have come under his observation, before entering upon a theoretical discussion of the connection between chronic rhinitis and acne.

Case.—J. H., aged thirty-eight years, suffered from stoppage of the nose for several years, and every morning he blew out large scabs. After this his nose felt clear but dry, and he had lost the sense of smell to a very large degree. For two or three years he had noticed a redness of the external integument of the nose, which had become gradually worse, so that now it had spread from the nose to the cheeks, and pimples had made their appearance. The rest of his face was free from pimples or redness. He was a total abstainer from alcohol. His general health was good.

The anterior nasal chambers were filled with dry scabs of hardened mucus, and beneath the mucous membrane was unusually pale. The lower turbinated bone was barely projecting from the wall of the nose, and the turbinated cavernous tissue apparently absent. This condition caused the anterior chambers to be abnormally large. Irritation with the probe caused but a very slight amount of moisture to gather around the spot touched, while the whole of the mucous membrane was abnormally dry. There was no odor.

The treatment consisted in cleansing the nasal cavities morning and night with an alkaline wash, and in stimulating the mucous membrane with dilute nitrate of silver in powder, a small quantity of which was blown into the nostrils two or three times a week. In order to keep up the stimulation a tampon of cotton was introduced into the anterior nasal chambers and placed against the side of the nose, in place of the atrophied inferior turbinated bone, which tampon was renewed by the patient after the cleansing morning and night. As an application to the skin a lotion was prescribed consisting of alcohol and precipitated sulphur, to be applied every night with a tuft of cotton, and to be washed off in the morning with soap and water.

Under this treatment the acne gradually diminished, and the mucous membrane of the nose became again bathed with secretion, until after a little over three months the redness had entirely disappeared, and the cotton tampons could be dispensed with, because the lower turbinated bones, or at least the cavernous tissue, began again to project into the lumen of the anterior nasal chambers. The patient was seen three years later, unfortunately without having an opportunity of examining his nose, but he said that there had been no return of the acne, and that his nose troubled him but little, and then only when he neglected to use the alkaline wash; the sense of smell had also returned to a large degree, but was not as acute as he might wish.

The short notes of this and two other cases suffice to show that there is a connection between atrophic rhinitis and acne of the face. Although a large number of such cases could be cited to demonstrate still further this

point, it would be waste of time to do so, as they are all, more or less, repetitions of each other.

According to the statements of different authors on skin diseases, acne occurs with equal frequency in both sexes, and usually makes its appearance at the time of puberty, and is frequent until the age of thirty. As predisposing causes are mentioned, gastric disturbances, either lack of or excess of sexual connection, onanism, insomnia, and intemperance, but no mention is made of atrophic rhinitis as a predisposing or existing cause. That the genital organs have a great influence upon the production of the disease cannot be doubted, for many cases are cited in which acne showed itself only during pregnancy, or at the menstrual period, in women; and it disappears with the cessation of the practice of self-abuse in boys and men; also, the fact that it is most frequent at puberty, would point in that direction. Some authors lay so much stress upon this that they direct their treatment altogether to the sexual organs, by passing a bougie into the male urethra, and prescribing vaginal douches and medication, having no faith in local applications to the skin of the face.

Two factors must act in conjunction with each other to produce acne, one as an obstruction to the efferent channel of the sebaceous glands by the introduction of dirt into it, and the drying of the secretion behind it, producing the so-called comedones, and also a diminution in the activity of the gland itself, which causes an alteration in the consistence and quantity of the secretion, which thus is not able to remove the foreign body in the mouth of the duct by pressure from behind, as undoubtedly occurs in the healthy skin. Thus the retention and accumulation of the secretion causes by pressure a localized inflammation, which is finally relieved by the formation and evacuation of pus. In acne rosacea, the rarer form of the disease, we find no formation of pustules, but simply a general, more or less, diffused inflammation, which is probably due also to a perverted action of the sebaceous glands, but does not lead to a retention of the secretion.

Dr. Seiler had not been able to find an opinion as to the direct cause of the glandular irritation, whether it is altogether local, and caused by obstruction of the duct in the formation of comedones, or whether it is due to reflex nervous irritation, or finally is produced by a more or less general disturbance of the capillary circulation in the skin of the face.

The first of these propositions may be at once set down as insufficient to explain the pathological condition, for comedones are frequent in almost every face, without being necessarily accompanied by acne. The other two propositions may be considered together, for we cannot have inflammation without disturbance of the circulation, and no disturbance of the circulation without nerve influence.

The above cited predisposing causes clearly indicate that an irritation of the nervous system must exist somewhere, be it in the mucous membrane of the stomach, or in the sexual apparatus; which, by reflex, acts upon the easily influenced capillary circulation of the skin of the face and neck, and thus, by causing a change in the capillaries around the sebaceous glands causes a perverted action of these glands if it is kept up for any length of time, or if no relief from blood-pressure is afforded. It is his belief that the cavernous tissue covering the turbinated bones provides such a relief, and that this is one of the functions of the erectile tissues of the body. This belief is strengthened by the fact that under mental excitement, which causes blushing of the face, the cavernous tissue in the nose swells up, while, on the contrary, under any emotion which causes paling of the face, the erectile tissue of the turbinated bones becomes paler, and diminishes markedly in bulk, facts well known to every laryngologist. Let this cavernous tissue be absent, or greatly diminished, as in the case in atrophic rhinitis, and very little or no relief is afforded for the excessive blood-pressure in the capillary circulation in the skin of the face, and the result will be acne if any of the predisposing causes be present. In the cases above cited, and in many others under his observation, the acne disappeared *part passu* with the reformation of the cavernous tissue, and thus these would seem to be of some importance as clinical proofs of this theory.

Dr. Seiler was fully aware that a single line of cases observed by one observer, are by no means a sufficient guarantee for the acceptance of a theory, and it will require many more cases observed by many observers, to prove or disprove it. At the same time he cannot but think that atrophic rhinitis may be one of the etiological factors of acne.

CORRESPONDENCE.

GLEDITSCHINE—STENOCARPINE.

To the Editor of THE MEDICAL NEWS.

SIR: The fact, seemingly well proven by the experience of Drs. Seward, Claiborne, Knapp, Jackson, Mitchell, and others, that the newly discovered alkaloid, gleditschine, is largely like cocaine in its power as a local anæsthetic, has prompted me to determine whether it has a value akin to the coca alkaloid, as a stimulant in the treatment of opium habitués, and I am now experimenting in this direction, using a two per cent. solution exclusively by subcutaneous injection.

That cocaine, hypodermatically, is a valuable aid in treating the opiate neurosis, is beyond question, in my opinion, though it is not a specific, and should never be given for this purpose by the patient himself, be he physician or layman.

Should gleditschine have a similar value, it may be found free from the ensnaring danger of cocaine, though assuming the fact of its stimulant power, this freedom from risk will not be likely, and we shall note, probably not far in the future, baneful effects from its abuse, and gleditschine inebriety be added to the list of toxic neuroses.

It has been stated by Dr. Seward, that "he has observed antidotal effects to gleditschine from morphia," and W. H. Mitchell asserts "it is a direct antagonist of morphine and opium, ten drops of the two per cent. solution neutralizing one grain of morphine or six of opium." Experiments on rabbits, now being made by myself, will, it is to be hoped, sustain these claims.

J. B. MATTISON.

BROOKLYN, October 1st, 1887.

NEWS ITEMS.

An International Congress of Ophthalmology in 1888.—The Ophthalmological Society, at its recent meeting at Heidelberg, determined to hold an international congress of ophthalmologists next year, with Professor Becker at the head. The attendance at the Society's recent meeting was over 100.

Pasteur's Work in Italy.—Since July 1st 1010 cattle and sheep have been inoculated against anthrax in Italy. The Director of the Veterinary College at Naples has applied for material to inoculate, in addition, 1000 sheep. The results are good.

The Gynecological and Obstetrical Society of Baltimore at a meeting held October 11th, elected the following officers for the ensuing year:

President.—Dr. H. P. C. Wilson.

Vice-Presidents.—Dr. F. E. Chatard, Jr., Dr. John Morris.

Secretary.—Dr. Charles O'Donovan, Jr.

Treasurer.—Dr. Robert T. Wilson.

The Tent Service in the Boston City Hospital.—The last annual Report of the Boston City Hospital states that the tent service in connection with the hospital, which affords fifty-six beds, was in active use, and of the utmost advantage, especially for the most serious surgical cases, during the summer months. Its maintenance is comparatively inexpensive, and experience has amply demonstrated the advantages of treatment under these conditions; moreover, opportunity is thus afforded of vacating and renovating in turn the permanent wards.

Since the publication of this report, we understand the tent service has been further extended, so that medical patients share in some degree in its benefits.—*Boston Medical and Surgical Journal,* October 13, 1887.

A Hospital Damaged by the Elevated Railway.—Dr. C. F. Taylor, has, after three trials, won a verdict of $12,000 against an elevated railway for damages to his private hospital in New York.

Counterfeiting the Labels of Merck & Co., of Darmstadt.—The *New York Medical Journal* of October 15, 1887, states that action has been begun against a firm of New York druggists, for counterfeiting the labels of this well-known German firm.

Emmet's "Gynecology" has been favorably reviewed and well received by the French, who commend especially the carefulness and conscientiousness of his work.

The Discussion Regarding Cholera in the Vienna Congress of Hygiene.—As was anticipated, the International Congress of Hygiene at Vienna last week, offered an opportunity for a duel of words between the leaders of sanitation who differ so widely concerning the best means of keeping cholera out of a given territory. The members of the Congress included many members of the last International Quarantine Commission which met at Rome, and at which there were distinctly formed a quarantine and an anti-quarantine party. Prof. Gruber, of Vienna, described his experience with cholera in Austro-Hungary in 1885 and 1886, and said that the intercourse between human beings provided the greatest opportunity for the spread of cholera, but its spread depended largely upon the season and weather. Prof. Gruber expressed himself as being a firm believer in Koch's bacillus theory and a strong adherent of the quarantine system. Two Japanese delegates then stated that cholera was always introduced into Japan by English or French ships coming from China. When Max Von Pettenkofer, of Munich, of the anti-quarantine school, and Dr. Proust, of Paris, his able opponent, joined in the debate, the climax of the discussion was reached. Pettenkofer upheld the English idea of sanitary preparation to prevent the disease from getting a foothold, and claimed, that while he did not deny the discovery of the bacillus by Koch, that its existence alone could not explain all the phases of the disease as seen in India and elsewhere. Dr. Proust advocated isolation, detention, and disinfection, and the Congress adopted by a large majority, five resolutions moved by him setting forth the views of the quarantine party.—*Sanitary News,* October 8, 1887.

Dr. John H. Rauch on Quarantine Defences.—The efficient President of the Illinois State Board of Health is quoted as follows on this subject by the *Sanitary News* of October 8, 1887:

"Sooner or later the national government will be compelled not only to assume supervision of exterior quarantines, but to provide for a permanent system of coöperation with State and local governments in the administration of international sanitation; in order, on the one hand, to prevent the introduction of exotic epidemic diseases, and, on the other, to prevent their spread from State to State along the great intranational highways of travel and commerce. This is a national duty. It is one that the national government only can adequately discharge, and its expense is, equitably, one which should be defrayed from the national treasury." Also, "Congress should give the President the power to issue a proclamation, upon the recommendation of the national health authority, forbidding immigration into the United States from infected districts of other countries, and it should provide some method of international sanitary coöperation between this country and the dominion of Canada, whose interests are substantially the same as ours in these matters, and whose contiguity makes coöperation of vital importance."

The Need of Caution in Contagious Diseases.—The following instance of direct contagion from the corpse of a diphtheritic patient should prove an instructive reminder of the dangers attending such diseases:

Information just received at the Michigan State Board of Health office, illustrates the immense importance of extreme care in dealing with contagious diseases. A young man whose parents live in Brighton, died in Detroit a few weeks ago, after a week's sickness. The attending physician called the disease at various times, "putrid sore throat," "gangrenous sore throat," and "ulcerative tonsillitis." He died of failure of the heart, a common mode of death in diphtheria. The remains

were sent to Brighton, and on the casket was a certificate that he died of heart-disease. As the boy was well known in Brighton, it was proposed that the high school go in a body to the funeral, but the principal of the school, and the health officer of the village, suspecting that all was not right, vigorously objected to any children attending the funeral. About August 1st, the lady with whom the boy lived in Detroit, visited the boy's parents in Brighton, bringing his clothing that had been left with her. In ten days after her arrival, two children in the family were taken with a malignant form of diphtheria, one dying August 23d, and the other, when last heard from, being in great danger.

From the statement of the case there can be little question that the boy died in Detroit of diphtheria. The father says that if his children in Brighton have diphtheria, then his boy in Detroit had diphtheria, because, he says, "it is the same thing." The members of the family in Detroit have since had sore throats.—*Medical Age*, September 10, 1887.

GENERAL GREELEY'S EXPERIENCE IN THE USE OF ALCOHOL DURING ARCTIC EXPLORATION.—In the *Forum* for August, General Greeley relates his experiences as follows:

"The subject of alcohol was frequently and generally discussed during the winter at Cape Sabine, and all, without exception, concurred in the opinion that spirits should be taken after a day's labor was over, and not before or during exhausting work, nor while suffering from exposure that was to be continued. . . . Later, when the party had been slowly starving for many months, and when the supply of food was so diminished as to necessitate a greater reduction of rations, the pure alcohol on hand was issued as food, being diluted by about three times its weight of water. Each man received daily, perhaps a quarter of an ounce of alcohol, the effect of which was most beneficial. The general impression, with which I most heartily agreed, was that the alcohol supplemented food, and had a decided alimentary value. There could be no question of its beneficial effects as a mental stimulus to every member of the party, under our unfortunate condition at Sabine."

PHYSICAL DETERIORATION FROM OVERCROWDING AT SCHOOL.—At the recent Congress of Naturalists and Physicians at Wiesbaden, PREYER reported, as the result of his investigations, that over sixty per cent. of scholars entering practical life from school were physically unprepared for work and poorly developed. Of the first year scholars only one-third were in good condition; one-fourth were short-sighted. One-fourth of all the scholars were injured in process of education, in physical health or development. Short-sightedness increased in frequency and degree from the lower to the highest grades.

THE HYGIENE OF TO-DAY.—ROCHARD's speech at the recent Vienna Congress of Hygiene, characterized the hygiene of the present as taking the laboratory for its domain. It must demonstrate to the public that the efforts of workers in scientific hygiene are not limited to commissions, volumes of transactions, and conferences, but that, acting upon positive knowledge, the scientific hygienist will "combat the indifference of governments, popular ignorance, and administrative failure."

THE LAST DISTURBANCE CAUSED BY PRANZINI.—The Paris Faculty of Medicine has been exercised by a rumor that two officials had received gifts of card-cases, made from Pranzini's integument. The offenders were at once sought, and the desecration of the corpse of the murderer was indignantly repudiated by the medical men who had to do with it. On investigation, it was found that a servant in the amphitheatre of the Faculty had been formerly servant to an officer. Wishing to make a gift to his former master, he had taken a piece of Pranzini's integument to a manufacturer, stating that it was sheepskin, and had manufactured two very handsome card-cases. On exonerating the medical men engaged in the examination of the body, an apology was rendered, and the matter was dropped.

SILVER ABSORPTION IN PLATE WORKERS.—It is not generally known that the skin of workmen who have to manipulate silver is liable to become impregnated with metal. Observations made on 800 silver workers in Berlin have shown that all of them had the characteristic patches of coloration. These patches are round or oval in shape, varying in size from a millet-seed to a broad bean. As a rule they are not raised; they are anæsthetic, and occur principally on the dorsum of the left hand. Only workers in silver are thus affected, and not those who manipulate gold or copper. The absorption of the metal seems to have no effect on the general health. Microscopical examination shows that the patches are caused by the deposit of metallic silver in the tissues, and they are soluble in nitric acid and cyanide of potassium. It was noticed that the men effected were invariably those who had some ulceration or abrasion of the hands through which the metal was absorbed. The nature and shape of the metallic deposit warrants the supposition that the metal enters in a soluble form, and is then precipitated. Curiously enough, three workmen, who were being treated for syphilis with mercury, developed a number of fresh stains in a comparatively short space of time.—*British Medical Journal*, August 6, 1887.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY, FROM OCTOBER 11 TO OCTOBER 17, 1887.

ALEXANDER, CHARLES T., *Lieutenant-Colonel and Surgeon.*—Relieved from duty as attending surgeon and examiner of recruits at St. Louis, Missouri, and ordered for duty at Fort Meade, Dakota.—*S. O. 236, A. G. O.*, October 8, 1887.

CUNNINGHAM, E. V., *Captain and Assistant Surgeon.*—Died, October 12, 1887, at Fort Lewis, Colorado.

APPOINTMENT.

JARVIS, NATHAN S.—To be Assistant Surgeon, United States Army, with the rank of First Lieutenant, October 14, 1887.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

ORIGINAL ARTICLES.

SOME GENERAL REMARKS ON TUMORS OF THE BLADDER, BASED ON THE REPORT OF A CASE OF PAPILLOMA OF THE BLADDER IN A FEMALE,[1]

BY W. H. WENNING, M.D.,

PROFESSOR OF OBSTETRICS AT THE WOMAN'S MEDICAL COLLEGE OF CINCINNATI; GYNECOLOGIST TO ST. MARY'S HOSPITAL.

TUMORS of the bladder have but recently received that attention which their importance demands, not that the occurrence of neoplasms in this viscus had not been previously recognized, but the imperfect methods of examination, together with insufficient modes of treatment, failed to give an opportunity for a satisfactory exposition of this subject in all directions. Owing to the recondite nature of tumors of the bladder, the diagnosis was often not clear; in many cases cystitis, which here was only a symptom, and not the disease, was undoubtedly dependent upon the presence of a tumor, and even calculi were mistaken for neoplasms. Whilst, therefore, tumors in other parts of the body have long since attracted the closest attention for the purpose of diagnosis, as well as of treatment, those of the bladder have, until little more than a decade ago, received but a passing notice. The confusion that surrounded both diagnosis and treatment also prevented a close examination of their pathological character, hence the reason why so little is found in the older works on special anatomy on tumors of the bladder, and why, even at the present time, considerable difference of opinion exists regarding their exact pathological classification, respectively their benign or malignant character.

A new impetus, however, was given to a study of this subject by the labors of two men who proposed new methods of exploring the bladder by that best of instruments, the index finger, by which new light was thrown upon a hitherto obscure subject. Gustave Simon, of Heidelberg, developed a safe and ready method of exploring the female bladder through the dilated urethral canal. Sir Henry Thompson, of London, devised a new operation, called by him external urethrotomy, by which the same object, digital exploration, was attained in the male organ. It is true both these operations had been occasionally resorted to by others before their time, for the purpose of extracting foreign bodies from these regions, but to Simon and Thompson belong the credit of first having systematically developed and practised their methods for diagnostic purposes. But not alone as a means of diagnosis have these operations proved of inestimable value, but also as a method of treatment. Hence, if they should not reveal the presence of a tumor or other foreign body, the simple dilatation of the urethra in the one, and "button-holing" the same in the other, have acted as a remedial measure in otherwise intractable cases of vesical catarrh and other affections of the bladder. It may, therefore, be said that both operations have now been universally accepted as valuable contributions to the diagnosis and treatment of a variety of disease of the bladder. The shortness and dilatability of the female uretha render Simon's operation the simpler of the two, as it is bloodless and comparatively painless, at least after repeated attempts. The length and narrowness of the male urethral canal necessarily demanded an artificial opening somewhere near the end of the long urethra, through which the finger could be introduced. For this end, as already mentioned, Sir Henry Thompson devised his external urethrotomy. Simon published his first article on a new method of making the female bladder accessible, in 1875, and Sir Henry Thompson performed his first urethrotomy followed by the removal of a vesical tumor, November 6, 1880. Since this time, diseases of the bladder have received a greater degree of study, and several valuable treatises have been written on these subjects, the most important of which are Sir Henry Thompson's lectures on the *Diseases and the Surgery of the Urinary Organs*, including his monograph on *Tumors of the Bladder*, and Winckel's work on *Diseases of the Female Urethra and Bladder*, as a part of Billroth's *Handbuch der Frauenkrankheiten*. It is to these two works that I am chiefly indebted for the statistics regarding the frequency of vesical disease, notably to the latter.

The early statistics are both meagre and faulty, due to the fact that probably many cases had not been recognized, at least their true nature not understood, owing to the absence of positive symptoms, or they had been confounded with each other as calculus with tumor, tumors with chronic cystitis, hypertrophy of the mucous membrane, etc.

A study of the statistics has been pursued in three directions: 1, the proportion of the diseases of the bladder to diseases in general, including the mortality; 2, the percentage of vesical diseases in males and females respectively, and, 3, the percentage of the various forms of vesical diseases to each other. As regards the first point, Winckel has endeavored to form some estimate from the records of three of the largest hospitals in Berlin. In nearly 42,000 cases of both sexes (25,733 men, and 16,077 women), he found 235 cases of vesical disease (187 men, and 48 women), making a percentage of 0.5, or one-half of one per cent. for all, or 0.7 per cent. for men, and 0.3 per cent. for women. Winckel, however, concludes that little

[1] Read before the Cincinnati Academy of Medicine Oct. 10, 1887.

information can be derived from a study of these statistics, except that vesical diseases are much more frequent in women than in men. The mortality list in Vienna in 1874 shows that out of 17,316 deaths only 33 men and 6 women were registered as having died from some disease of these organs, or 0.2 per cent. of the whole. This, of course, would not form a true estimate of the comparative frequency of vesical trouble, as many cases might have died from other diseases complicating disease of the bladder. Here again, however, we find a preponderance of the male over the female sex. From a report of the medical district of Musser, from 1807 to 1872, it appears that of 58,466 sick people 353 had kidney disease, 309 bladder affections, and 577 gonorrhœa, making vesical diseases more frequent than those of the kidneys, or 0.68 per cent. of the whole.

As regards the proportion of vesical disease to other affections in the same sex, and for our purpose we will simply take the female, we find again, quoting Winckel in his reports of 3775 sick females, there were 246 cases, or 6.5 per cent. of diseases of urethra and bladder, but 118 of these, or 15 per cent., occurred in the last 776 cases, showing that the percentage increased as the affections were more earnestly sought after.

The same author also selected as a basis for his statistics 2505 female cases out of a total number of 6861 autopsies collected at his request by Birch-Hirschfeld, from the records of the Dresden City Hospital in twenty-five years, from 1851 to 1876. Of these, 184, or 7 per cent., showed post-mortem evidences of urethral or vesical disease. Of these again, 45, or 21.7 per cent, had some form of tumor, 37 being cancer, besides 36 cases of vesico-vaginal fistula caused by perforating cancer. Winckel's own list of 575 female autopsies shows 144 cases of vesical disease, or 25 per cent., and 16 of these had some form of new growth, excluding tuberculosis of the bladder, of which there were 5 cases.

Although women suffer from tumors more frequently than men, it does not seem to follow that new growths in the bladder are more frequent in the former. For Gult found in 101,411 sick cases in the three largest Vienna hospitals, 16,637 suffering from tumors; 11,140 of these were women, and 16 had tumors of the urethra, 1 fibroma, 3 papillomata, 3 polypoid growths, 1 sarcoma, and 8 carcinomata. 20 had cancer of the bladder, as against 46 men that suffered from it. In 119 cases of primary tumor in both sexes, Sperling found 41 fungoid growths (fibromata or papillomata, 19 medullary carcinomata, and 5 scirrhus (25 cancers altogether), 10 mucoid polypi, 6 myomata, 7 carcinomata, and 6 fibrosarcomata. Of the fibromata, two thirds occurred in males and one third in females, and carcinomata were four times more frequent in men than in women. Rauschenbusch found 10 females affected in 22 cases of papillomata of the bladder. In his list of 20 operations for tumors of the bladder, Sir Henry Thompson records 2 women, the remaining 18 being men. The great majority of these were papillomata. Of about 50 specimens belonging to the London museums, examined by him, 43 belonged to adults and 8 to children. The sex of the former was not recorded, but of the latter, 6 were females. In his historical notes on tumors of the bladder, Thompson relates about a dozen cases, all males, from the first operation performed by Corvisart in 1639 until his own first case, in 1880.

From all these statistics we simply conclude that vesical disease occurs more frequently in men than in women. This may be owing to the frequency of disease of the prostate causing greater obstruction to the flow of urine, and the greater length and narrowness of the male urethra, which in turn increases the tendency to disease of the bladder, from retention of urine, calculi, etc. Whether benign primary tumors are more common in men is doubtful, although it seems that primary carcinoma is more frequent in the former than in the latter. Secondary carcinoma is probably more common in the female, owing to the greater frequency of primary carcinoma of the uterus and vagina, from which the disease may extend to the bladder and the urethra. It is difficult to form any estimate from statistical reports as to the comparative frequency of benign and malignant growths, on account of great discrepancy both among microscopists and clinicians regarding the essential characteristics necessary to determine their benignity or malignancy.

Whilst all authorities admit that the bladder may become subject to the development of benign tumors, some deny that the bladder ever becomes primarily the seat of malignant disease. Others, again, assume that a malignant tumor may form the case upon which fungosities may spring, which present microscopically the appearance of non-malignant growths. The greatest point of contention is the so-called "villous cancer" or villous tumor, called by the first name by those who assert its malignancy, by the latter by those who claim its benignity. Klebs, for instance, denies the occurrence of primary carcinoma in the bladder in any form. Rindfleisch says that papilloma of the bladder is sometimes also called villous cancer, but a better term would be villous tumor, because the growth has nothing to do with carcinoma, for even a superficial examination will show that it consists of nothing besides branches of villi. He admits, however, that a papilloma may develop into an epithelioma, or the two may exist together. He also mentions the observations of other authors, that the mucous membrane over a subjacent carcinoma may develop into a papilloma, but states at the same time that he has not witnessed its occurrence. According to Virchow, a papilloma is at first a simple hyperplasia caused by the irritation of a neighboring carcinoma; but afterward it may become converted into a true villous cancer, if the carcinomatous growth underneath invade the connective tissue of the papillæ. "This change," he says, "most commonly takes place in the stomach and bladder." It is a curious fact that these two organs are normally said to be devoid of papillæ. Birch-Hirschfeld says: "Occasionally the base of a papilloma undergoes cancerous infiltration, either the villi proliferating on a cancerous base, as happens in other mucous membranes, or the carcinoma develops subsequently in the groundwork of a papilloma." Ro-

kitansky, after enumerating the following neoplasms which may occur in the connective and submucous tissue—polypoid and papillary excrescence of the mucous membrane, fibroid tumor, epidermidal degeneration (cholesteatomata), lymphoid formations, and cysts—states that *primary carcinoma of the bladder is not rare*, in the form of a medullary villous cancer, which is usually situated in the trigonum or its vicinity. Very rarely this form of cancer springs from the submucous connective tissue, and extremely rare is a fibrous, carcinomatous degeneration of the walls of the bladder. Secondary deposits are common in carcinomata of the sexual organs of women. Very frequently the bladder is infected *ex contiguo* by a medullary carcinoma of the uterus, or a medullary or colloid cancer of the rectum.

From all this it may be seen that the papillæ themselves alone are no positive evidence of non-malignancy, as they may complicate cancerous growths, or form a part of them. Some confusion also seems to exist regarding the terms papilloma and villous tumor, these terms being regarded as synonymous by some whilst others make a distinction, calling a papilloma a benign growth, whilst a villous tumor is a form of cancer. As the papillomata differ among themselves, depending upon the greater or less amount of fibrous tissue and the preponderance of epithelial proliferation, it would be expedient to make a division between the two. Sir Henry Thompson has made this distinction, after having had all of his twenty cases carefully examined by competent microscopists. He ranges all tumors of the bladder under two heads, which he calls homœoplastic and heteroplastic. Homœoplastic are such tumors as consist more or less of elements identical with the normal tissues of the bladder; heteroplastic, those which consist more or less of elements never found in the tissues of the healthy bladder. To the former, then, would belong the papillomata, from their nature being homologous with the normal tissue, benign in character; to the latter carcinomata, heterogeneous and consequently malignant. Papillomata are again subdivided into two forms, the fimbriated variety, ordinarily known as the villous growth, and the fibro-papillomata, or ordinary, simple papillomata, so-called. This classification would dispose of the villous tumor, ranging it under the head of benign growths. But the same author recognizes a third variety, which he calls the "transitional type." In this form, although the base is still homologous, with the normal bladder, there are certain cells which are foreign to this structure. He states, however, "that the mere presence of papillæ on a tumor, whether met with in the simple or long fimbriated form, does not characterize a growth, because they may be met with springing from the surface of heteroplastic growths, as epithelioma or cancer. The distinguishing feature of the transitional type is the arrangement of the ground-substance and the presence of irregularly shaped cells, which do not belong to the normal tissue of the bladder on the one hand, or to distinct new-growths on the other."

From what has already been said, it may be inferred that, as a rule, homœoplastic growths are benign in character; heteroplastic, malignant; although there may be exceptions, for a dermoid growth is heteroplastic, and yet not malignant. Such a tumor has occasionally, though rarely, been observed in the bladder, either as a result of a bursting into this organ from a locality in its vicinity, as dermoid cysts of the ovary, or a primary development of the tumor in the walls of the bladder itself. In this connection it might not be uninteresting to cite the opinions of some American authors. Speaking of villous growths in the bladder, Van Buren and Keys say, "There is nothing cancerous about their structure. Their cause is unknown. They never lead to secondary cancerous deposits elsewhere. They do not spontaneously ulcerate. The lymphatic glands are not implicated. There is no characteristic cachexia. When they kill, death seems to be due partly to a loss of blood and exhaustion from pain."

Skene seems to be undecided as to the cancerous or non-cancerous character of villous tumors, for, after calling attention to the difference of opinion between the German and some English authorities on one hand, and the American authors just quoted on the other, he ranges them under the head of carcinomatous growths, stating, "not that I am satisfied that they are malignant, but for lack of positive evidence of the new idea, temporarily at least, adhere to the old one."

These preliminary remarks are induced by the history of an interesting case which I am about to report, which presents a field for study not alone to the clinician, but also to the microscopist. The obscurity of the symptoms in the beginning, the presence of physical symptoms which suddenly disappeared and left no trace of their previous existence, and the successive pathological changes which occurred in the continued growth and recurrence of the tumors after removal, prompted me, for a better understanding of the case, to trespass for a little while upon your patience in travelling over a ground on which, perhaps, many of you are more at home than myself. I will not, therefore, tax your patience any longer, and at once pass to the report of the following case:

Mrs. M. S., German, aged fifty-two years, widow, was admitted to St. Mary's Hospital, February 3, 1887. She was extremely emaciated, and her countenance bore the expression of great suffering. Her general appearance was both anæmic and cachectic. The patient, who was a lady of more than ordinary intelligence, gave me a clear and interesting history of great suffering from a chronic disease of the bladder, and, as evidence, showed me a vial containing a large number of small, fleshy bodies, varying in size from a filbert to a chestnut, which she had passed from the bladder within a short space of time. Besides these small tumors, the vial contained a fluid having the appearance of muco-pus. In reciting to me the history of her complaint, she stated she had been under the treatment of Professor Winckel, formerly of Dresden, now of Munich, who had operated upon her for tumor of the bladder, and had described her case fully in his work on *Diseases of the Female Urethra and Bladder*, and in Billroth's *Handbuch der Frauenkrankheiten*. As I

was fortunately in possession of this celebrated work, I consulted it on my arrival home, and from it I borrow the following clinical history of the case up to the time she passed out of the hands of the distinguished German gynecologist.

"*Large papilloma of the posterior wall of the bladder; rapid dilatation of the urethra by means of the finger, and extirpation of the growth; recovery of the patient.* — Mrs. M. S., aged thirty-nine years, from New York, suffered when a child from a severely itching eruption, probably urticaria. When four years of age, after eating some unripe plums, she was seized with severe pains on micturition, which disappeared in the course of several weeks, after proper medicinal treatment. In her fifteenth year she had regular periodic attacks of fever, lasting one month. Her menses first appeared in the beginning of her sixteenth year, and since that time returned regularly every twenty-six days. In 1866 she had an attack of cholera. In 1868 she was married, but just previous to this event, *she fell with the full weight of her body against a corner, receiving the blow upon the right side of her body.* At that time she feared that she had received an internal injury. The pain, which was very severe at first, soon, however, disappeared. On the 10th of May, 1869, seven months after her marriage, she was delivered of a living child without artificial means, the duration of her labor being eleven hours. The abdomen remained enlarged after this labor. In consequence of mental depression, attributed to the death of her child, she experienced for the first time, in July, 1869, *a feeling alarming weakness in the right side of the lower part of the abdomen*, and was absolutely unable to emit a loud word or walk a step. This condition of weakness was frequently repeated, and soon was accompanied by severe cramps in the whole body. Some weeks later she says she found in her urine small granules of pus, about the size of a pin-head, to which a small amount of blood was constantly adherent. A year later she was seized, upon the slightest exertion, with hot, burning stitches, proceeding from the urethra upward, and passing to the right, which caused her to cry out aloud. The abdomen grew large and very painful, but the chief pain was always situated in the lower part of the bladder and near the urethra. Appetite was enormous, sleep heavy and profound. In the beginning of the year 1872, the patient, according to her own report, first plainly felt, during micturition, a crowding of floating bodies toward the orifice of the urethra during the flow of urine; sometimes this occurred so rapidly that the bodies completely obstructed the urethra. After this a spasm of the sphincter took place, which relaxed only after drinking a large quantity of hot water and the local application of a sponge dipped in hot chamomile-tea, after which the urine was again completely voided. The following symptoms are described by the patient herself; she says: 'Soon afterward a new affliction set in. Every morning, when increased action of the bowels begins, and the gases that are formed seek an outlet, they do not escape through their natural outlet, but, like a stream of burning lava, pass from the upper right side into the bladder, where they scatter between the foreign bodies, as the smoke from an engine encircles the tops of trees. Even at that time I experienced, in the midst of the most horrid pains, the branched and tree-like growths, but was laughed at or decried as insane when I described them. About this time I discovered, in front of the cushion encircling the orifice of the urethra, a tumor highly inflamed, resembling in shape the end of a quill; I touched it with nitrate of silver, and in three or four weeks, after having previously passed a great quantity of blood and pus with the urine, the first three granulations, the size of a bean, forced their way through the urethra, causing labor-like pains. A few pieces followed the next day. I was now greatly relieved, but the pains reappeared after one month. October 23, 1872, Dr. de Moor, of New York, after a careful examination, declared my disease to be an *enlargement of the right ovary.* He asserted that *the whole ovary had already descended into the bladder.* I was painted with tincture of iodine, and, after one month, suddenly the morning pains, already described as due to the passage of wind, ceased, and have not returned since that time."

"The patient's condition remained the same up to the time that I first saw her, in the summer of 1873, four years after the inception of the trouble. She was of medium height, had a considerable amount of gray hair, her features were pale, and bore the marks of suffering, although her nutrition was rather good. The abdomen was tense, with a considerable amount of adipose tissue, which rendered the detection of a tumor difficult. Touching the urethra and examining the vagina caused such excruciating pains that she anxiously begged to be put under the influence of chloroform, which was given her.

"To the right of the uterus, projecting somewhat above the line of the pelvic inlet, I could feel a tense, elastic, and immovable tumor, which seemed to me to proceed from the right ovary. The urine removed by the catheter was clear, containing no foreign bodies, whereas the patient had shown me an abundance of warty bodies, each about the size of a hazel-nut, filling an ordinary tumbler, which had passed from her urethra from time to time. My diagnosis, therefore, coincided with that of Dr. de Moor, that a papillary ovarian cyst had perforated the wall of the bladder, and the papillary tumors had been discharged in this manner. But as I could feel no tumor in the bladder with the catheter, and found nothing foreign in the urine, there was no cause for operative interference.

"During the following eight months gradually more fragments passed from the bladder, at one time amounting to enough to fill a 100 grammе (3-ounce) vial. Meanwhile, bloody discharges occurred, coming away in drops, and more at a time, and causing such intense pain that the patient determined to submit to any operation that would promise her a relief from trouble. Consequently, on June 10, 1874, for the purpose of closer observation, I admitted her to my clinic. She then had no fever, had a good appetite; her bowels were sluggish, but were easily moved by large injections. She was restless at night, but soon improved under small doses of tincture of opium. After copious draughts of hot drinks, the patient passed, June 11, 1048 grammes (33 ounces); June 12, 1180 grammes (37 ounces), and June 13, 1350 grammes (42 ounces), of urine, containing a mixture of pus and blood, but no solid masses.

"June 17. I had her put under chloroform, and, after having first had the urine drawn off with a catheter, carefully introduced the left index finger into the dilated orifice of the urethra and penetrated the canal in the course of two or three minutes without exerting any undue force, whereupon I could feel on the *posterior wall of the bladder, about the region of the orifice of the right ureter*, a large movable, villous, soft tumor, which could be crushed and separated into smaller pieces with the finger. After this had been done in all directions, I removed the finger and injected through the syringe about 150 grammes (5 oz.) of warm water, then introduced a Carus bivalve dilator uteri into the bladder and allowed the severed fragments to flow out through the blades in large quantities. The finger was again inserted to remove all remnants, and as the pedicle of the tumor constantly evaded the finger, I attempted to introduce a small pair of forceps

along its side. Although I succeeded with some difficulty, I could not then feel the growth with the finger, and therefore had to remove the instrument again. In three or four successive attempts I succeeded in crushing off all the sensible projections on the posterior wall, and removing them from the bladder in the manner described above. Hemorrhage was moderate; the sphincter promptly closed immediately after the withdrawal of the finger or dilator, so that none of the injected fluid passed off. At the close of the operation I detected a small fissure *in the upper portion of the mucous membrane of the urethra and a small depression in the lower left border of the urethral orifice.* The patient had vomited once during the anæsthesia. This vomiting recurred several times in the following night, the next day, and the second night following. This, however, constituted the sole reaction which the patient showed; for the pulse ranged constantly between 72 and 80, the patient was wholly without fever, had but slight pain on micturition, and the urine which had in the beginning contained considerable blood, small clots and fragments, improved gradually in appearance. Warm baths were very refreshing to the patient.

"I was highly interested to find during the examination made during anæsthesia, before the operation, that the uterus was entirely healthy, normal in size and mobility, and *nothing* to be found of the tumor on the right side. It is true the bladder seemed to be depressed at the spot where the pedicle of the tumor appeared to be inserted, but no connecting passage or adherent bands could anywhere be found.

"The nature of the tumor removed corresponded exactly with the masses discharged previously by the patient. At first sight it can be recognized as a *papillary* tumor, of which the separate papillæ are somewhat distended about the size of a millet seed to a grain of barley. The papillæ consisted of lamellated and proliferated pavement epithelium on the surface, with a very delicate connective tissue ground, containing several large vessels which send branches into the papillæ. Had there been a cystoma of the ovary in this case, there would undoubtedly have been a recurrence of the growth and extension in another direction after the primary fistulous opening into the bladder had cicatrized; for I have repeatedly witnessed the perforation of such cystomata into the rectum or umbilicus after the communication outwardly had been cut off. Such was not the case in this instance. The patient has recovered entirely; she lives in my neighborhood, has presented herself two years after operation, and there is *no trace of an ovarian tumor,* nor a recurrence of papilloma of the bladder."[1]

To continue this interesting history as given by Professor Winckel, the first part of which the patient had furnished him in writing, she made to me the following oral statement. After leaving Professor Winckel she enjoyed an immunity from the disease for about eight years, but then gradually the former symptoms again set in; pain on micturition, associated with the discharge of pieces of tumor. She managed to do without treatment for a year, after which she was compelled again to seek medical advice, but received no benefit until she was finally referred again to Professor Winckel by her physicians. She revisited him; he made a thorough examination, but, to her knowledge, he removed nothing except allowing some pieces to pass away spontaneously through the dilated urethra. He at first thought of making a cystotomy, but soon abandoned this idea and recommended simply injections of a solution of salicylic acid. She continued this treatment nine months, under which she improved slightly, so that she could again move about, though with great pain. As the salicylic acid gradually lost its efficacy, she of her own accord injected a solution of nitrate of silver into the bladder for over two years—from May, 1884, to July, 1886. This in turn gave her some relief, but as her trouble finally grew steadily worse, she consulted Professor Küster, of Berlin. This gentleman at once ordered the discontinuance of the nitrate of silver and again ordered salicylic acid injections. She yielded reluctantly to his order, but failing to obtain any relief she again had recourse to injections of nitrate of silver. This time, however, they failed to give her any relief. She then resumed the injections of salicylic acid, and continued them up to shortly before her admission to the hospital. She left Europe in September, 1886, arriving in Cincinnati the same month. Her trouble gradually became worse until she became bedfast on November 2, 1886. Her condition remained unchanged, except that in Christmas week incontinence of urine set in, which continued to the time she was admitted to the hospital, February 3, 1887.

The first thing that struck me when I entered her room the next morning after her admission, was a terribly penetrating odor which pervaded the whole room. Searching for the cause I found a vesselful of thick purulent urine on the floor at the bedside, into which the urine flowed as it passed from her bladder into a rubber cloth over the bedding. Notwithstanding her miserable condition, the patient was of a somewhat cheerful temperament, thoroughly resigned to her fate. Her pulse, although weak, was regular and not rapid, her appetite good, her bowels somewhat constipated, but easily moved by injections, and her sleep good so long as the fragments in the bladder found free exit from the urethra. After ordering the necessary disinfectants, I proceeded to obtain the history as it has been given. As my interest had been aroused I proposed an examination to the patient, to which she reluctantly consented upon the condition that I would administer chloroform. Thereupon I called Dr. Jones to my assistance and he administered the anæsthetic. The examination revealed the same state of affairs as given in the history of Professor Winckel. The uterus was small but normal and perfectly movable; no ovarian complication could be found—in fact, the ovaries could not be felt. The urethra showed several lacerations in its border and was dilated, but not sufficiently to admit the index finger. I consequently introduced a bivalve urethral speculum and gradually dilated the canal. During the process a number of round bodies passed out through the blades of the instrument varying in size from a

[1] The translation of the history of this case was made from the first German edition of Winckel's work, before the English translation appeared. In Vol. X. of the Cyclopedia of Obstetrics and Gynecology, published by William Wood & Co., just issued, which is a translation from the second German edition, I find the following additional sentence: "In July, 1882, eight years after the first operation, she returned to me in trouble again. I found the entire posterior vesical wall diffusedly infiltrated with a new growth, extirpated a part, and found that there was carcinomatous degeneration. She moved away soon afterward, and I do not know whether she is still alive."

grain of corn to a hazel-nut. After the dilatation had been performed I introduced my index finger and came at once upon a large field of roundish bodies in the posterior wall of the bladder, which rapidly gave way to pressure. At this stage of the examination, however, the patient seemed to succumb to the influence of the anæsthetic, so that further exploration had to be immediately suspended and artificial respiration instituted. With some difficulty the patient was made to rally and put at once to bed, thus abruptly terminating the examination. The patient soon recovered, and owing to the discharge of a great number of fragments, expressed herself as somewhat relieved. Nevertheless she soon experienced her former difficulties, the pain becoming most intense when large pieces blocked the urethral orifice. As a disinfectant measure a solution of thymol was injected into the bladder a number of times daily by the patient herself, who had become skilled in the use of the reflex catheter. Other agents were occasionally substituted, but she declared that she obtained the greatest relief from the thymol injections, and therefore used them diligently.

During all this time there was no hæmaturia, except a slight amount at one time, every specimen of urine having been carefully inspected for the purpose of accurately settling this point. The aforesaid warty growths continued to pass out of the urethra assisted by several daily irrigations of the bladder which the patient diligently instituted. These bodies, according to the patient's description, had at first been firm and of an opaline appearance; now they gradually became darker in color and more friable, but still remained of variable size. To determine the microscopic character, several of the older specimens which the patient had brought with her were given Dr. Kebler for examination, who reported that he found no evidence of anything but papillomatous growths, with no positive proofs of malignancy. As the patient continued to discharge these bodies, several later specimens were given to Dr. French for examination, whose report will be found appended to this history.

The patient's condition remained about the same, with the exception that she gradually grew weaker, and the treatment was simply symptomatic. Nothing but stimulants were administered in the meantime, until she finally succumbed by exhaustion on April 3, 1887.

A post-mortem examination was made by Dr. French, the Pathologist of St. Mary's Hospital, on April 4th. On opening the abdominal cavity the peritoneum was found thick and adherent to the bladder, which was considerably larger than normal, with much thickened walls. The outer surface of the bladder was roughened by the inflammatory product and the walls appeared very friable. The dimensions of the organ were as follows: Length of cavity, 7¼ inches, width, 5 inches, thickness of the walls over ¾ inch, making the external measurement about 8 x 6 inches. The entire internal surface was covered with these round papillomatous bodies, varying in size from a pea to a hazel-nut. The bladder, ureters, and kidneys were filled with pus; the ureters were dilated to a size large enough to admit the finger, and the pelvis of each kidney contained a large accumulation of pus, with several small metastatic abscesses in the cortical portions. The ovaries were small and shrunken, and bore no evidence of cystic degeneration. The uterus was externally of normal appearance, but on section a number of small fibroids about ¾ of an inch in thickness were found imbedded in the walls. The lumen of the cavity was correspondingly lessened. The organs of generation showed no evidence of disease, the degenerative changes having taken place only in the urinary organs; the bladder, ureters, and kidneys. The inguinal lymphatic glands were enlarged.

Several microscopic sections were made from different parts of the specimen. The papilla-like bodies presented the same characteristics as did those examined some time before the death of the patient. The structure of all the specimens was that of a rather soft, medullary carcinoma. No other tissue could be found.

A study of the case just mentioned presents several interesting features: first the question as to the cause of the trouble; secondly, the duration; and finally, the pathological character of the tumors.

If any stress be laid upon the very beginning of the history, the bladder trouble must have begun at a very early age. The patient stated that when she was four years of age (forty-eight years before her demise) she was seized with severe pains on micturition, lasting a number of weeks before they disappeared under appropriate treatment. She attributed this to the eating of unripe plums. Perhaps no significance would have been given to this symptom, if such a serious vesical disease had not set in, yet it is not impossible that even at this early age there was disease of the bladder which was perhaps congenital. Hypertrophy of the bladder and polypoid growths have been observed in very young children and even detected at autopsies made upon newborn infants. Winckel mentions a case where two mucous polypoid growths, one the size of a pea, were found in the body of an infant born in the eighth month of gestation. Martini describes a case of dermoid tumor in a newborn child. Podrazki cites a case of J. Cooper, where a papilloma was found in a female child four years of age. Gross removed a number of mucoid polypi from a boy, and Billroth, a large fibroid tumor the size of a fist also from a boy twelve years of age. Owen describes a sarcomatous tumor in a boy who died when six years of age. According to the same author, Giraldès gives two examples of polypoid tumors; one protruded in a fungating mass through the meatus urinarius of a female infant. According to him, Burkett and others have reported similar cases. It is not impossible, therefore, that our patient had the beginning of her trouble at a very early age. It is true, the condition of the bladder at that time might have been only that of mucous hypertrophy, no foreign growths as yet existing to block up the discharge of urine, as this was the most troublesome symptom a long time afterward. Nearly twenty years ago (1868) the patient first met with an accident, a fall, to which the be-

ginning of her trouble could be unmistakably referred, but it was about three years later that a positive obstruction of the urethra could be felt, and this was preceded by the discharge of small particles of pus and blood in her urine, as early as one year after the receiving of the injury. There was evidently, therefore, an extravasation of blood into the wall of the bladder at the time the injury was received, and this gave rise to the development of the new growth. Hutchinson describes a case similar to Winckel's and mine, where a woman twenty-three years of age was suddenly seized with a severe pain while lifting a heavy weight and gradually developed the symptoms of papilloma of the bladder. The length of time elapsing between the receipt of the injury and the first obstruction may be explained by the fact that the neoplasm was not of sufficient size to cause any material obstruction to the flow of urine. In fact, the mechanical difficulty depends as much upon the situation of the growth as upon its size. Tumors upon the anterior wall and sides of the bladder are said not to offer the same degree of obstruction as those developing in the trigonum, which is the most common seat of attachment. Hence if the triangle between the orifices of the ureters and the neck of the bladder be not obstructed or detached patches be floated toward the urethral canal, the symptoms of difficult micturition caused by obstruction may be absent. Some cases have been recorded where tumors were found post-mortem in the bladder that had caused no symptoms during life.

The removal of the tumors in 1873 gave relief for a long time, and Prof. Winckel was justified in assuming that he had cured the patient when she remained free from a relapse for eight years. Then all the former symptoms reappeared and the tumors seemed to grow with increased rapidity. From this time another phase developed in the character of the neoplasm. There can be no question that from a microscopical examination made at the time of the first operation the tumor was benign, and this is further substantiated by the long lapse of time before a recurrence set in. It is very probable that a carcinomatous degeneration occurred in the bases of the papillomata removed, and this led to the rapid infiltration of the interior of the whole bladder, or possibly all of the growth was not extirpated and these remaining portions underwent cancerous degeneration.

It has already been stated that, according to some pathologists, a carcinoma may be secondary to papilloma, or *vice versa*, or both may exist together. This may explain why Dr. Kebler, to whom I referred the first specimen for examination, found no evidence of anything but true papillomatous structure, although Winckel had already detected a carcinomatous degeneration, when the patient revisited him the second time in 1882.

There was, however, no clinical proof of carcinoma, for the same symptoms and fatal termination could have occurred from the excessive proliferation of simple papillomata. A remarkable feature was the almost entire absence of hemorrhage. The patient stated to me that the loss of blood had never, except in the beginning, amounted to much, and only occurred later when large masses were torn away from the base at the time of operation. Such a thing as persistent hæmaturia was not observed.

The prognosis could, of course, be nothing else than fatal, and hence no further surgical attempt was made by me. When the pain from the obstruction was most severe, I reluctantly proposed a cystotomy, but the patient declined, stating to me, what has already been mentioned, that Prof. Winckel had contemplated performing the same operation but soon abandoned the idea. She requested that her last days be made simply as comfortable as possible, and welcomed the approach of death as a harbinger of peace and relief from long years of suffering.

THE TREATMENT OF PULMONARY CONSUMPTION, WITH A REPORT OF FORTY CASES.[1]

By THOS. J. MAYS, M.D.,
PROFESSOR (ADJUNCT) OF DISEASES OF THE CHEST, PHILADELPHIA POLYCLINIC.

This paper is devoted to a consideration of the therapeutics of pulmonary consumption, but the therapy of any disease is meaningless unless the underlying pathological conditions are correctly interpreted, and we shall, therefore, at the very outset, endeavor to outline, in as brief a manner as possible, the recognized principles of the pathology of this disease, and then follow with a discussion of those measures which experience has proven to have the power of controlling and of dissipating it.

Now, pulmonary consumption is generally an extension of chronic bronchitis into the alveoli, or is the product of acute catarrhal pneumonia. In either case, it is a catarrhal affection of the alveolar epithelium. The pulmonary capillaries become engorged, and the epithelial cells multiply and accumulate, and clog up the alveoli with their products. The filling up of the alveoli with these catarrhal aggregates produces small bodies which partake of the shape and size of the former. In this way one alveolus fills up after another, until a whole group or a cluster of them is involved, giving rise to roundish nodular bodies, which are so frequently mistaken for tubercles. They are not tubercles at all, in the technical meaning of that term, but are mere *accumulated inflammatory or catarrhal products*. This train of pathological changes is due to a disturbance of the relationship existing between the production and expulsion of epithelial products. If such a relationship were preserved, or could by any means be restored, it is evident that the disease would at once be called into abeyance. Thus far, the process is chiefly limited to the alveolar walls, their epithelium and their bloodvessels; but the continued accumulation of catarrhal products exerts a decided pressure on the surrounding pulmonary and bronchial capillaries, and the blood supply and nourishment are gradually diminished and finally cut off from these infiltrated areas which, in due course of time, become isolated and circumscribed foreign masses, prone to undergo a slow process of cheesy

[1] Read before the Pennsylvania State Medical Society, Bedford Springs, June 30, 1887.

degeneration, and leave behind cavities, large or small, according to the amount of tissue destruction.

In curing this stage of excavation that the true tubercle is brought to life. A specific poison is derived from the caseating catarrhal nodules, which is chiefly absorbed by the lymphatics. These vessels transport this specific element along their ascending courses as they arise in the alveolar wall, and twine around the walls of the bloodvessels and the bronchioles, and it is here, in the beginning, and in the channels of the lymphatics, that this poison incites new nodular growths, which are *genuine tubercles*, but differ from the yellow, or catarrhal nodules, already considered, both in genesis and in structure. They are evolved from interstitial connective or lymphatic tissue, and are growths, or a hyperplasia, and not mere epithelial or catarrhal aggregations like the so-called yellow tubercles.

It must be distinctly understood, however, that pulmonary consumption is such an intensely sectional disease that what has been said so far in regard to the catarrhal origin of the disease pertains almost exclusively to the apices of the respiratory organs. And it may, therefore, be laid down as a safe rule in the diagnosis and prognosis of chest diseases, that, in by far the great majority of cases, partial or complete consolidation of an apex denotes the first stage of pulmonary consumption. While it is not absolutely true that every case of apical infiltration terminates in pulmonary cavitation, it is enough for the practitioner to know that it is the beginning of a process which, if not checked, certainly tends to end there.

It is very evident, therefore, that the focus of disturbance in pulmonary consumption is an infiltration of the vesicular structure of the lung, and a consequent consolidation, and that the one great desideratum in its treatment is as to the best method of removing this; or, in other words, how is resolution of the affected part to be accomplished? In croupous pneumonia the intra-alveolar infiltration, which consists principally of a fibrinous infiltration, is quickly removed through a process of fatty degeneration; but in catarrhal pneumonia the infiltration does not consist of fibrinous exudation, but, as we have seen, of an accumulation of epithelial products, and, instead of tending toward fatty degeneration, it undergoes a process of caseation. The difference between fatty and cheesy degeneration is the line which divides the fatal nature of the latter from the non fatal nature of the former disease; and if the therapeutic art can devise a method by which the catarrhal infiltration can be resolved into a fatty, or into a calcareous instead of into a caseous degeneration, the problem of the treatment of pulmonary consumption will be forever solved.

The great obstacle to the successful treatment of pulmonary consumption, however, is the inability to introduce agents which reach and act on the focus of the disease, viz., on the seat of infiltration. Efforts have been repeatedly made to apply medicaments locally through the air-passages by inhalation, as well as through the blood, either by hypodermatic injection, or by gaseous enemata according to the now famous method of Dr. Bergeon. But we have already seen that the most pronounced seat of infiltration is entirely beyond the reach of bronchi or bloodvessels, hence, it cannot be expected that any of these methods have the power to antagonize the citadel of the disease, however capable they may prove themselves in removing some of its concomitants.

We have here then, in most instances, a condition which, to all intents and purposes, is a deposit of inflammatory products differing, in principle, in no wise from a similar deposit in any other part of the body, and the dictates of common sense point out that that which is useful in the one condition is also useful in the other. Every physician can testify to the inestimable value of counter-irritation, and of passive motion in producing resorption of chronic inflammatory deposits in joints, and in the external surfaces generally, and in consonance with this view we have, for a number of years, applied hot flaxseed meal poultices, as well as friction to the chest, in such affections, and, we believe, with the most gratifying results. There is reason for believing that these external applications have the power of increasing the circulatory, the lymphatic, and the cellular activity of the affected part, and, in this manner, gradually remove the most pronounced pulmonary infiltration.

The manner of making these external applications will be briefly described here. First then as to the poultice: This is made by boiling the ground flaxseed meal in a sufficient quantity of water to make a thick paste. Spread it quickly in a layer an inch thick between two pieces of flannel cut in the shape of a jacket, which is well fitted to the top, front, and back of apex, as well as to the anterior and posterior aspects of the affected lung. The edges are sewed or tied together, then it is adjusted to the chest, and the outside well covered with oiled-silk, or some thick woollen material, in order to prevent a too rapid radiation of heat. It must be changed every two or three hours, or sooner if it becomes cooler than the body. This process is to be continued from morning until night, when the poultice is taken off, and the chest is well wrapped with woollen flannel for the night, in order to avoid a sudden disturbance of the bodily temperature during the sleeping hours. The next morning the same programme is begun and continued in the same way for at least three weeks, and so much longer as is necessary. It is much more expedient to poultice during the day only, and allow the patient to rest and be free from the poultice during the night. In fact, this is very important, for if you insist on poulticing during the night also, you are very apt to worry and discourage the patient, and get him to refuse the application altogether.

In a course of five or eight days' poulticing, or perhaps sooner, the change in the physical signs will become most marked. Where previously there was heard nothing but a rough or bronchial respiration, sub-crepitation, perhaps crepitation, and mucous râles show themselves, leading one to suspect that the disease is advancing instead of receding. In the course of a short time, however, the whole part will clear up and become dry. Associated with

these changes in the physical signs, is an improvement in the patient's general condition. He experiences more freedom in his respiratory movements, the cough becomes easier, the expectoration looser, the appetite begins to improve, and he coughs less at night and sleeps better.

In addition to the application of moist heat, we also employ local or general massage once or twice a day. This has the happy effect of counteracting the constitutional lethargy present in phthisis, as well as arousing the local cell activity in the pulmonary organs. Dr. T. Henry Green, in his lectures on the "Pathology of Pulmonary Consumption," delivered in the Brompton Hospital for Consumption, in 1878, speaking of external treatment in this disease, says (p. 102):

"That in these last named cases (cases where much intra-alveolar matter exists which is capable of removal) attempts to stimulate the circulation in the diseased lungs by douches and friction, and other similar means, such as have been recently advocated by a Dr. A. von Sokolowski, would appear to me to be more in accordance with the teachings of pathology."

Next in importance in the local treatment of this disease, comes the inhalation of medicated air under a very slight pressure, and the introduction of gases by means of enemata. The pathology of the disease as well as the experience in its treatment, teaches, however, that the principal value of both of these methods lies in their power to disinfect the catarrhal products which are located in the bronchial tubes, and in such cavities as may be in communication with these tubes, and that they have but very little, if any, decided influence on the catarrhal products of a solidified lung.

Fig. 1, which is a true representation of a completely infiltrated and caseating nodule with its surroundings,[1] shows us that neither of these channels has any direct communication with the truly solidified portion of the lung, yet it also shows us that there are a few permeable bloodvessels which penetrate nearer to the centre of caseation than the bronchi, hence on the surface it appears that any medicament which is contained in the blood will be carried further into the territory of disease than it will be conveyed by the air tubes. It must not be forgotten, however, that substances administered by inhalation are also absorbed by the blood, and while they do not come in contact with these diseased centres on their first introduction, they will just as certainly come in contact with them ultimately, as if they had been thrown directly into the circulation by means of the hypodermatic syringe, or indirectly by means of gaseous enemata.

One of the most valuable acquisitions to the local treatment of chest disease is the inhalation of compressed and the exhalation into rarefied air, or *vice versâ*. Much has been said and written in regard to this subject, and the opinion is generally held that it is a means of supplying a larger amount of oxygen to the blood than is obtained through ordinary respiration; there is good reason for believing, however, that nearly the whole sum and substance of the value of this practice lies in its mechanical influence on the lungs. If it were true that the ques-

tion of aëration of the blood was simply one of diffusion of air in the lungs, and not one of a chemical affinity between the hæmoglobin and the oxygen, undoubtedly more oxygen could be utilized by the lungs under this procedure. At the same time it cannot be denied that by a more complete expansion of the lungs under such circumstances, a larger quantity of hæmoglobin will be exposed, and will combine or absorb more oxygen than under ordinary atmospheric conditions, yet from all the experimental data which we have on this point, it is very probable that the increased absorption is very slight.

Any one who has given the method a faithful trial has found abundant evidence of its usefulness in

[1] On Catarrhal Pneumonia and Tubercle in the Human Lung, by D. J. Hamilton, M.B., F.R.C.S. Ed. Practitioner, vol. xxiv, page 258.

nearly all forms of chest diseases, and especially so in the treatment of the disease under consideration. It gives complete ventilation to, and increases the capacity of, the chest, it relieves the dyspnœa, and acts as a powerful tonic to the whole body. It should be employed with great care, and not be used during a high temperature, nor in an active inflammatory condition of the lungs, except under the very lowest pressure. Indeed, it seems that we have obtained the very best results from it after the activity of the disease had receded, and when convalescence was well under way.

Another important method in the local treatment of this affection is the application of the constant electric current to the chest, according to the recommendation of Dr. Bastings, of Brussels. This procedure consists in chiefly employing the ascending current, and it has special value in those cases in which there is associated with the internal trouble immobility of the thorax, myalgia, or intercostal neuralgia.

In connection with the local treatment we must not lose sight of the marked benefit which may be derived from internal treatment, especially in so far as the question of supplying force and matter to the body is concerned. Pulmonary consumption is preëminently a wasting disease, not necessarily of the lungs but of the whole frame, and any food or medicine which supplies this constant waste, or facilitates digestion and assimilation, is very strongly indicated, and for this reason nutritious foods, cod-liver oil, hypophosphite preparations, etc., are of such great value, if used with discretion. So far as the force-producing value of foods is concerned, there can be no question that cod-liver oil, and the fatty and saccharine foods rank very high, but very frequently we find an aversion to the first, and fermentation following the ingestion of the last two; and hence they must be in a great measure avoided. The non nitrogenous foods which are least likely to undergo fermentation are cream, butter, and alcohol, and the dietetic value of these articles increases in proportion as it becomes necessary to exclude the other foods of this class from the dietary list. The best nitrogenous foods are beef, mutton, eggs, oysters, milk, bread, peas, beans, etc. Animal food often renders the best service when it is chopped into a pulp and consumed when raw. In cases of complete anorexia forced feeding, either by the stomach or by the rectum, must be resorted to, and the food administered regularly three or four times a day, with the addition of a few drops of muriatic acid and a little pepsin. Milk alone does surprisingly well sometimes in this form of feeding.

I have the records of forty cases which have been treated in accordance with the plan here advocated, and we believe that the practical results which it achieved warrants us in recommending it to our fellow-practitioners. The first twenty of these cases were reported by us in a contribution to THE MEDICAL NEWS of October 10, 1885, and we take pleasure in stating that the prognosis which we then gave in regard to these cases has been fully confirmed by subsequent observation. Of the entire forty cases thirty-two recovered. The sixteen of the first twenty cases who recovered have been under occasional observation during a period of from two to nine years, and, so far as we know, are all well at the present time.

In conclusion, we beg to state that these forty cases do not embrace the whole number which we treated according to this system of medication, but, with a few exceptions, include all those of which we possess a complete history in each individual case, from the beginning of the treatment up to the time of death, or to that of recovery. The considerable time which has elapsed in the majority of these cases since suspension of treatment is an important indication as to the value of the latter. We do not by any means parade these statistics with a view of showing that this is a new means for resurrecting the dead consumptive, nor are we unmindful of the fact that just as long as the professional mind is willing to be blown about by every passing therapeutic breeze, so long will a successful solution of the treatment of this disease remain futile; but we earnestly believe that the system which we advocate here, and which has withstood the test of experience in our hands for nearly half a score of years, offers greater prospect of success than any other, and shows that a great deal more can be than has been done for this unfortunate class of patients

TRANSIENT BENIGN PLAQUES OF THE TONGUE (CASPARY)—EXFOLIATIO AREATA LINGUÆ (UNNA).

BY M. B. HARTZELL, M.D.,
ASSISTANT PHYSICIAN TO THE DISPENSARY FOR SKIN DISEASES, HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA

I DESIRE to call attention to a rare, curious, and but little known affection of the tongue, which, within a comparatively recent period has been described by various authors under the names lingual lichenoid, transient benign plaques of the tongue, exfoliatio areata linguæ, wandering rash, annulus migrans.

That the disease is a rare one and little known, may be inferred from the fact that but two cases have been reported in this country up to the present time. This infrequency, and the remarkable character of the affection, have induced me to report with some minuteness the following case, which, having been under observation at short intervals for more than two years, has afforded me ample opportunity to study its various phases and note its peculiarities.

E. C. J., aged forty-two, railroad engineer, in excellent general health, weighing about 175 pounds, consulted me in June, 1885, with regard to a peculiar eruption upon the tongue, which he had first noticed a few weeks previously. Upon inspection, the tongue presented a small, pin-head sized, whitish, slightly elevated lesion, which resembled at first glance an ordinary vesicle upon the mucous membrane. Within a day or two this whitish elevation, having increased to the size of a pea, began exfoliating, leaving a circular patch, deprived of epithelium, surrounded by a narrow, slightly elevated white border.

This patch increased in size from day to day, until it had attained the size of a dime, when it became

stationary; in a few days the tongue gradually resumed its normal appearance. After an interval of ten to fourteen days, during which the lingual mucous membrane seemed perfectly healthy, a new lesion, similar to the first one, made its appearance; ran the same course, and disappeared in the same manner. The eruption required from ten days to two weeks to pass through its various stages. The disease has continued to come and go in this manner until the present time, exhibiting considerable regularity in its different phases. There has never been more than one plaque present at a time; and the disease has been strictly limited to the right side of the organ, never crossing to the smallest extent the median line. Recently, the lesions have been less regular in outline than formerly, but otherwise there has been no change in the appearance of the malady since its first manifestation over two years ago.

The patient had noticed that slight stomachic disturbances, manifest chiefly through eructation of gas, preceded by a few days each new outbreak. Subjective symptoms were almost entirely wanting; but occasionally slight tingling and pricking sensations were present.

In an inaugural dissertation in 1872, under the title of "An Unnamed Affection of the Lingual Mucous Membrane," Bridou first called attention to the disease under consideration, his communication being based upon the study of five cases. Since that time the affection has been further studied, and cases reported by Caspary and Unna in Germany, Gubler, Vanlair, Parrot, and Molénes in France, and by Barker and T. Collcot Fox in England.

Up to the present time the only notice of the disease in the literature of this country is a short article, reporting two cases, by Kinnier.

The affection usually first manifests itself as a small, yellowish or white, slightly elevated patch, ordinarily situated near, or upon the tip of the tongue; this patch soon begins to desquamate, leaving the surface upon which it is seated smooth, shining, and of a bright red color. The lesion enlarges peripherally, preserving its circular outline until the edge of the organ is reached. There may be several lesions at the same time upon the tongue; or, new ones may appear before the old ones have disappeared, and these patches uniting, produce the peculiar appearance which has suggested the name, "geographical tongue."

The yellow hue of the border around the areas denuded of epithelium, upon which Caspary lays considerable stress, is by no means a constant feature—in my own case this border was white; and Unna states that he does not always find the yellow margin described by Caspary, "but more frequently this margin is bluish, grayish, or even silvery white."

In the great majority of cases, subjective symptoms are very slight, or even entirely absent; but in a few cases intense itching of the tongue, with profuse flow of saliva accompanied the appearance of the eruption; and in one case, reported by Vanlair, there was decided pain.

The individual lesions usually run a rapid course; a few hours sufficing often to change the entire aspect of the disease; but, as is evident from the case reported above, this rapid course is not invariable, and each lesion may last a week or more.

The dorsal surface is the usual site of the eruption, but the under surface may also be affected through the extension of the plaques to this latter locality; as a rule, however, the lower surface is not involved.

Owing to the circular shape of the lesions and the mode of extension, the disease has been supposed to be identical with tinea circinata; but thus far, every effort to find the fungus peculiar to this latter affection in the lingual epithelium has failed. Nor has any other fungus been found which may not be found upon the normal tongue. Indeed, apart from the failure to find any microörganism peculiar to this affection, the course of the malady makes the idea of its parasitic origin extremely improbable. The complete spontaneous disappearance for days, weeks, and even months; its strict limitation to the lingual mucous membrane; and the absence of all evidence of contagion, are sufficient to prove its non-identity with tinea.

Although there is a decided resemblance between this affection and some of the syphilitic lesions of the lingual mucous membrane, most observers unite in the opinion that it is entirely independent of syphilis. Parrot, however, whose observations were made in the Hospital for Foundlings, is an exception, and unhesitatingly affirms his belief in its syphilitic nature, declaring that for him it is only a manifestation of syphilis; and he names the disease accordingly desquamative syphilis of the tongue.

I do not think the malady in any way dependent upon syphilitic infection. My patient, I feel quite sure, was free from any specific taint. There was no evidence of such in his own person, nor did any members of his family—he was the father of two children—show any signs of syphilis. Moreover, specific treatment was without effect.

In view of the frequency with which digestive disturbances preceded or accompanied the eruption upon the tongue, a causal relationship between the gastric disorder and the lingual affection seems quite probable. My patient was able to predict the appearance of the plaques upon his tongue by means of the slight stomachic derangement, noted above, which he usually experienced some days previous to their appearance. All three of the cases reported by Molénes suffered from dyspepsia; and in one of them a dyspeptic attack was always accompanied by the appearance of these patches upon his tongue.

Although the malady is usually described as a disease of childhood, I think an examination of the ages of the cases reported makes it evident that it occurs with almost equal frequency among adults.

Of the fourteen cases reported by Unna, but two were children; and Molénes three cases were adults.

That the disease is not a common one, may be learned from the statement of Collcot Fox, that he had met with but ten cases in three years. Although I have examined the tongues of many persons in the past two years, with a view to the discovery of other cases, I have not met with any other example of the malady than the one reported in this paper.

The disease is, as a rule, but little influenced by treatment, local or constitutional. Unna claims to

have derived benefit from the application of sulphur to the diseased mucous membrane. In my own case local treatment was entirely without effect; but the internal administration of arsenic seemed to lengthen the intervals between the attacks. Before the use of this remedy the paroxysms appeared with great regularity every ten days or two weeks; but soon after beginning with pil. arsenicos. $\frac{1}{10}$ gr. the interval between the attacks was prolonged to three or four weeks, and the individual lesions ran a shorter course.

THE COMPOSITION OF GLEDITSCHINE OR STENOCARPINE.

BY JOHN MARSHALL, M.D.,

DEMONSTRATOR OF CHEMISTRY IN THE MEDICAL DEPARTMENT OF THE UNIVERSITY OF PENNSYLVANIA.

THE introduction within the last few months of a substance having the names above given and claiming to rival cocaine as a local anæsthetic has brought forth quite a number of papers descriptive of its powers from members of the profession who have used it clinically, notably the articles of Dr. Knapp, of New York, and several other observers of almost equal eminence. All these writers, and those of the profession in this city, reported that it possessed the power of anæsthetizing mucous membranes in much the same manner as cocaine, and that the mydriasis produced by it was not only more marked but more prolonged than with the former drug.

Believing that a drug promising so much should be studied as to its influence on the general system, Dr. de Schweinitz and Dr. Hare began the necessary physiological tests. No sooner did they inject some of the so-called stenocarpine solution into the jugular vein, than the typical manometer tracing produced ordinarily by atropine developed itself, and it was, therefore, requested that at least a few tests should be applied to determine its chemical constituents. The following results, obtained in the chemical laboratory, will, I trust, prove to the profession that they have once more been duped by a specious fraud.

Solution of stenocarpine, labelled two per cent., is a straw-colored liquid, having an odor resembling the leaves of erythroxylon coca. Upon the addition of an aqueous solution of bromohydric acid, containing free bromine, a dense, yellowish precipitate was formed, which was almost a solid mass. Upon diluting the so-called stenocarpine by another addition of the bromohydric acid reagent, the yellowish precipitate was produced, of course, in less amount, and, upon standing, small, microscopic crystals, characteristic of atropine, were observed, mixed up with the amorphous precipitate.

According to Niemann,[1] the discoverer of cocaine, the alkaloid when in combination as an auric salt, and when heated in a tube decomposes, with the evolution of a dense sublimate of benzoic acid. The auric salt produced by the addition of auric chloride to the so-called stenocarpine solution, when dried and heated in a glass tube, gave off copious vapors of benzoic acid, which latter was deposited in partly crystalline form on the cooler portions of the tube. This sublimate, when dissolved in water to which a couple of drops of ammonium hydrate had been added, and evaporated at a low temperature until all free ammonia had been driven off, gave a decided flesh colored precipitate of ferric benzoate upon the addition of ferric chloride.

Wöhler and Lossen[2] found upon heating cocaine several hours in a sealed glass tube with concentrated hydrochloric acid, that the cocaine split up into benzoic acid and ecgonine. On treating the stenocarpine in a sealed tube with strong hydrochloric acid, and extracting with ether and evaporating the latter to dryness, a residue was obtained, which, when dissolved in water containing a few drops of ammonium hydrate, and the excess of free ammonia driven off, gave, on adding ferric chloride, the characteristic precipitate of ferric benzoate.

From these tests we may conclude that the solution contained cocaine.

In order to decide whether an alkaloid was present belonging to the atropine group, the following tests were performed: A drop of the solution was evaporated to dryness at a gentle heat, and Vitali's test applied to the dry residue, but there was no response. The solution was now rendered slightly alkaline by the addition of sodium hydrate and the alkaloids thereby precipitated. The solution was now shaken with ether, which extracted the alkaloids in their free state; the ethereal solution was allowed to evaporate spontaneously and Vitali's test applied to small portions of the dry residue with marked success, the blue color produced by the one or more alkaloids of the mydriatic group with this test was quite distinct.

To determine the presence of chloride and sulphate, as cocaine and atropia are generally employed in this form, a portion of the solution was evaporated to dryness with a few drops of sodium hydrate solution and some crystals of potassium nitrate, and incinerated over a naked flame. The residue was now dissolved in water, acidulated with HNO_3 and boiled, to drive off the nitrous acid. A portion was now tested for chlorine with $AgNO_3$ and a curdy precipitate of silver chloride was formed. To still another portion barium chloride was added, and a cloudiness was produced, showing the presence of a sulphate.

Notwithstanding the fact that the solution was marked 2 per cent., it was found to contain 7.34 parts of solid residue. We may, therefore, safely conclude that this so-called new anæsthetic is but a joining of old remedies in a new dress, namely, a mixture of cocaine and atropine, or another of the mydriatic group, and that it is nothing more than a scheme for the obtaining of money without proper return. As it has been sold to physicians for the high price of $1.25 per drachm of a 2 per cent. solution (?), it seems but right that its falsity be exposed.

MEDICAL PROGRESS.

The "Alternative," Non quarantine System of England.—England, one of the foremost nations in hygiene, has rejected the quarantine system; and the "alternative" method now in use is thus described by Dr. Thorne, in the *Practitioner* for October, 1887:

Having deliberately abandoned the system of quarantine, we began, many years ago, to organize the system of medical inspection with isolation. The medical inspection comes first into operation on our coasts. The Customs officers board the vessels coming into our ports, and they at once communicate to the sanitary authority the occurrence of any case of cholera, choleraic diarrhœa, or suspected cholera. A vessel so affected is detained until the medical officer of health has examined every member of the crew and passengers. Those actually sick of cholera or choleraic diarrhœa are at once removed to the port sanitary hospital, and any person certified to be suffering from any illness which that officer suspects may prove to be the cholera is detained for a true period of observation not exceeding two days. The medical inspection is thus followed by isolation of the sick. Unlike a quarantine system, this process does not interfere with the healthy, or expose them to risk by herding them together with the sick, but the names of the healthy, and the places of their destination are taken down, and the medical officers of health of the districts in question are informed of the impending arrivals. This part of our system has been named our first line of defence, but it would be of little value if we stopped there. Our main trust is in the promotion of such local sanitary administration in every part of the country as shall rid us of the conditions under which alone cholera can spread. In periods of emergency, as during the past three years, a special medical survey of such districts as are most exposed to risk is organized under the supervision of the medical officer of the Local Government Board, and where needed the sanitary authorities are urged to action. Important as have been the results of the recent survey, they would go for little were it not for the steadily maintained work of sanitary authorities and their officers throughout the kingdom; and we who have been taunted abroad for opposing quarantine because its restrictions touched our commercial interests and our pockets, may justly feel proud that in England and Wales alone the people have, during the past ten years, of their own accord, and apart from Government dictation, spent by way of loan or in current expenditure, over eighty millions sterling, for purposes mainly of a sanitary character. And we may fairly ask whether any corresponding expenditure has in other countries given evidence of real faith in a quarantine system.

The truth is that this kingdom still takes the lead as a progressive Power in the matter of public health. The cost incurred has been immense, but it has not been in vain or unremunerative. Our cholera death-rate, which was 30 per 10,000 in 1849, fell to 11 in 1854, and again to 7 in 1866. Since then we have labored hard to prevent the disease from securing a footing amongst us; and though our labors are far from complete, and the disease has on several occasions been imported, yet it has each time been at once checked. "Our "fever" death-rate, falling with the advance of sanitation, is now less than one-third of what it was before 1866; and our general death-rate has during the same period been reduced from about 22 to 19 per 1000.

On Cholera.—At the Vienna Congress of Hygiene Professor Pettenkofer expressed himself as follows: He was decidedly of opinion that the bacteria alone are by no means sufficient for the spread of the infection, just in the same way as the leaven alone is not sufficient for the making of beer. He was far from believing that all symptoms of infection could be explained by the presence of the bacteria alone; for him, only the x had been found, but not yet the y and the z of the equation. In the first place, the first question that had to be answered was as to the behavior of cholera in its epidemic home, India; whether it derives its origin from patients affected with cholera or from localities which are infected with the disease. It must be taken into consideration that, though the Pendschal is traversed by railways, and though there is a good deal of traffic in that region, some districts in it have remained free from cholera. This proved that the condition of the locality has a predominant influence in the spread of this epidemic. The influence of the season is also very striking. In India the period of maximum intensity of cholera in Lahore is said to be the month of August, and the minimum in the month of April; whereas in Calcutta the opposite is the rule. It would, therefore, be extraordinary if the cholera outside India is absolutely independent of local and seasonal conditions. The statistics of mortality in cholera cases in Germany for twelve years (1848–1859) are as follows: Prussia, 20; Posen, 0.5; District of Leipzig, 16; District of Dresden, 3; Upper Bavaria, 26; Upper Palatinate, 0.3 out of 10,000; and yet the comma-bacillus had come into all these districts. It is also characteristic that with us the cholera disappears completely for a longer or shorter interval of time, and must again be imported from India, which is not the case with other diseases, such as smallpox, syphilis, and other affections, which were equally imported from the East. It is evident from this that the human organism *by itself* does not present a favorable soil for the development of this infecting microörganism. The influence of the season was also shown in a striking way during the abovementioned invasion of cholera in Germany. Out of 167,000 persons who succumbed to the cholera in Prussia from September till April, 1866, 50 000 died in the month of April, and 30,000 in the month of September. In Genoa, where the disease had up to the present prevailed nine times, the cholera period always lasted from July till November, when no case of cholera was observed during the rest of the year. He (the speaker) did not wish to oppose the bacteriological theory, but was also anxious to insist that this narrow speculative horizon should be abandoned, and the conditions of locations and seasons should be attentively studied, as the immunity of certain places cannot be at all explained without these conditions being taken into account. These considerations also include the condition of drinking water. In conclusion, he alluded to England, which, since the opening of the Suez Canal, in spite of the numerous importations from India, was

nevertheless free from cholera, owing to the preventive system which had been carried on in that country.—*British Medical Journal*, Oct. 8, 1887.

COUMARIN, WITH IODOFORM.—LANGLEBERT, of Paris, has employed coumarin, a derivative of tonka bean, to disguise iodoform, in the following formulæ:

Iodoform. pulv.	gr. ¾.
Coumarin.	gr. ½.

For 1 pill.

For a solution.

Iodoform.	gr. 15.
Coumarin.	gr. 5.
Alcohol	q. s.

For local use.

In powder.

Iodoform.	gr. 15.
Coumarin.	gr. 3.
Lycopodii	gr. 3.

In liquid vaseline, the following solution may be made:

Iodoform.	gr. 15.
Coumarin.	gr. 3.
Vaselin. liquid.	℥ 5.

—*Gazette de Gynécologie*, September 15, 1887.

THE ADMINISTRATION OF CHLOROFORM.—ROBERTSON advises the following precautions in the *Glasgow Medical Journal* for October, 1887:

1. I never give chloroform at an earlier period than four hours after easily digestible food has been taken.

2. Always examine the patient's heart immediately before giving it.

3. Ascertain by personal examination that every article of clothing about the chest or waist is quite loose.

4. Bare the neck and chest so that both pulsation and respiration may be easily seen.

5. Never give chloroform in other than the recumbent position.

6. Always have at hand a pair of tongue forceps, and a hypodermatic syringe containing 10 or 15 ℳ ether; or, failing the latter, some amyl nitrite.

7. Always have a third person present.

8. Before holding the towel or inhaler over the mouth and nostrils, it is well to ask the patient to close the eyes, and to count slowly and audibly during the inhalation of the drug. It is also well to know the person's Christian name beforehand.

9. Never bring an inhaler or towel saturated with the anæsthetic suddenly down over the patient's face.

10. Always allow a sufficiency of air to gain access to the mouth and nostrils.

11. Watch most carefully the respiratory movements, and note the cardiac action by an occasional peep at the lips. Should the former become impeded or irregular, or if, when anæsthesia is well advanced, the patient should have greatly protracted expirations accompanied by groaning, stop the chloroform, raise the chin, and by forcibly opening the mouth, bring forward the tongue. This, in my experience, has never failed to promote regular respiration, after which anæsthesia may be carried on.

Should the heart's action fail, as is always manifested by a sudden blanching of the lips, stop the chloroform; lower the head; inject hypodermatically the ether at hand, and begin artificial respiration. A few drops of amyl nitrite applied to the nostrils will be found useful.

In the event of these means failing, I would endeavor to restore animation by *rhythmical compression of the heart*, combined with artificial respiration. The rhythmical compression has been frequently successful in restoring animals poisoned with chloroform; and, although I know of no case where it has been tried on man, I certainly would adopt it should the necessity ever arise. The compression of the heart causes a slight movement of the blood, and also acts as a rhythmical cardiac stimulus.

Bohm asserts that he has restored animation by this means in the case of cats after the heart's action had been arrested by chloroform for as long as forty minutes.

12. The chloroformist should on no account allow his attention to wander from his duties; nor should he ever allow himself to be drawn into conversation by any looker-on. The safety of the patient demands his whole and sustained attention.

13. Watch carefully from time to time the condition of the pupil: if the anæsthesia be profound, and the pupil have been contracted to almost a pin point, and then begins to dilate—the chloroform still being given, and the breathing diaphragmatic—at once stop the drug, and do not continue it until respiration is again quite normal, and the pupil again begins to contract. During the early stage of anæsthesia the centre for dilatation of the pupil (viz., cervical-sympathetic and trigeminus) is stimulated, so that the pupil dilates. With complete narcosis this centre is partially paralyzed, so that the pupil no longer dilates. With more profound anæsthesia, this centre becomes completely paralyzed, and the oculo-motor or third nerve comes into play, by which the pupil may be contracted to the size of a pin's head provided that the paralysis of the centre for dilatation be maintained by the drug being pushed. After a time the oculo-motor, or centre for contraction, becomes in turn paralyzed, and rapid and complete dilatation takes place. It is at this stage that death rapidly ensues, unless means be taken to prevent it. Syncope occurs—caused by reflex stimulation of the cardio-inhibitory centre of the vagus, through the connection between the vagus and sympathetic in the cardiac ganglia.

A SIMPLE INTESTINAL TONIC.—DE SINÉTY is credited with the following combination, by *L'Union Médicale* of October 13, 1887:

R.—Rhei pulv.	5 parts.
Natrii bicarbon.	
Quinquinæ pulv. . . .	ää 10 "

Used to advantage in dyspepsias, especially those complicating uterine disease.

PREPARATIONS OF MEAT FOR INVALIDS.—DUJARDIN-BEAUMETZ has used meat prepared after the following formulæ to advantage in prescribing meat diet:

Filet of beef	60 parts.
Marine salt	1 part.
Jelly (any fruit the patient may desire)	500 parts.

Also

Uncooked meat	50 parts.
Sweet almonds	15 "
Bitter almonds	1 part.
White sugar	16 parts.

To be pounded together in a mortar or on marble, and then an emulsion to be made with water.

Also

Uncooked meat, grated	100 parts.
Pulverized sugar	40 "
Wine (sherry, port, etc.)	20 "
Tincture of cinnamon	3 "

The only counter-indication to the use of these preparations is the danger of the eggs of tænia.

Meat may be dried at 100° C. (212° F.) and powdered. Microscopic examination of such meat should be made, however, and if bacteria are present in great numbers, the specimen should be discarded.

The powder may be incorporated with the food in various ways, in soups, chocolates, mixtures with beans and peas.—*Les Nouveaux Remèdes*, October 8, 1887.

The Results of Laceration of the Cervix Uteri.—Noeggerath, of Wiesbaden, has studied 100 cases of laceration of the cervix uteri occurring in his practice, and finds the following conclusions warranted from these cases.

Women having uterine diseases conceive more easily if the cervix be lacerated than if it be intact; they abort less easily in the first condition than in the second.

The position of the uterus is not influenced by laceration of the cervix.

The axis of the uterus is not lengthened by cervical laceration.

Erosions and ulcerations are equally frequent in lacerated and intact cervices, and disease of the connective tissue of the cervix is no more frequent in lacerated than in uninjured cervices.

Lacerations of the cervix have no influence on the development of uterine diseases, either in frequency or intensity.

Eversion of the lips of the cervix is never the direct result of lacerated cervix.

Noeggerath believes that a laceration of the cervix is only of importance when recent, when it opens a door for the entrance of infectious organisms into the blood.

The influence of scar tissue on the nerves of the uterus the writer considers great; but the restoration of uterine form he considers without influence on the condition of the organ.—*Berliner klinische Wochenschrift*, October 8, 1887.

Oil of Wintergreen in Therapeutics.—In collecting evidence regarding the value of this substance, Dr. Squibb found that every physician who had used it frequently, had found cases in which it was either powerless, or was not well borne by the stomach, and some of these cases were afterward benefited by sodium salicylate or salicylic acid. But all the testimony elicited was favorable to the use of the oil, and this especially in the large class of cases wherein the attacks were not severe. In all such it seemed to have important advantages over the sodium salicylate. In severe cases wherein the pain was very severe and the elevation of temperature great, the conditions were controlled more promptly and more effectually by the sodium salt.

There was no dissent from the general conclusion reached that the oil, whether natural or artificial, or whether from wintergreen or birch, was an important agent for obtaining the best results of salicylates in a very large class of cases.—*Ephemeris*, October, 1887.

For Pityriasis Versicolor.—Ihle employs resorcin in the following combination:

Resorcin	gr. 75 to ʒ 2½.
Ol. ricini	ʒ 11¼.
Alcohol	ʒ 37½.
Balsam. Peruv.	♏ 8.

—*L'Union Médicale*, October 1, 1887.

Diagnosis of Defective Sight in Infants.—Nettleship, in a clinical lecture printed in the *London Ophthalmic Hospital Reports*, Vol. xi., Part iv., speaks as follows on this point: "It will be self-evident that no exact tests of vision can be applied, and that an infant's sight may easily seem worse than it is. The chief things to notice are whether the child turns its eyes toward the window, or follows the flash of the mirror in the dark room (or, what comes to the same thing, turns its head away or blinks its lids under the same tests), the presence or absence of nystagmus and the state of the pupils. No doubt all babies do not learn to notice—*i. e.*, follow and look at objects, at the same age—I believe that they usually look at a bright light thrown steadily into the eyes a day or so after birth, but that from three to six weeks' education is necessary to enable them to follow a moving object in such a way as to give the appearance of intelligence or "noticing"—and it is failure to "notice" that raises the mother's apprehension, especially if she has had other children whose behavior was different. If the infant's eyes oscillate rhythmically, or even wander constantly though irregularly, its sight is almost certainly bad, for we know very little of primary nystagmus from nervous disease in infants. The pupils are less useful in babies than in adults, because the movements of the infant's eyes at once embarrass observation, and lead to associated movements of the pupils independently of alterations in light, and because the natural range of pupillary action in infants seems to be less than it is when the eye has attained full development. Though I need hardly add that in infants as in adults serious loss of acuteness of vision is compatible with fairly active pupils, I think it is less generally known that, in children at any rate, the light reflex may be present even though the child be absolutely unconscious of light, a condition of which I shall be able to give several instances further on. In examining the pupils of a baby, avoid touching the face or head, and so provoking movements of his head or eyelids."

The Treatment of Whooping-cough by Boric Acid.—Dr. Halloway, of London, has obtained excellent results with the following treatment of whooping-cough:

I confine the patient to one room for a week or ten days, and I instruct that each nostril be insufflated

every three hours during the day, and once during the night, with from two to three grains of finely powdered boric acid. I make no difference in the diet, unless there is some special circumstance which calls for it. At the end of ten days I allow the child to go out in favorable weather. My chief trouble at first was with the nurse-tender. An ordinary insufflator of small size acted fairly well for a day or two, and then became inefficient from the powder fouling the valve, and finding its way into the ball, at the same time it was much too costly to come into general use among the poorer patients.

In this case I invented the tube of glass, and is made so that in case of breakage a child might fix in another. The two bends are to do away with the necessity for a valve. The powder is put in the hole in the horizontal position, and lying in this position cannot easily be shaken down into the ball. The end of the sliding arrangement is to cover the aperture, the forefinger of the left hand is simply placed over it, the ball being pressed at the same time with the right. The aperture of the nozzle is not made very small, so that the powder is scattered over the whole surface of the nasal mucous membrane.—*British Medical Journal*, October 15, 1887.

For instance:

R.—Acid. carbolic. pur. . . gr. xx.
Menth. hydrochlorat. . . . gr. iss.
Acid. boric. . . . . 3 i.
Vaselini . . . . . 3 iss.

—*Revue de chirurgie et d'orthopédie*, October 10, 1887.

The Value of Roasted Coffee as an Antiseptic.—Heine has experimented with infusions of roasted coffee upon bacterial cultures, and reports the following: He found that under conditions favorable for the development of the spheroidal cells of cholera the growth of bacteria was hindered, in some instances checked, in some cases they were destroyed. Ten per cent. solution of strong infusion, five per cent. coffee gelatine, and five-tenths per cent. solution were fatal, the latter was inert. In an emergency freshly roasted and ground coffee, in powder and infusion, may be used to advantage upon superficial wounds.—*Wiener medicinische Wochenschrift*, No. 17, 1887.

The Report of the Committee Appointed by the Edinburgh Medico-chirurgical Society to Investigate the Bacillus of Scarlatina.—This Committee conclude their investigations as follows: 1. That they find that an organism resembling that described by Mr. Eddington as bacillus scarlatinæ is, in a certain proportion of cases, present in the blood taken with due precautions from scarlatinal patients. 2. that they believe that the streptococcus scarlatinæ of Klein is identical with the organisms found by Eddington; 3. that they have as yet failed to corroborate the conclusions arrived at by Mr. Eddington as to the pathogenetic value of the bacillus scarlatinæ. The Committee ask to be allowed to continue the function of the Society to continue the investigation, particularly as to (a) the morphology of the several organisms, (b) the susceptibility of various animals to infection with scarlatinal blood and with the various organisms, their investigations so far having led them to doubt whether calves are susceptible to the action of human scarlatinal poison.

Dr. Roswell Park, of Buffalo, is pursuing investigations with cultures of this bacillus; his cultures have been examined by Dr. Eddington, who could detect no points of difference between the microörganism isolated by Dr. Park from the blood of a scarlatinal patient and that which he had found.—*British Medical Journal*, October 15, 1887.

The Nutritive Value of Kreatin, Kreatinin, and their Allies.—Dr. Mays, in an article in the *Practitioner* for October, 1887, concludes as follows from his experiments with meat extracts containing these substances:

From these results it is evident that there is quite a marked difference between the action of kreatin and kreatinin and the other agents which were examined; that the action of the two former is similar to that of blood, milk, etc., in sustaining the heart's action, and hence can no longer be regarded as devoid of nutritive properties. It may be true that they are the products of a destructive metamorphosis which begins with the albuminous foods and tissues and ends in the urea, but then these experiments show, too, that their influence as nutritive agents compares favorably with that of a two per cent. blood solution, as will be observed on the tracings. Indeed, I repeatedly found that after working for many hours with a frog's heart, and after it became so thoroughly exhausted as to refuse to respond any longer to the stimulant action of blood, the transfusion of kreatin or of kreatinin, in the proportion of one part to one or two thousand parts of saline solution, would at once spur it on to renewed contractions which were continued for some time longer; thus showing that their power for calling forth cardiac pulsations exceeded that of the blood to a great degree.

In view of the fact that asparagin, theine, and caffeine bear a very close chemical relation to kreatin and kreatinin, to which they are also supposed to be similar in action, it was deemed important to test their influence on the frog's heart; but in no instance were they shown to be capable of reviving the heart's contractions, and hence they must differ in their physiological properties from the two latter agents. In conclusion I will call attention to the striking analogy between the tracings obtained from kreatin and kreatinin, and to those which were obtained from the beef extracts shown in my previous article, which suggests the probability that the stimulating and nutritive virtues which these preparations contain chiefly reside in these two extractives.

Chronic Lichen Simplex.—May be treated to advantage by

Glycerole of starch . . .	30 parts.
Pulverized tartaric acid . .	1 part.

In chronic lichen about the genitalia a mixture of

Glycerole of starch . . .	30 parts.
Oil of cade	5 "

is useful; the proportion of the latter ingredient may be raised to equal parts by gradual increase, with advantage.—*L'Union Médicale*, October 6, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,
PER ANNUM, IN ADVANCE, ... $5 00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, OCTOBER 29, 1887.

CHOREA AND HEART DISEASE.

IT has long been recognized by clinicians that serious valvular disease might have its origin in an attack of chorea, but the general impression has been that the cardiac mischief was rather the result of the rheumatism which so often accompanies the choreic outbreak. The subject has been investigated anew by OSLER, who has given the results of his observations in *The American Journal of the Medical Sciences* for October, 1887. The questions considered are the condition during the attack and the state of the heart some years subsequent.

A very common symptom of chorea is a systolic murmur, usually in the mitral region, the cause of which has given rise to considerable controversy. Osler regards it as evidence of endocarditis, relying on the extraordinary frequency, almost constancy, indeed, with which this lesion is found post-mortem; on the character and location of the murmurs, which are those which experience has shown are usually associated with inflammation of the mitral segments; and lastly, on the record which he is able to give of the subsequent heart history of 110 patients. This forms the most valuable part of the paper, as it represents, for the first time, the results of the examination of a large number of choreics at periods long after the attack. No cases were examined in which the chorea had come on after March, 1885. Of the 110 cases, in 43 the heart was normal, in 54 there were signs of organic disease, and in 13 there was functional disturbance. The very large proportion of those with heart disease may be in part due to the fact that such individuals would be more likely to return when requested, having had intimations of heart trouble, but it is stated that in only 22 was there palpitation or pain. Even with this allowance the number is very large, and shows that chorea plays a more important rôle in the causation of valvular disease than we had supposed.

The influence of rheumatism is indicated by the fact that 40.7 per cent. of the 54 cases had had articular trouble, but the large balance of 59.3 per cent. shows that this is not the sole factor in producing the endocarditis. No attempt is made to discuss the pathology of chorea in the light of the heart lesions. We infer that the author regards the endocarditis, in the majority of cases, as of choreic, not of rheumatic origin, and he urges greater care in the management of those patients in whom a mitral murmur develops during the course of the disease.

GASTROTOMY FOR FOREIGN BODIES IN THE ŒSOPHAGUS.

UP to a very recent period the view was held that when a foreign body was impacted in the œsophagus, and could be neither extracted by the mouth nor pushed into the stomach, it should be removed by cutting into the canal, provided it was not seated very low down or near the cardia. In the latter event the case was left to nature, with the hope that in the near future it might be vomited up, or find its way into the stomach and be passed by the rectum. Remarkable instances of these occurrences have been recorded as early as three months and as late as thirty-two months, the arrested substance, in the interval, giving rise to very little inconvenience. Such a fortunate issue should not, however, be anticipated, since, whether seated high up or low down, the foreign body is likely to set up inflammatory mischief which may result in death.

When the intruder is arrested near the entrance of the œsophagus into the stomach, particularly if it be angular or irregular in shape, though of only moderate volume, we may be permitted to express the belief that the axiom formulated by Arnott in regard to a foreign body seated high up, namely, that the rule of practice ought to be removal by incision, although no urgent symptoms may be present, when it has resisted a fair trial for its extraction or displacement, is correct. Whether the future will verify the wisdom of this statement remains to be seen; but that the foreign body should be extracted through a gastric incision when it gives rise to much suffering, along with progressive emaciation and loss of strength from difficulty in swallowing nourishment, or when it effectually prevents the passage of food into the stomach, is an assertion, the truth of which the reflecting surgeon can scarcely deny, especially as it has been successfully confirmed in two cases.

In the first of these cases, recorded by RICHARDSON in the *Boston Medical and Surgical Journal* of

December 16, 1886, a denture of four teeth, which had lodged near the cardiac end of the œsophagus, and had, in eleven months, greatly reduced the man's weight, maintained continuous pain in the epigastrium, and scarcely permitted him to swallow enough liquid food to keep him alive, was extracted by an incision through the abdominal wall and the stomach, which admitted the hand and half of the forearm. At the end of four months, the man was enjoying excellent health, and had gained fifty-four pounds. In the second case, reported by BULL in THE MEDICAL NEWS of last week, a peach-stone so completely blocked the canal at the distance of thirteen inches from the incisor teeth that alimentation by the stomach was rendered impossible. All efforts to dislodge the body having proved fruitless, it was extracted by gastrotomy, and the child made a rapid recovery.

The operation, as performed by Bull, the steps of which are fully described, will commend itself to the practical surgeon, particularly as gastrotomy for foreign bodies in the stomach is a procedure which has heretofore been attended with comparatively little risk.

TETANUS IN PREGNANCY.

THERE is no more characteristic phenomenon of the pregnant state than exalted nervous susceptibility: and analogy would lead us to expect that tetanus would be frequently met with among the many nervous disorders of this condition. Such, however, is not the case; an English writer has reported a considerable number of cases in India, under conditions peculiarly favorable, but Sir James Simpson had been able to collect but 28 cases, and MEINERT, of Dresden, has found but 9 cases in the literature of the subject, to which he adds, in the *Archiv für Gynækologie*, Band 30, Heft 3, a case recently treated by himself.

His patient was a robust washerwoman, aged forty. The predisposing cause appeared to be residence in damp, ill-lighted rooms. Her first and second pregnancies, however, were normal; in the second month of the third pregnancy tetanus, mild in degree, but typical in its symptoms, appeared, and resisted treatment, recovery following the birth of the child. The fourth and fifth pregnancies were normal, but in the fourth month of the sixth pregnancy tetanus was ushered in by a sensation of heaviness in the extremities, which often occurred suddenly during sleep, or when entering a warm room. Painful, tonic spasms of the fingers; painful sensations pervading the upper extremities; twitching in the eyelids; irregularity in respiration and speech; and violent movements of the arms, which often inflicted blows upon the patient's body, were the phenomena characterizing an attack. The paroxysms occurred daily, lasting several hours, and often returning several times in twenty-four hours. In the interval between the attacks her condition was normal.

The medication which Meinert employed was 30 grains of potassium bromide three times daily, and 2½ drachms of chloral hydrate in 6 ounces of water, a teaspoonful every ten minutes until the paroxysm remitted. Three days after the commencement of treatment a tænia was expelled, its variety was not ascertained. The paroxysms continued, but under the medication employed gradually diminished in severity.

After the birth of a healthy child at term, tetanic contractions of the hands and feeble spasms of the facial muscles persisted for several days. The child was attacked, eight days after birth, by convulsions which yielded to chloral, but in which it died, during a relapse.

Analysis of Meinert's collection of cases, eliminating those of doubtful character, shows that the disease occurs most often in women more than thirty years old. This corresponds with Gower's analysis of 142 cases of tetanus in women, from various causes, where the average age is between thirty and forty. In males the average age is between ten and twenty. The attacks occurred before the sixth month of pregnancy. All ended in recovery, although of Sir James Simpson's cases but five recovered. In four cases the cure was spontaneous, and followed parturition.

The cases collected show no complication or sequelæ, and the writer's case is peculiar in the occurrence of trophic disturbances of the nails of the feet and hands, and the formation of double cataract. The possible influence of an intestinal parasite in Meinert's case is freely recognized, but the sequelæ and the death of the child make a more profound affection of the nervous system than that usually produced by tænia probable.

Bleeding has been practised in these cases in treatment, but Meinert saw no reason to exceed the sedatives which he employed.

Eclampsia of renal origin at once suggests itself as the condition most nearly allied to the case described. The writer, however, has evidently differentiated his case to his own satisfaction from this affection, although he does not mention the clinical tests employed. As an example of one of the most serious disturbances of the nervous system to which the pregnant woman is liable, Meinert's case is highly interesting and instructive.

IS ERGOT A PROPER DRUG TO COMBINE WITH DIGITALIS?

IN the *Berliner klin. Wochenschrift*, No. 34, is an article by ROSENBACH on the combined use of these

two drugs, in which he recommends their administration particularly in aortic insufficiency, in idiopathic dilatation of the heart, with alterations in the elasticity and contractility of the bloodvessels, and in asthma.

Notwithstanding the fact that he reports favorable results from such practice, we doubt very much whether the ergot, at least in the first disease mentioned, did as much good as it did harm, since its physiological action, when considered with the physiology of the circulation, really contraindicates its use. The reader will recall that the ventricular systole in driving out the blood into the systemic circulation produces a sudden increase in the arterial distention over and above the blood current, and that having done this, it no longer acts directly in causing the onward flow of the blood, but is in a manner supplemented by the aortic valves. The blood is now between several opposing forces, for the vital contractility of the arterial wall presses on it and its onward flow is resisted by the muscular arterioles. If the aortic valve is perfect, however, and no regurgitation can take place, the blood, unable to go backward and compressed laterally, chooses the path of least resistance, viz., through the arterioles. It is, therefore, seen that the aortic valve influences very greatly the onward flow of the blood stream, and that in direct proportion to its lack of integrity and the resistance offered by the arterioles is the leakage back into the ventricle. It at once becomes evident that the administration of ergot in contracting these arterioles in a case of aortic insufficiency must induce an increased regurgitation.

Again, we have always held the opinion, and we think that most therapeutists will agree with us, that aortic insufficiency is of all the valvular lesions of the heart the very one which rather contraindicates the use of digitalis, in that it not only prolongs diastole, but likewise increases the ventricular capacity, thereby permitting a greater opportunity for regurgitation into the ventricle.

A meeting of the Executive Committee of the Congress of American Physicians and Surgeons, for the purpose of organization, was held on October 5th in the Hall of the College of Physicians of Philadelphia. The special societies were represented as follows:

American Surgical Association, Dr. Claudius H. Mastin, of Alabama.

American Otological Association, Dr. Cornelius R. Agnew, of New York.

American Ophthalmological Association, Dr. D. B. St. John Roosa, of New York.

American Laryngological Association, Dr. J. Solis Cohen, of Pennsylvania.

American Neurological Association, Dr. L. Carter Gray, of New York.

American Dermatological Association, Dr. I. E. Atkinson, of Maryland.

American Climatological Association, Dr. A. L. Loomis, of New York.

Association of Genito-Urinary Surgeons, Dr. John P. Bryson, of Missouri.

American Association of Physicians, Dr. William Pepper, of Pennsylvania.

The Committee was organized by the election of Dr. Pepper as Chairman, and Dr. Bryson as Secretary.

It was decided to hold the Congress of 1888 in Washington, D. C., on Tuesday, Wednesday, and Thursday, September 18th, 19th, and 20th, respectively. The sessions of the Congress will be held in the evenings, leaving the mornings and afternoons free for the sessions of the special societies participating.

The following officers of the Congress were elected:

President.—Jno. S. Billings, M.D., LL.D., U.S.A., of Washington, D. C.

Vice-Presidents.—The Presidents-elect of all the participating societies.

Treasurer.—Dr. W. H. Carmalt, of Connecticut.

The arrangement of the programme for the sessions of the Congress was referred to the President, the Secretary, and the Chairman of the Executive Committee.

The Michigan State Board of Health has received information from Dr. Sifton, Health Officer of Sutton's Bay township, which illustrates in a striking way the manner in which this country obtains contagious diseases from the old countries. October 2, 1887, a family arrived in Sutton's Bay, Keelanaw County, direct from Norway. The family came over in the steamship Ohio, of the Inman Line, reaching New York on September 30th. Scarlet fever was on board the steamer during the passage, one child dying before the landing, and "several more were sick in the same way." One child of this family was taken sick with scarlet fever the day after reaching New York. The family, however, proceeded over the New York Central, and the Lake Shore and Michigan Southern Railways, to Michigan; then over the Detroit, Grand Haven, and Milwaukee, and the Grand Rapids and Indiana Railways, to Traverse City, then to Sutton's Bay. Another child of the family has since come down with the disease. The family had a certificate, signed by the surgeon of the steamer, that they had been protected by vaccination against smallpox; so they passed the quarantine authorities at New York without detention, after they had been exposed to a contagious disease which

causes more deaths by far in this country than does smallpox.

The following new appointments have been made at the New York Post Graduate Medical School and Hospital:

Dr. Robert Abbe, professor of clinical surgery.

Dr. Henry D. Chapin, professor of diseases of children.

Dr. J. U. Girdner, instructor in clinical surgery.

Dr. A. M. Phelps, professor of orthopedic surgery.

The new buildings of the New York Skin and Cancer Hospital, at the Country Branch, Fordham Heights, will be formally opened to-day, at two o'clock. W. Q. Riddle, Esq., President of the Hospital, will give an address of welcome, and Dr. A. Jacobi, President of the Medical Board, will give an address on Cottage Hospitals. The Country Branch Hospital is situated at Fordham Heights, New York City, about one mile above High Bridge, between Sedgwick Avenue and the old McComb's Dam Road.

The New Jersey Sanitary Association holds its thirteenth annual meeting at Trenton, on October 28th and 29th, under the presidency of Dr. W. K. Newton, of Paterson. The object of the Association is to bring together all who feel an interest in the investigation of facts and principles relating to public and personal hygiene, and who desire to diffuse among the people such information as will secure deliverance from avoidable causes of disease. The titles of a number of interesting papers are on the programme.

The Sixth International Congress of Hygiene was held in Vienna, in the early part of this month, and appears to have been a most interesting and successful gathering. The next Congress will be held in London, in 1891, and the following Committee of Organization was appointed: Dr. Brouardel, for France; Dr. Dobroslavine, for Russia; Dr. J. S. Billings, for America; Prof. F. de Gruber, for Austria; Dr. Roth, for Germany; Dr. Mosso, for Italy; and Prof. Corfield and Mr. Shirley Murphy, for England.

REVIEWS.

Transactions of the American Gynecological Association. Volume II., for the year 1886. 8vo. pp. 512. New York: D. Appleton & Co., 1887.

This Society now numbers fifteen Honorary and fifty-eight Active Fellows, the number of the latter being limited to one hundred. The recent meeting in New York, from the advantages of the place selected, and the fact that many invited gynecologists of Europe were present, was one of unusual interest, and will no doubt aid to increase the Fellowship of the Society in both orders. Prof. Alexander J. C. Skene, of Brooklyn, had the honor to preside.

Space will not admit of more than a mere notice of the volume under review. Dr. H. P. C. Wilson read a paper in which, after an extensive experience, he advocated the old and now generally condemned operation of division of the cervix backward in some forms of anteflexion of the uterus, with dysmenorrhœa and sterility. After performing the operation in 400 selected cases, he was prepared, from the results attained, to recommend it.

Dr. Ellwood Wilson, of Philadelphia, reported six cases of recent lacerations of the cervix uteri, cured by applications of the nitrate of silver in strong solution.

Prof. Fordyce Barker drew attention to the many remarkable coincidences on record, which have led to the belief that the fœtus in utero may be influenced by maternal impressions received later than the usual period for the perfection of embryonic form.

Dr. George J. Engelmann, of St. Louis, presents a treatise on "Electricity in Gynecology," of 148 pages, or more than a quarter of the volume. Three observers —Drs. John Byrne, Engelmann, and William H. Baker —collectively occupy more than one-half of the volume with the curative results of galvanic appliances in some of the diseases peculiar to women.

Dr. James R. Chadwick, of Boston, enters at some length into the value of the bluish color of the vaginal entrance as a sign of pregnancy, and shows the peculiar appearance by a colored plate.

Seven papers are given that were presented by applicants for election to active fellowship. These are very creditable to their authors, and some bear evidence of being the product of a large experience in gynecological practice. While the volume is in some of its papers one of much interest, it is, as a whole, less instructive and inviting than some of its predecessors. We hope to see a revival of interest from the work of incoming Fellows, some of whom are in their days of youth and activity.

Public Health. The Lomb Prize Essays. Award made at the Thirteenth Annual Meeting of the American Public Health Association, Washington, D. C., Dec. 10, 1885. With Appendix. Second edition. 8vo. pp. 198. Concord, N. H. 1886.

I. Healthy Homes and Food for the Working Classes. By Victor C. Vaughan, M.D., Ph.D., Professor in the University of Michigan.

II. The Sanitary Conditions and Necessities of School-houses and School-life. By D. F. Lincoln, M.D., Boston, Mass.

III. Disinfection and Individual Prophylaxis against Infectious Diseases. By George M. Sternberg, M.D., Major and Surgeon, U. S. Army.

IV. Preventable Causes of Disease, Injury, and Death in American Manufactories and Workshops, and the best Means and Appliances for Preventing and Avoiding them. By George H. Ireland, Springfield, Mass.

Through the liberality of Mr. Henry Lomb, of Rochester, N. Y., the American Public Health Association

has been enabled to publish these admirable essays, which were selected as the best among many offered in competition for prizes. The present volume has been prepared in its handsome and durable style for public and private libraries, but a cheap edition in pamphlet form has also been issued for general circulation. The object of the publication is to diffuse useful information upon sanitary topics of universal interest as widely as possible, and as a basis for the success of this praiseworthy aim the papers have been written in a clear, attractive style by authors thoroughly familiar with their subjects and the wants of the public.

The selection and endorsement of these essays by the Association is a sufficient guarantee of their reliability and meritorious character, and careful examination does not fail to corroborate the good judgment displayed in making the awards. Though most of the essays are designed for the improvement of the environment of school children and the working classes, there is instruction for every one in the whole series of papers.

The book has a copious index, and is well printed on fine paper, and handsomely bound in a style uniform with the annual volumes of the Public Health Association. The essays are also prepared separately in pamphlet form, and are sold at cost, and most liberal inducements have been made for the widest distribution of the work. It is the desire of the Association that a copy may be placed in the hands of every family in the country, a wish which we sincerely hope may be most fully realized.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, October 12, 1887.

The President, J. Solis-Cohen, M.D., in the Chair.

Dr. Wharton Sinkler read a paper on

MIGRAINE IN CHILDHOOD.

Migraine, he said, is more common in children than is generally realized. Popularly, the attacks of "sick-headache" which many children have, are attributed to disorder of the stomach from some indiscretion in diet, and many physicians hold the same view.

The fact that migraine is a disease which is especially likely to begin about the period of puberty has long been recognized. Many children begin to suffer from characteristic attacks as early as seven or eight years of age, and continue to have them until adult life; or, indeed, the attacks may continue all through life. Still, it is most often the case that when migraine begins in early childhood, it becomes more severe at puberty, and ceases by the time full development is attained. The influence of heredity is seen to a marked degree in migraine. The children who suffer from migraine often belong to neurotic families, and it is common to find among the near relatives instances of other nervous disorders. Children who suffer from this disease at and before the time of puberty may, in later life, become the subjects of some of the grave neuroses, such as epilepsy or insanity. The great value of the early recognition and cure of the disease is, therefore, apparent.

In addition to the influence of heredity, there are many other causes which may induce migraine in children. Improper food, bad atmosphere, and, above all, an insufficient amount of sleep, with overtaxing of the brain, all tend to predispose to or directly bring on migraine. When a child first begins school he often complains of more or less headache. The close air of the school-room and too little exercise are enough to account for some of these headaches. In other children, mere mental effort brings on attacks of pain in the head. The same holds good of migraine observed in chorea, namely, that it is the studious, ambitious children, who stand at or near the head of their classes, who suffer from both of these affections. In many instances there are ocular defects, which cause eye-strain, and in those cases the attacks of migraine continue to become more and more frequent in proportion as the eyes are used, until the eye-defect is corrected by glasses. It is not in all cases, however, that the headaches which follow excessive use of the eyes are due to ocular defect. The following case, which Dr. G. de Schweinitz described to the writer, illustrates this fact:

Charles C., aged fifteen. A slender lad, who has grown rapidly; clear, fair skin; slightly anæmic. No noteworthy illnesses. Goes to school and studies hard. One year ago he began to have headaches, as follows: sudden hemiopia, followed by intense pain on left side of head, and marked numbness along the arm of the corresponding side, and terminating finally in nausea, and occasionally in sick stomach. Attacks varied in frequency and in severity. With the exception of the migraine, the anæmia, and an imperfect digestion, no unsoundness was discovered.

Examination of eyes: color of eyes blue: pupils normal and equal. Vision: R. E. $\frac{15}{XV}$; L. E. $\frac{15}{XV}$. Accommodation: R. E. 8.3 D.; L. E. 8.5 D. Muscular anomaly, slight insufficiency of interni; color perception normal; refraction error, hypermetropic astigmatism. *Ophthalmoscopic examination:* R. E., nerve of normal color; slight conus out and some retinal striation around disk; choroid disturbed; numerous lymph reflexes. L. E., similar disk; retina more striated, with veiling of lower edges of disk. Field of vision normal. The treatment was largely dietetic and hygienic. The medicines used were, after the correction of the dyspepsia, syrup of the hypophosphites, strychnia, and iron. The refractive error was not corrected. The headaches have practically ceased.

Migraine from eye-strain is not uncommon in children. Dr. de Schweinitz has kindly furnished me with the following case, which is also of interest on account of the superficial optic neuritis which exists:

W. C. W., aged seven. When two years old had "gastric fever," from some imprudence of diet. Has had whooping-cough and varicella. Since two years of age, has experienced great difficulty in digesting and assimilating food, often going for long periods without being able to take any solid food. One and a half years ago, or when he began to go to school, began to have dull frontal headaches. Occasionally has paroxysmal headaches, quite different in type, beginning with extreme pallor, violent head pain, confined to one-half of forehead, and followed by nausea, but no vomiting. There are no visual disturbances preceding these

attacks, but no aura of any kind. These headaches have been present since he was two years old. An unusually healthy looking boy; lives in the country. Examination of urine negative. The boy is unusually bright and quick at his lessons, but he has been pushed.

Examination of eyes: color of eyes blue; pupils normal and equal. Vision: R. E. $\frac{15}{XV}$, L. E. $\frac{15}{XV}$. Accommodation: R. E. 12 D., L. E. 12 D. Muscular anomaly: insufficiency of superior recti; color perception normal; refraction error, hypermetropia = 1 D. *Ophthalmoscopic examination*: R. E., disk an irregular ovoid, all edges hazy, those on nasal side hidden; surface of disk gray-white; lymph sheaths full; veins tortuous; L. E., optic ovoid; all edges, especially nasal, hazy; veins full and tortuous.

Diagnosis—Supernal neuritis and hypermetropia.

Migraine does not appear to affect one sex more than the other, but if any difference does exist the preponderance is on boys. Precocious sexual development in either sex often leads to this form of headache. It is very seldom that we meet with it in robust and hearty children, but is seen in those who do not get enough fresh air and who are thin and pale, or in children who think and read too much, and who do not romp and play, but prefer to sit with older people and drink in conversation far beyond their years.

The symptoms of migraine in young children are not far different from those in adults. The attacks are markedly paroxysmal, occurring from two to six weeks apart, and become more or less frequent, according as the conditions for their development are favorable or otherwise. There may be only one or two attacks a year. The attacks may be preceded by premonitory symptoms, such as chilliness, and a feeling of lassitude, and the child is dull, and indisposed to play. Sometimes there are subjective ocular symptoms in the form of specks floating before the eyes, muscæ volitantes, or balls of fire, and bright zig-zags. Occasionally the child complains of hemiopia. These symptoms last half an hour or more, and may be followed by subjective numbness of the tongue, lips, or of the entire half of the body. Putnam had a patient in whom in boyhood migraine was represented by repeated attacks of numbness and tingling of the right side of the face, and right half of the body, with aphasia, and hemianopsia, followed by little trifling headache, or none at all. Later in life there were severe attacks of pain. Usually as soon as the subjective auras disappear the pain begins. At first the pain is dull, and it may be confined to one side of the head; generally, in children, the pain is on both sides of the head, at least they complain of the pain as being general, and it may be either frontal or occipital; most frequently it is frontal. There is often nausea throughout the attack, or it may terminate in vomiting, or a free flow of urine, or sometimes there are two or three diarrhœic stools. After the crisis is reached the child may fall asleep, and after a nap waken well. The attack does not always terminate in a crisis; after a gradually increasing headache for several hours it gradually subsides. The face in the beginning of an attack may be pallid, and as the pain increases the face becomes deeply flushed, and the eyes suffused.

The treatment must be preventive and curative. If a child is of a neurotic family, insist on ten hours' sleep at night, and keep him from too prolonged application to his books. Encourage outdoor sports of all kinds, and, if possible, keep such a child in the country for many months in the year. The diet should be abundant and nutritious, milk, eggs, soups, and broths, with meat in moderation, and the various cereals, and plenty of vegetables and fruit. Such children can eat largely, and plenty of fatty articles of food are well borne and are of great advantage.

If a child has already begun to have attacks of migraine, nothing is of more value than attention to the general health. Such children are often pale and thin, and have but little appetite. If change of air can be secured, it is often enough to obtain relief from the attacks. If we cannot send the patient away, we must resort to tonics and good feeding. Cod-liver oil, if it can be borne by the stomach, is of the greatest possible use in such cases. If the child cannot take oil, we must introduce fat into the system in some other way. Cream and plenty of butter may be given.

Special anti-neuralgic drugs are seldom indicated in these cases, but sometimes the bromides may be given with great advantage, especially in those children who are of a very nervous temperament, and in whom any effort at brain-work causes headache. It should be given in small doses, and continuously for some weeks.

In many cases some ocular defect will be found which will require correction by glasses, and many cases of migraine in children have been cured by this means alone. In all cases of migraine we should look carefully into the condition of the teeth, and have any unsound ones filled or removed.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, October 20, 1887.

The President, A. Jacobi, M.D., in the Chair.

Dr. Clinton Wagner read a paper on

COLORADO SPRINGS AND DAVOS-PLATZ AS WINTER HEALTH RESORTS, COMPARED.

Having alluded to the change which had taken place in the minds of the profession in regard to the kind of climate most beneficial to patients suffering from phthisis, since a few years ago, when warmth and equability were considered the prime essentials, he said that Davos is half the year covered with snow, and that at Colorado Springs the difference between the temperature of the day and night is sometimes as much as 130° F. Yet both these places were once held in the highest esteem as health resorts for this class of cases. There is, in fact, no section of country in the world which combines warmth and equability with dryness. Dr. Denison, of Colorado, in one of his valuable papers, has said that variability is characteristic of dryness, and equability is found only with dampness. It was Dr. Herman Weber, he believed, who was the first to recommend high, dry altitudes for phthisis.

Dr. Wagner said that he could speak of both Colorado Springs and Davos from his own personal observations while residing at these resorts. Colorado Springs

is at an elevation of more than 6000 feet above the sea, and five miles to the north of it is Pike's Peak, over 14,000 feet in height. It has the dryness of an inland desert, the climate is exhilarating, the atmosphere more clear than that of Italy, and its scenery compares with that of Switzerland. From September to the latter part of April or first of May, there is no rain. There are no fogs or mists, and while rain occasionally falls, it rapidly disappears. The sun shines for 330 days in the year, and in the sun the temperature is warm, 90° to 130°. There are always at least 50 degrees between the temperature of the sun and shade.

If the atmosphere were not cold and dry, the heat of the sun would be intolerable. Sometimes at night the thermometer falls considerably below zero. One great advantage of Colorado Springs is that the invalid can be so constantly out of doors. The wind is the most disagreeable feature of the place, and this is worst in the months of November and March. On the whole, however, there is less wind than in the resorts of the Riviera. In pulmonary diseases the results are excellent, and cases with tuberculous cavities have been reported cured. Nervous and irritable patients, with a tendency to vascular excitation, should, however, never be sent to Colorado Springs, as the climate is too stimulating for individuals of this class.

From all that he could learn, this resort is not contra-indicated in laryngeal phthisis, provided the patients are improving in other respects. He had seen one case of this kind cured, and one other that was improved and on a fair way to recovery.

The hotels and boarding-houses are excellent, and good furnished houses, provided with all the modern conveniences, can be secured at reasonable rates. There are fine schools, churches, libraries, a theatre, and a club. The society is excellent, and there are plenty of horses which can be bought or hired cheap, so that riding and driving are conspicuous features of the life there. Moreover, the accessibility of the place is a great recommendation to Americans.

Davos is an Alpine Valley in Switzerland, 5300 feet above the level of the sea, and protected from the winds by neighboring high ranges. The climate in many respects resembles that of Colorado Springs, although the temperature in the shade averages lower—from zero to 25 below. The north wind is thoroughly exhilarating and bracing, but the south wind is enervating, damp, and disagreeable. When the snow melts the atmosphere is naturally full of humidity. The snow usually lasts from the latter part of October to the early part of April. The invalid's day is very short, lasting only from 10 A. M. to 3 P. M. So far as his observations went, very serious cases do not recover at Davos, and he thought it a resort better suited to patients with incipient phthisis and those who retain a certain amount of robustness. The air is entirely too cold to sit out of doors when there is no sun.

Dr. Wagner then proceeded to enumerate some of the points of difference between the two places and the advantages of the American over the Swiss resort. At Colorado Springs there is an average of twenty-eight good days in the month; at Davos, twenty. At Colorado Springs there are eight hours of sunshine in the day, at Davos four hours and a half. At Colorado Springs the invalid can indulge in riding, driving, tennis, picnics, etc., while at Davos the only out-door diversions are skating and tobogganing, and these are too violent exercises for many patients. At Colorado Springs the invalid can enjoy the comforts and advantages of home life, while at Davos he is compelled to stay in a hotel, and it is well known that hotels frequented by many phthisical patients always partake more or less of the nature of hospitals and are depressing in their influence. At Colorado Springs the patient can remain throughout the year; but at Davos he is obliged to leave in the early spring on account of the dampness from the melting snow. At Davos the hotels are excellent, and there is plenty of amusement. Formerly the drainage of the place had been very defective, but within the last few years a most efficient system of drainage, said to be the best in Europe, has been introduced. As much cannot be said for Colorado Springs, where there is no public system of drainage whatever, and cesspools and old-fashioned privies are still in use. He understood, however, that a complete system is now in contemplation, and, with the natural facilities of the place for good drainage, he had no doubt that it could be made very perfect.

On the whole, he would say that while Davos is, no doubt, the best high altitude health resort in Europe, the advantages of Colorado Springs are greatly superior in many respects. Moreover, there are at Manitou conditions very similar to those at Davos, although it is at an altitude more than a thousand feet greater, and the shortest days for the invalid are six hours in length. It is well sheltered from the winds, and possesses some excellent mineral springs. At present, however, it is comparatively deserted in the winter.

Dr. Alfred L. Loomis said that the climatic treatment of phthisis is constantly being regarded with more and more favor, and deservedly so. Eighteen years ago he read a paper before the American Medical Association, in which he took the ground that it was very wrong to send patients to warm climates, because a stimulating air was required in order to enable the patient to take out-door exercise. From his studies in connection with this subject since that time he had arrived at certain conclusions. In the first place, he did not believe that there is any locality which is *par excellence* the place for phthisical patients; but he recognized that two things are absolutely essential for a curative effect. The first is a pure atmosphere, an aseptic atmosphere, if we choose to call it so. Pure air can be taken into the lungs on the same principle that antiseptics are employed in external diseases and in surgical cases. He did not think it is possible to treat tuberculous cavities with antiseptic solutions, and doubted whether inhalations or other forms of applying antiseptic agents have any real effect in destroying bacilli. But if we can keep the lungs constantly bathed with an aseptic atmosphere, we are doing all that is in our power to arrest the disease. Under the beneficial influences of such an air the temperature is reduced and distressing nervous symptoms are relieved. This element, therefore, must be sought for in whatever locality is selected for the patient. Purity of atmosphere is naturally to be looked for in high altitudes, but the number of inhabitants, and various other circumstances, may contaminate it to a very

marked extent. He had no doubt that the air of Colorado Springs and Davos was originally aseptic, but since they had become crowded with hotels and consumptives he found that this is no longer the case, and he believed that the benefit of residing at these places will grow less and less until, finally, they will be altogether abandoned as health resorts.

The second essential for a curative effect is the presence of conditions which should be conducive to outdoor life. It is perfect folly, he thought, for a phthisical patient to go to any resort and spend twenty hours out of the twenty-four shut up in a hotel or boarding-house. It is much better to remain at home, and if the patient is not well enough to take outdoor exercise he is not well enough to be sent to these places. This is why those in the first stage of phthisis are so often relieved; and the reason that those with cavities live is because they go to the health resort in a condition rendering them able to live out of doors. It is, however, not necessary to go to Colorado to find a pure air, and, besides, he did not believe that high altitude of itself is of the slightest practical importance. The great essential is purity of atmosphere; but as it is desirable that the patient should spend the most of his hours in the sun, Colorado Springs is preferable to Davos. As regards recovery in those places, if the patient does not remain in them for two or three years after all trouble has disappeared, the disease is almost certain to reappear within a few months. This is the great objection to high altitudes for consumptives, and he thought it possible to secure a perfectly pure air at a lower altitude, and that, too, much nearer home.

DR. R. P. LINCOLN said that he agreed with Dr. Wagner in believing that Colorado Springs is superior to Davos, and chief among its advantages over the latter is the large amount of sunshine obtainable there. With the sun there is dryness; so that we should naturally look for the best results there. On the 1st of January there was sun for only four hours and fifty-seven minutes at Davos; while at Colorado Springs, at the same date, there was sun for over nine hours, or nearly twice as long. There was also much less moisture at Colorado Springs than at Davos. As to the advisability of sending a patient with laryngeal phthisis to high altitudes, there had of late been a considerable change in professional opinion, and Dr. Solly, of Colorado Springs, had told him that he had known three cases to recover at that resort.

DR. BEVERLY ROTINSON, being unable to be present, sent a letter in which he stated that he could not say as much of any health resort in this country or Europe as of Colorado Springs. A residence there, he thought, is of special benefit in the first stage of phthisis, and patients could there breathe the aseptic air which can only be secured at high altitudes, while the remarkable prevalence of sunshine enabled them to pursue the outdoor life which is so important a desideratum.

DR. KRETSCHMAR said that Dr. Wagner was mistaken in supposing that Dr. Herman Weber was the first to call attention to the efficacy of high altitudes in phthisis, as the first one to do this was Dr. Bremer, who did so in a work entitled *The Curability of Phthisis Pulmonalis*, which was published in 1852. He thought that Dr. Loomis was mistaken in supposing that the aseptic character of the atmosphere necessarily becomes diminished in such health resorts as those referred to, as statistics show that before the year 1853, when Dr. Bremer established his famous hospital at Gerberstoff, there was actually a greater proportion of deaths from phthisis in that place than there has been since, although more than 13,000 patients have been treated in it. It was also a fact that none of the Sisters, who acted as nurses, or other attendants in the institution had contracted the disease.

As regards Davos, Dr. Wagner was mistaken in his statement that there are no accommodations to be had except in hotels. There is no dust, which is an objection to Colorado Springs, and the snow unquestionably helps to preserve the aseptic condition of the atmosphere. In the spring, when the snow melts, the patients very properly leave. The most serious drawback that Davos has as a resort for consumptives is the admixture of pleasure-seekers and invalids, since the latter are tempted to indulge in habits that are injurious to them.

THE PRESIDENT said that while certain places have a considerable immunity from phthisis, this immunity is only relative. While it may exist among the agricultural population, this would not be the case among those engaged in indoor employments. One element claimed as an important one in the climatic treatment of phthisis had not been referred to this evening, and that was the necessity of ozone in the atmosphere. This is supposed to be due to the sunlight, and it is found among mountains and evergreen forests, as well as near the sea and on the sea. As to the immunity of the nurses and other attendants in Dr. Bremer's hospital, he understood that in this institution it was claimed that the air in the rooms was completely changed five times every hour.

DR. LOOMIS referred to the beneficial effect of antiseptic emanations, and said that many places which are not naturally aseptic are rendered so by those emanations, especially those from evergreen forests.

DR. WAGNER said that he saw no reason why a patient should not be taken to Colorado Springs, even if he was not able to take exercise. The journey could now be made with comfort in a comparatively few hours, and when he arrived there he could sit or ride out in the open air, which was not the case at Davos.

CORRESPONDENCE.

OCULISTS AND OPTICIANS.

To the Editor of THE MEDICAL NEWS,

SIR: I desire to bring to the notice of the profession an evil which, if not corrected, will do incalculable harm to many honest and striving gentlemen. I refer to the indiscriminate recommendations given by members of the highest standing to men-venders of various wares, not in the profession, and who, if they have received degrees, are practising their calling wholly without the pale of support by physicians.

A few days since there came to Charleston two scientific opticians from Chicago, whose business is to examine the eye, *correct errors of refraction, prescribe*, and sell glasses. As to the mere selling of glasses there is nothing to be said. All books on ophthalmology contain chapters most carefully written on errors of refrac-

tion, as produced by hypermetropia, myopia, and astigmatism, explaining the true nature of these deformities, and giving the minutest directions as to the correction and treatment. Further still, the authors of these works enumerate and dwell upon the ills that may be caused by the above conditions, but at no portion of their writings do they refer such cases to the *optician* who shall prescribe the proper glass. The optician is a most important and necessary person, but he fills a prescription for glasses as does a druggist for medicines.

These "scientific opticians" not only make and sell glasses, but examine the eye in order to prescribe the proper glass. They come recommended to do this work by many of the *best physicians* of the country and *members* of the *American Medical Association*. Upon their arrival in a new place they immediately call upon the most *eminent general practitioners*, produce the ponderous tome of recommendations containing the signatures of well-known physicians of other cities, of Governors, Senators, ministers of the gospel, and other important functionaries. At the same time they are very particular to impress upon the gentlemen that they are not oculists, do not treat *diseases* of the eye and, therefore, cannot interfere with the oculist in any way. The general practitioner is for the nonce somewhat staggered by the array of prominent names, all thoughts of the oculists' work is forgotten, and he cannot resist the urgent appeal for his autograph, nor can he remember afterward the exact object for which it has been extracted, while he has been dazed as it were by gas. His begets others, and finally the names seem to jump to the book without much persuasion. In like manner ministers of the gospel—they always call upon them too—append their names, though some of them have never worn a glass and would recognize no difference between them. (One minister signed because his physician's name appeared on the list. The physician's was withdrawn but the minister's is still there.) Do they call upon the oculist? No, they do not, though every general practitioner has advised their doing so, it would be more proper for the oculist to call upon them. They next proceed to put a very taking advertisement in the daily papers, to which are appended the names of the eminent physicians, divines, etc.

This game was partially repeated in Charleston, the names of physicians secured and all went as merrily as the marriage bell, but certain members of the County Medical Society thought the proceedings irregular and a special meeting was called, the matter investigated and by unanimous consent the names withdrawn, and thus the general practitioners of Charleston, who at first were doing an injustice to brother specialists, manfully acknowledged their error caused by a misapprehension.

No slur is cast upon these opticians or the quality of the glasses they supply, but my real object is to bring this matter before the profession for careful consideration. Specialists in various branches are recognized when they devote their time to the branch chosen, and it behooves the general practitioner to stand by his brother when in good repute. The glass is an orthopœdic instrument to the eye, but no one would think of sending a child with a club-foot to the instrument maker without first consulting the surgeon—yet the cases are parallel. No one can deny at this day that correcting errors of refraction and prescribing the necessary glass is a most important factor in the practice of the ophthalmologist.

Therefore, is it right and fair for gentlemen of prominence in the medical profession to give their names for *publication* for the benefit of non-professional men, when the practice of these men interferes with that of the specialist in good standing, who cannot even let it be known by a simple word on his door-plate that he practises in diseases of a special branch?

Charles W. Kollock.

Charleston, S. C., October 21, 1887.

NEWS ITEMS.

The Managers of the Pennsylvania Hospital have determined to create in the Department for the Insane positions for resident physicians; and they have authorized Dr. John B. Chapin, Physician-in-chief of the Hospitals for the Insane, to select and refer to the Board one physician for each department, to serve for so many months, as may be decided upon hereafter. This will give young physicians an opportunity to observe and study the various stages of mental diseases, which will be of great value to them in their professional life, in the early treatment of such patients coming under their care.

The New York Quarantine.—The *Sanitary News* of October 15, 1887, publishes its investigation of the New York Quarantine as follows:

Summing up, with reference to the exclusion of cholera and smallpox, the quarantine plant and facilities of the port of New York are unrivalled, the printed regulations judicious, and with proper vigilance the service should suffice to prevent either of these diseases from obtaining access to the country through this avenue. But the entire system is hampered by a vicious financial policy which is, in effect, a farming-out of the service. At the other important ports the fees go directly to the municipality or State, and the chief executive officers are paid fixed salaries, and are provided with such employés as may be necessary to the proper and efficient conduct of the quarantine.

New York may exclude cholera under the present system, but more confidance would be reposed in the result if less were demanded of professional ability, personal integrity, and executive firmness in the health officer, and if the system were freed from influences which are most deprecated by those who, without prejudice, best understand them.

Cholera found its way through this port to the eastern portion of the country in 1849, and to the country generally in 1865. No attention is paid to the vaccinal status of immigrants unless the disease is actually on vessels. As a natural consequence, smallpox has repeatedly been introduced into the interior through this port.

The Western Pennsylvania Medical College at Pittsburg, we are informed, has begun its second session, with a class of nearly 100 students.

The Congress of Hygiene adjourned October 2d to meet in London in 1891.

THE QUEEN has appointed William Scovell Savory, F.R.S., President of the Royal College of Surgeons of England, and Surgeon to St. Bartholomew's Hospital, to be Surgeon Extraordinary to Her Majesty, in the room of Richard Quain, deceased.

SIR WILLIAM GULL has suffered from a paralytic stroke, but of mild degree. The latest accounts of his condition are favorable. The paralysis is of the right side, and power has been regained in the upper extremity.

THE EMPEROR OF BRAZIL.—The *British Medical Journal* states that this active and intelligent monarch is a diabetic, in a somewhat advanced stage of the disease.

DR. KOCH, Director of the Hygienic Institute of the Berlin University, has received the Russian Order of St. Stanislaus of the 1st class.

A COMMITTEE TO INVESTIGATE HYPNOTISM.—Charcot, Brouardel, Marey, and others have been appointed a committee of the French Academy of Medicine to investigate results obtained by Luys under hypnotic conditions.

THE SURPLUS FUND FROM THE VIENNA CONGRESS OF HYGIENE is to be devoted to the establishment of an institution for perfecting hygienic manufacture in all its aspects.

LEGISLATION AGAINST COLOR BLINDNESS.—In a recent number *Science* had occasion to refer to the beneficent law now existing in several of the States, prohibiting the employment of color-blind persons on the railroads of those States, and instanced Massachusetts as the first one to enact such a law. At a meeting of the Brotherhood of Locomotive Engineers, just held in Boston, at which three thousand railroad-engineers were said to be present, one of the speakers who addressed the audience was received with great applause, because, as the chairman said in introducing him, "he secured the repeal of the obnoxious color-blind law,"—a questionable honor, if true; but, from the best information which we are able to obtain, the law still exists, although it has been modified in a manner which in no wise weakens, but, on the contrary, rather strengthens, its practical working. It is not to be wondered at that railroad employees object to a test of their qualifications which may result in the loss of their positions, but we imagine that any attempt to repeal the law would meet with the determined opposition of the entire travelling public. The single instance which occurred in Connecticut, where twenty-one railroad employees were found wholly color-blind, is sufficient proof of the necessity of such a law, and, instead of endeavoring to repeal existing laws, a strong and continuous effort should be made to extend their provisions to other States.—*Science*, September 30, 1887.

THE ITALIAN UNIVERSITIES.—During the last academic year 15,161 students were enrolled at Italian Universities, an increase of 722 over the preceding year. Naples was most frequented, 4083 students having attended there.

THE SUPPLY AND CONSUMPTION OF COCAINE.—DR. SQUIBB describes his manufacture and the consumption of cocaine as follows in the *Ephemeris* for October, 1887:

The one kind is a light green, thin, small leaf so very much broken up that hardly an unbroken leaf can be found. This contains a small proportion of stems and twigs, and quite a number of the yellow seed capsules. It has the appearance of having been beaten off of the trees, and certainly is not hand-picked.

The other kind is a very much larger, thicker leaf, much less broken, of a duller, darker green, or brownish green color, and less uniform in color. A considerable proportion of the leaves are unbroken, and stems and twigs are absent or rare. This variety looks as though it was hand-picked.

The first kind is called in the market Truxillo coca, and the lots now command as they arrive 23 to 25 cts. per pound. The second is called Huanuco coca, and about 30 to 32 cts. per pound is asked for it whether here or to arrive, an advance on both varieties of about 15 per cent. The localities which give the market names to these kinds are both in Peru, and considerably north of Lima,—the first near the coast, the other farther south and inland, but whether they come from these localities or not is uncertain, since names are sometimes used to conceal sources of supply. The present high price of Huanuco is based upon the customary report of a failure of a crop.

What has become of the fine quality of coca produced in Bolivia during the last six months is not known, none having reached either this market or Hamburg or London, so far as known to this writer. All received appears to have come from Peru.

The writer has used since his last report in these pages 238 bales of coca, 153 of the first variety and 85 of the second—total, 41,858 pounds. The highest price paid was 32 cts. and the lowest 15 cts., average 19 cts. —total cost, $7957.

This was all manufactured into hydrochlorate of cocaine and gave a total yield as sold and in stock of 922,917 grains or 131 pounds 13½ ounces.

This was made and sold within the ten months following the last report—that is from November, 1886, to August, 1887, both inclusive, an average of about 13¾ pounds per month, the demand pretty steadily increasing from about 6 pounds per month to about 18 pounds —both the lowest and the highest being, however, exceptional.

All was sold in three forms, namely, as hydrochlorate, as 4 per cent. solution of hydrochlorate, and a small quantity as uncombined alkaloid.

A large proportion of it was put up with much labor and expense in vials of 5 to 30 grains each, and the loss in putting up, so as to give full weight in each vial, exceeds 6 per cent. The loss in putting up eights, quarters, halves, and ounces was about 5 per cent., and for larger quantities was insignificant. The available yield as put up and sold is therefore below the real yield by the amount of these losses, and of all other incidental and accidental losses, but it is what the manufacturer must always base all his calculations upon.

The available yield from 41,858 pounds of coca being 922,917 grains, gives (922,917 ÷ 41,858 =) 22.05 grains of the salt to the pound of coca—all being calculated as hydrochlorate.

The Quain Bequest. — Mr. Richard Quain, F.R.C.S., F.R.S., has bequeathed almost the whole of his fortune, amounting to about £75,000, to University College, London, subject to certain annuities to family connections. The College will, we are informed, at once benefit to the extent of about £60,000, which sum is left to four trustees, to apply the annual income in "the promotion and encouragement in connection with University College, London, of general education in modern languages (especially the English language and composition in that language) and in natural science." The trustees, Lord Justice Fry, Sir William Jenner, Mr. George Brodrick (the Warden of Merton), and Sir George Young, are authorized to carry out the testator's wishes, "either by salaries or other payments to those who teach, or by endowing professorships, or by pecuniary aid to those who are being taught, as by endowing scholarships or fellowships, or in any other manner which the trustees may in their absolute discretion think proper," and they are requested to place themselves in communication with the Council of University College, with a view to preparing a scheme for carrying out the objects of the bequest. The testator desires that in any statement of the foregoing bequest the name of his brother, the late Sir John Richard Quain, shall be associated with his name.—*British Medical Journal*, October 8, 1887.

"Steeple Chase" Medical Journalism.—A writer in the *Gazette Hebdomadaire* of Paris of October 7, 1887, in speaking of the liberality of an American journal which offered to its exchanges full reports of the recent Washington Congress, remarks that in the large number of recent Medical Congresses at Washington, Vienna, Pavia, Toulouse, Carlsruhe, Wiesbaden, and Heidelberg, it has preferred to publish reports carefully analyzed and criticised by special correspondents and competent reviewers rather than to accept the hasty reports of impromptu reporters, vieing with each other in what the writer styles "steeple chase journalism." For this reason the *Gazette* did not publish the report to which reference was made, deeming those selected of more scientific value.

The Mutual Relations of Physician and Pharmacist.—The *Pharmaceutical Era*, of Detroit, offers a prize of $50 for the best essay on this subject, under the following conditions: 1. Any one interested in the subject may compete. 2. The essay must not exceed 2000 words in length, and must be received previous to January 1, 1888. 3. The MSS. must be free from the author's name, address, or other marks of identification. 4. The author's name and address must be inclosed with the manuscript on a separate paper. 5. All the essays submitted in competition for the prize are to be the property of the *Pharmaceutical Era*, to be published or not, at the discretion of the editor, but names of authors will be suppressed if requested. 6. A Committee consisting of five representative men chosen from the medical and pharmaceutical professions, to whom the essays shall be submitted anonymously, shall award the prize, and the names of the Committee will be announced with their decision.—*New York Medical Journal*, October 22, 1887.

Attempted Suicide of the Chief of the Vienna Hospital. — Dr. Länger, *primararzt* of the great Vienna Hospital, after a somewhat unpleasant interview with Prof. Boehm, the newly appointed director of the hospital, took a large dose of morphia with the intention apparently of committing suicide. He was, however, promptly treated by the performance of tracheotomy and the mechanical inflation of the lungs through the opening. By this means his life has been saved. Dr. Länger, who is greatly respected, has been for some time past subject to melancholia.—*Lancet*, October 15, 1887.

The Throat Hospital, Golden Square, London, has established a post-graduate course of instruction in diseases of the throat and nose, which promises to be well supported. Instruction in diagnosis and treatment is given by the physicians to the institution, Drs. Wolfenden, Bond, and Macdonald; and the practitioner is allowed the opportunity of handling the patients himself, under the guidance of members of the staff and their clinical assistants.

A Uterine Support for Horsewomen.—Finding that the women who ride in the "Wild West" Company now in London suffered severely at times from the jolting which they received, an English instrument maker has made a supporter consisting of a peculiarly shaped pad, with straps crossing the sacrum and meeting in front. Those who used them experienced marked comfort from them.

Calisthenics in Schools.—An important movement in the London schools has for its object the physical training of the pupils, and at present 1200 teachers are receiving instruction in this department, and such teaching has been introduced into 250 schools.

The Influence of Mental Impressions upon Wounds.—Professor Delboeuf of Liège is certainly the most versatile of living investigators, when one considers the great originality and suggestiveness of all the work he does. Ancient and modern languages, logic, general physics, and physiology, and especially experimental psychology, have received his attention by turns. His latest contribution is to therapeutics, and is a communication made on June 4 to the Belgian Academy, which will probably turn out to be of the greatest theoretical as well as practical importance.

We all are familiar with accounts of the wounds inflicted on themselves by African dervishes; but the statement which the narrators always make, that the wounds do not inflame, or may even be quite healed in twenty-four hours, probably often tends to discredit their whole description in the reader's mind. Delboeuf's observations now make these stories wholly plausible. It is well established that in certain hypnotic subjects a suggestion made during trance, that to a part of their body a cautery or a blister is applied, will produce, after due lapse of time, an actual vesication of the skin. The

hallucinatory feeling of inflammation produces in these persons a genuine inflammation. M. Delboeuf argued from this, that the feeling of pain, however useful in other respects, must itself be an inflammatory irritant, and went on to infer that the abolition of it from an actual wound ought to accelerate its healing. He immediately thought of some hypnotic subjects whom he had made anæsthetic, and in whom he had often admired the rapidity with which the wounds of punctures and pinchings disappeared, and proceeded to more systematic experiments, which, so far as they go, seem to verify his hypothesis perfectly. On a young woman whom he could make insensible by suggestion, he marked two corresponding spots, one on each arm, and made on each an identical burn with the hot iron, announcing to the patient that the one on the right should not be felt. The suggestion took effect; and the next day, when the bandages were taken off, and the left arm presented a vesicled sore with an inflammatory area three centimetres in diameter, the right arm showed only a clean scorch of the skin of the exact size of the iron (eight millimetres diameter), without redness or inflammation. On another subject similar results were obtained with burns and blisters, the spots chosen being near together on the same arm or on the neck. The experiments are few in number, and ought to be multiplied; but the reader will immediately see the vista which they open. Many of the results of the "mind cure," and the strange fact, so long known, of opium controlling inflammations, are explained by M. Delboeuf's principle. So is the popular belief in "hardening" one's self by a little judicious indifference, and neglect of one's condition. Local pain is useful in leading us to protect the wounded part from mechanical abrasion—several of M. Delboeuf's experiments were inconclusive, because the subjects, being insensible at the seat of their injuries, allowed them to get scraped, etc.—but it has the drawback of exciting reflex changes of nutrition of an unfavorable kind. Anæsthetizing a wound prevents these reflex changes. M. Delboeuf, suggesting to a very sensitive subject that she should not feel a severe dental operation, was assured by the dentist that what he found most extraordinary in the whole performance was the absence of the salivary secretion which would usually have accompanied it.

It is to be hoped that others, with better facilities for surgical experimentation than a professor of classical literature like M. Delboeuf, will follow the example he has so happily set them.—*Science*, September 30, 1887.

POISONOUS CANDIES.—Prof. Erastus G. Smith, professor of chemistry at Beloit College, Wisconsin, has been analyzing samples of candy purchased at the shops in that city, and found them colored with cochineal for red, lead chromate (poison) for yellow and green, and aniline for orange. The hoarhound candy was highly colored with eosine. Purchasers of confection highly colored should be careful and refuse yellow and green, as chromate of lead is a deadly poison. Several cases of poisoning from this coloring on confection have occurred at Pittsburg.

THE JOHNS HOPKINS HOSPITAL.—It has been authoritatively announced that the Johns Hopkins Hospital will be opened for the reception and treatment of patients in the fall of 1889. This institution is in no wise affected by the failure of the B. & O. R. R. to pay its semi-annual dividend, as has been intimated. The funds of the hospital are not invested in B. & O. stock. —*Maryland Medical Journal*, October 22, 1887.

VON LANGENBECK.—The funeral of this distinguished surgeon was fully attended by the representatives of German science.

The feeling of profound and affectionate honor in which he was held is expressed by the *Berliner Wochenschrift* as follows: "We honored him, the gentle, kindly, genial master at whose feet we all had sat, whose incessant general labors we had beheld with admiring astonishment; we one and all honored and loved him as a kind father, and this feeling of affection and honor accompanies him to his grave, and will mourn over his perishing form."

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY, FROM OCTOBER 18 TO OCTOBER 24, 1887.

WOLVERTON, W. D., *Major and Surgeon*.—Detailed as a member of the Army Retiring Board at Washington, District of Columbia, convened by *S. O. 78, A. G. O.*, April 5, 1887, vice Major C. C. Byrne, Surgeon, hereby relieved.—*S. O. 241, A. G. O.*, October 15, 1887.

GARDNER, EDWIN F., *Captain and Assistant Surgeon*.—Relieved from duty at Fort Reno, Indian Territory, and ordered for duty at Fort Lewis, Colorado.—*S. O. 242, A. G. O.*, October 15, 1887.

EWING, C. B., *First Lieutenant and Assistant Surgeon*.—Granted leave of absence for one month, on surgeon's certificate of disability.—*S. O. 112, Department of the Missouri*, October 18, 1887.

COCHRAN, JOHN J., *Captain and Assistant Surgeon*.—Now on duty at the Presidio of San Francisco, California, is assigned to temporary duty at Headquarters, Division of the Pacific, as assistant to the Medical Director of that division.—*S. O. 244, A. G. O.*, October 19, 1887.

JARVIS, NATHAN S., *First Lieutenant and Assistant Surgeon*. Ordered for field duty in the Department of the Platte.—*S. O. 240, A. G. O.*, October 21, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING OCTOBER 22, 1887.

BEYER, H. G., *Passed Assistant Surgeon*.—Ordered to hold himself in readiness for orders to the "Trenton."

WHITE, S. S., *Assistant Surgeon*.—Ordered to hold himself in readiness for orders to the "Trenton."

STEPHENSON, F. B., *Passed Assistant Surgeon*.—Detached from the "Bache," and ordered to the Navy Yard, Boston.

STONE, E. P., *Assistant Surgeon*.—Detached from the "New Hampshire," and ordered to the "Bache."

STREET, T. H., *Surgeon*.—Detached from the "Patterson," and placed on waiting orders.

A Naval Medical Examining Board is now in session at the Naval Hospital, Philadelphia, Pa., for the purpose of examining candidates for admission to the Medical Corps of the Navy. Circulars of information can be obtained on application to the President of the Board. There are twelve vacancies in the list of Assistant Surgeons.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

EXTRA ISSUE.

MEDICAL NEWS.

A WEEKLY MEDICAL JOURNAL.

Vol. LI. No. 18. Whole No. 772 | SATURDAY, OCTOBER 29, 1887. | Per Annum, $5.00. Per Copy, 10 Cents.

THE paramount importance to the public of preventing the importation of cholera into the United States calls for a special issue of THE MEDICAL NEWS, giving in full the report of the Commission appointed by the College of Physicians of Philadelphia, consisting of Drs. James C. Wilson, E. O. Shakespeare, and R. A. Cleemann, to investigate the condition of affairs in the Quarantine of New York.

It will be seen that the grave dangers which exist may render prompt action necessary with a view to establishing some national system of quarantine for the protection of the country.

REPORT OF THE COMMITTEE OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA

APPOINTED TO INVESTIGATE THE EFFICIENCY OF OUR QUARANTINE ARRANGEMENTS FOR THE EXCLUSION OF CHOLERA AND OTHER EPIDEMIC DISEASES.

TO THE PRESIDENT AND FELLOWS OF THE COLLEGE:

Your Committee appointed at the meeting of the College held October 5, 1887, to consider the present danger of the importation of cholera into this country, and to secure concerted action among the medical societies of the land in urging upon the State and National authorities the adoption of a uniform and efficient system of quarantine for all exposed ports, respectfully reports as follows:

The acceptance of the germ theory of infectious and contagious diseases, or the probability at least of its truth, places in a new light the management of quarantine for detention and disinfection of vessels and their passengers. Anterior to the promulgation of this doctrine the etiology of these diseases was so obscure, that it is not a matter of surprise that such diverse views existed on the subject of quarantine; as shown by its absolute abandonment in Great Britain, for instance, and, on the other hand, by its enforcement with unreasonable severity in the southern ports of Europe. There was no clear idea of that which was to be guarded against, and, therefore, no measures generally and unreservedly accepted as a means to the desired end.

In view of the nature of the work with which your Committee was charged, we found ourselves confronted with two questions of urgent importance:

I. What are the requirements of an efficient maritime quarantine against cholera?

II. To what extent do the existing arrangements at the ports of New York, Philadelphia, and Baltimore fulfil these requirements? [We speak of these ports only, because circumstances did not permit more extended personal investigations, and there is no reason to believe, from the published official descriptions, that the conditions of the other ports of entry upon our Atlantic and Gulf coasts are in any respect superior.]

I. In reply to the first of these questions, we cannot do better than quote at length from the editorial pages of a recent number of THE MEDICAL NEWS.[1]

"Measures of prevention, to give the greatest possible guarantee of success in extinguishing an incipient epidemic of cholera, should, in the first place, be based upon the most exact knowledge we possess of the cause, mode of attack, and manner of spread of the disease; and, in the second place, these measures should be intelligently, thoroughly, and rigidly enforced.

"What are the considerations involved in the first category? Probably nine-tenths of intelligent and experienced physicians all over the world, even including those of India, have for years admitted that there is most convincing proof that the active cause of the disease is a specific, material, living entity, of extremely minute size, endowed with the power of self-propagation, and of exceedingly rapid multiplication in enormous numbers; that among animals it naturally attacks man alone, assailing him only by way of the intestinal canal; that the evacuations from the bowels contain the active cause of the disease, and that when this agent in any manner—as through drinking water, milk, food, or the handling or washing of contaminated personal effects, etc.—reaches the intestines of another susceptible person, the disease may be thereby transmitted from the sick to the healthy; that the active agent exists in the dejecta of the lightest and most imperceptible no less than the severest and most deadly forms of the disease, and is known to be transportable from place to place through the movements of man and his personal effects.

"Proceeding from this basis, logical deduction and common experience alike demonstrate the absolute

[1] October 15, 1887, pages 455, 456, 457.

necessity and efficiency of such measures of prevention as the following:

"*a*. Speedy recognition and isolation of the sick; their proper treatment; absolute and rapid destruction of the infectious agent of the disease, not only in the dejecta and vomit, but also in clothing, bedding, and in or upon whatever else it finds a resting-place.

"*b*. The convalescents should remain isolated from the healthy so long as their stools possibly contain any of the infecting agent; before mingling again with the well they should be immersed in a disinfecting bath, and afterward be clothed from the skin outward with perfectly clean vestments, which cannot possibly contain any of the infectious material.

"*c*. The dead should be well wrapped in cloth thoroughly saturated in a solution of corrosive sublimate, 1 to 500, and without delay, cortège, or lengthy ceremonial, buried near the place of death in a deep grave, remote as possible from water which may, under any circumstances, be used for drinking, washing, culinary, or other domestic purposes. (Cremation, of course, is by far the safest way of disposing of cholera cadavers.)

"*d*. Those handling the sick or the dead should be careful to disinfect their hands and soiled clothing at once, and especially before touching articles of food, drinking, or culinary vessels.

"*e*. In the case of maritime quarantine, the well should be disembarked and placed under observation in quarters spacious enough to avoid crowding, and so well appointed and furnished that none will suffer real hardships.

"*f*. Once having reached the station, those under observation should be separated in groups of not more than twelve to twenty-four, and the various groups should, under no pretext, intermingle; the quarters for each group should afford stationary lavatories and water-closets in perfect working condition, adequate to the needs of the individuals constituting the group, and supplied with proper means of disinfection; there should be a bed raised above the floor, proper coverings, and a chair for each member of the group, each person being required to use only his own bed; there should be a common table of sufficient size to seat around it all the members of the group, who should be served their meals from a central kitchen, and with table furniture belonging to the station and cleaned by the common kitchen scullions.

"*g*. Drinking-water, free from possible contamination and of the best quality, should be distributed in the quarters of each group, as it is needed, and in such a manner that it is received in drinking-cups only; there should be no water-buckets or other large vessels in which handkerchiefs, small vestments, children's diapers, etc., can be washed by the members of any group.

"*h*. Immediately after being separated into groups in their respective quarters, every person under observation should be obliged to strip and get into a bath (a disinfecting one is preferable), and afterward be clothed with fresh, clean vestments from the skin outward. Every article of clothing previously worn should be taken away and properly disinfected.

"*i*. Then all of the personal effects should be at once removed to a separate building, washed—if possible—and thoroughly disinfected, or, if necessary, destroyed. After disinfection they should be temporarily returned to the members of groups, when occasion requires a further change of clothing.

"*k*. Under no circumstances whatever should washing of clothing by those under observation be permitted. All used clothing should be first thoroughly disinfected (by boiling, when possible), and then should be cleansed, the disinfection and washing being done by a sufficiently trained and absolutely reliable corps of employés supplied with adequate appliances.

"*l*. All of those under observation should be mustered in their own quarters and be subjected to a close medical inspection, *while on their feet*, at least twice every day, in order to discover and isolate as soon as possible new cases which may develop; and, of course, the clothing and bedding of these new cases should be treated without delay in the manner already mentioned. In the mean time a watch should be set over the water-closets, for the purpose of discovering cases of diarrhœa, and, when discovered, such cases should be temporarily separated from the rest; they should receive judicious medical attention at once, and precautions should be taken as if they were undoubted, but mild, cases of cholera.

"*m*. The quarters should be kept thoroughly clean, and every surface upon which infectious material could possibly be deposited, including the floors, should be washed with a strong disinfectant twice daily, and oftener when necessary; evacuations from the bowels should be passed into a strong disinfectant; the hopper of the closet should be then flushed, and finally drenched with a quantity of the same disinfectant.

"*n*. For the proper attention to the sick, there should be two or more competent and experienced physicians, assisted by a sufficient corps of intelligent and efficient nurses, with hours of duty so arranged that a physician with a sufficient number of nurses be in constant attendance in the wards of the hospital.

"*o*. For the prompt recognition and separation of new cases, their temporary medical attention, the proper treatment of discovered cases of diarrhœa or cholerine, and of other maladies, and the immediate correction of every insanitary practice or condition by constant, vigilant, and intelligent supervision, there should be at least two or more competent and experienced physicians, with hours of service so arranged that a physician is on duty night and day among those under observation; and he should have subject to his orders, at any and every moment, a sufficient and efficient corps of nurses and laborers to carry out properly and promptly his directions.

"*p*. In order to prevent the intermingling of the various groups, to enforce obedience and order, and to make it absolutely impossible for the quarantined and their personal effects to have any communication with the exterior, a well organized and sufficiently large police corps should patrol the borders of the stations and the buildings day and night.

"*q*. Any group among whom there has developed no new cases of cholera, or of choleraic diarrhœa, during the preceding eight or ten days, may be regarded as harmless, and allowed to leave quarantine after each one is finally immersed in a disinfecting bath, and reclothed with clean garments from the skin outward; the garments removed being destroyed, or thoroughly disinfected and cleansed as above indicated.

"As yet no reference has been made to the crew, ship, and cargo. What has been said of the treatment of those under observation, applies to every one of the ship's inhabitants. The observation, isolation, and cleansing of the crew and their effects, could safely be performed aboard ship if necessary. The ship should be thoroughly cleansed and disinfected, particular attention being given to the quarters of the emigrants and crew."

II. The second question is to what extent do the existing arrangements at the ports of New York, Philadelphia, and Baltimore fulfil these requirements?

Your Committee began its work by personally inspecting the quarantine stations at New York, Philadelphia, and Baltimore, arrangements having been previously made with the respective officials.

QUARANTINE STATION AT NEW YORK.

The quarantine establishment, visited October 8th, consists of a boarding station, which is the residence of the Health Officer, situated on Staten Island, four miles below the city, just within the Narrows at the entrance of the harbor, and in connection with New York city by telegraph and telephone; of an island of observation known as Hoffman Island, and of another, Swinburne Island, on which latter is erected a large hospital building. These islands are artificial, being made of foundations of rock, covered with sand; are situated in the lower bay about five miles below the boarding station, and two miles from the shore.

Hoffman Island is probably four acres in area, and rises some eight feet above the level of the sea. There are upon it two large brick buildings of two stories each, and a smaller building, the latter provided with cooking and heating apparatus for the larger buildings. One of the large buildings is furnished with water-closets in each story, and a lavatory in the upper. The rooms of this building are without furniture or bedsteads.

The water supply of this island is as follows: There is a cistern lined with brick, sunken beneath the surface of the sand near each of the large buildings, to collect rain-water from the roof, but at the time of our visit the sunken cisterns contained Croton water brought from the city of New York. The openings of these cisterns are provided with caps. In addition to these, there are two iron tanks of considerable dimensions in the large buildings in which the water-closets are located, and they are elevated some distance above the head. One of these tanks is intended for fresh water, to be used for bathing; the other for salt water to be used exclusively for flushing the water-closets. We found that owing to imperfection in the apparatus, several of the water-closets could not be flushed. The iron soil pipes into which these closets empty lead into the sea, each pipe having, as we were informed, a number of right angles in its course. In the corner of one of the rooms containing the water-closets there was a barrel nearly full of a solution of corrosive sublimate, one part to five hundred. This was employed for the purpose of drenching the pans of the closets *after* they have been used and flushed. We found the seats and the floors of these water-closets extremely wet.

The lavatory was a small room opposite the water-closets of the second story, containing two metallic bath-tubs, and a few stationary washstands, supplied with fresh water from the above-mentioned tank. We were informed that the bath-tubs had not been used during the present emergency. Immediately opposite the water-closets on the lower floor, and beneath the lavatory, was a small room devoted to the uses of a temporary hospital. This room contained four bedsteads with the corresponding bedding, but no other furniture, and was occupied by three recently developed cases of cholera.

In the other large building there were constructed in corners on the first floor two disinfecting rooms, fifteen feet by twenty, each having one or more windows communicating with the external air. These rooms appeared to be otherwise air-tight. The remainder of the first floor constituted a large wareroom for the storage of baggage. The disinfecting apparatus was supplemented by a large wooden vat, located in the boiler-house, for the purpose of subjecting clothing to the action of steam, but it was not placed in position until after the first week of detention.

This island was occupied by upward of five hundred men, women, and children, passengers from the cholera-infected steamship "Alesia," who at that date had been upon the island sixteen days. They roamed at will over the island and through the rooms of the large buildings, except the one in the second story of the building in which the disinfection had taken place, which was occupied by a number of people of the better class, who seemed to have exclusive use of it.

These two buildings were supplied with a limited number of mattresses and blankets, which were collected together in piles. We learned that this bedding had been supplied by the steamship company, but that none of it arrived until five days subsequent to the debarkation of the passengers upon the island. The immigrants were permitted access to a portion of their personal effects after disinfection. Many of the people were engaged in washing their clothing. This washing was done in vessels of various kinds and in the immediate vicinity of the mouths of the sunken cisterns. At the time of our visit the latter were uncovered, and the ground around them was saturated with the water which had been

used in washing, and a number of people were scouring with this wet sand, the pans and tins in which they received their food and drinking water. They drew the water from the cisterns by pails and vessels of various kinds. According to information received, these cisterns had not been cleaned out in a number of years.

By reason of want of facilities for perfect flushing of the water-closets, due to a defect in the pumps, a supplementary latrine had been extemporized by digging a long deep trench in the sand not more than fifty feet distant from one of the large buildings, and about thirty feet from one of the cisterns. Notwithstanding these arrangements, it was impossible on account of the inadequate police, to prevent the people from defecating in any convenient spot, and although they had been enjoined by the Health Officer against the use of the water in the sunken cisterns for drinking purposes, there were no means of enforcing this order, for access to the cisterns could indeed be had at all times. Drinking water brought from New York city was distributed upon application at a tank in one of the buildings. Food supplied by the agents of the steamship company, and, as we were informed, brought to the island in their vessels, was prepared in the kitchen and distributed in sufficient quantities. This food, which was well cooked, consisted of bread, soup, macaroni, potatoes, pork, and beans. The dishes were generally used in common by families or small groups, and the absence of knives and forks was noteworthy.

The police force of the island consisted of one watchman assisted by an improvised corps of twelve of the more intelligent of the immigrants, each of whom received for his services, one dollar per diem. In addition to the police force, there were three or four men in the employ of the Health Officer, whose duties were attention to the disinfection of bag age, to the water closets, to the cleanliness of the buildings, to the detection of new cases of cholera and their removal to the temporary hospital, and to other similar matters. Besides these there were a cook furnished by the agents of the steamship company, and an engineer.

There was no resident medical officer upon the island. The Health Officer, who is a physician, visited the island once, and sometimes twice daily, for the purpose of inspecting the immigrants, and for the general conduct and direction of affairs. At these times the new cases which had developed in the intervals of his visits, were transferred to the hospital on Swinburne Island.

At the time of the arrival of the "Alesia," there were on board eight cases of cholera, all of which were at once transferred to the hospital on Swinburne Island. The rest of the steerage passengers, apparently free from the disease, were, with their baggage, landed on Hoffman Island, the cabin passengers and crew remaining on board the vessel. The clothing of the cholera patients was taken back from the hospital on Swinburne Island to Hoffman Island to be disinfected, and the same course was afterward pursued with the clothing of those who, having been taken ill with the cholera, were from time to time removed to Swinburne Island. Up to the time of our visit, sixteen days after the arrival of the ship, twenty-seven new cases of cholera had developed, of which three were discovered on the day of our visit. Of the eight sick at the time of the removal of the passengers from the steamer, five died, and of the twenty-seven cases attacked upon the island, nine proved fatal, making a total mortality of fourteen. As soon as the immigrants were landed from the ship, their baggage was taken from them and stored on the lower floor of the large building in which disinfection was carried out. The process of disinfection was as follows: The articles were separated, shaken out and hung up in the disinfecting rooms, three pounds of sulphur being burned for every 1000 cubic feet of space. The disinfection of the baggage for the first time occupied five or six days, during which period the immigrants were denied access to their effects and continued to wear the clothing which they had on when they left the ship. The steam disinfecting apparatus before referred to, was not placed in position until toward the end of the first week. After that the baggage was for a second time disinfected, a double process being employed: the clothing being first subjected to the action of steam and then to the fumes of sulphur. After the first disinfection, those whose clothing was accessible, were permitted to change their garments, and were thereafter assigned to sleep in a separate room, but were not prevented from mingling with the other immigrants during the day. No effort was made otherwise to separate the passengers into isolated groups, nor indeed was there, in our opinion, any adequate provisions to prevent occasional communication by means of small boats, especially at night, between Hoffman Island and the shore. We were informed that boats had not infrequently been seen hovering around the island, and had occasionally been warned off.

Swinburne Island, on which the hospital is located, is somewhat larger than Hoffman Island. The hospital, consisting of several one-story wooden pavilions, and the grounds are in excellent condition. The water supply is contained in sunken cisterns for the storage of rain water, placed in the open spaces between the pavilions. The mouths of these cisterns are on a level with the ground, and are covered with stone slabs. There is an adequate heating and cooking apparatus, and there are also a small disinfecting room and an apothecary shop.

The *personnel* of this island consists of a resident superintendent, who is not a physician, and, at the time of our visit, two male nurses, one of whom at different times had attended medical lectures. There was also an intelligent Italian gentleman, without medical or nurse training, who had volunteered his services in the care of the sick. The wards of the hospital were supplied with a sufficient number of bedsteads and necessary bedding in good condition, and contained nine patients, including the three discovered on the day of our visit, and who had been brought over with us from Hoffman Island.

The dead were buried in shallow graves on a sand-spit at the extreme end of Staten Island, known as Seguin's Point.

QUARANTINE STATION AT PHILADELPHIA.

We visited this station, known as the Lazaretto, October 13th, and made the following observations: It is situated on the right bank of the Delaware River, eleven miles from the city, on Little Tinicum Island, a large tract devoted to farming, which is separated from the mainland by Darby Creek. It comprises twelve acres belonging to the city and six acres the property of the United States Government. There is a large main building of brick, substantially constructed at the beginning of this century. The central portion of this building is occupied by the steward, and contains offices of administration. There are two wings, two stories and an attic in height, one of which is used by the crew of the boarding steam-vessel, and the other is arranged for hospital purposes, with a capacity of forty beds; but it is at present unfurnished.

Some distance in the rear of this building is a two-story brick hospital, with a capacity of thirty beds, and containing a dispensary. The dead-house is at the end of the building, but does not communicate with it. Near by is a wooden building ten feet by twelve feet, with a double wall and without windows, used for disinfecting by sulphur. There are at the station thirty-eight bedsteads, mattresses, and corresponding furnishing. Two small brick buildings near the river front accommodate the Lazaretto Physician and Quarantine Master, respectively.

The water-supply is obtained from old-fashioned wells with hand pumps. There are no large reservoirs for water, or large steam-boilers, or bath-tubs. There are several privies, but no water-closets. The station is connected with the city by telegraph. The Lazaretto physician, the Quarantine master, the male nurse, the telegraph operator, the crew of the boarding vessel, and the other attendants reside at the station during the quarantine season, which, as a rule, lasts from the first of June until the first of October. The steward resides at the station during the whole year. When the quarantine station is closed, the port-physician examines the vessels in the stream opposite the city.

On the government property is a large stone warehouse, about 120 feet by 40 feet, two stories and an attic in height, and also two brick buildings, in one of which resides the government inspector. There are no means of heating this warehouse, and its numerous windows are without sashes.

QUARANTINE STATION AT BALTIMORE.

This station, which is a new one, having been occupied only two years, is situated seven miles below Baltimore on the right bank of the Patapsco River, upon a point of the mainland jutting out into the stream and known as Little Hawkin's Point. The territory embraced in the quarantine station consists of fifteen acres, upon which are erected three frame dwellings, namely, a hospital of two stories with accommodations for about sixty patients, a dwelling for the medical officers, and another for the use of the crew of the boarding tug. The water is supplied by a spring about two hundred yards distant, being lifted by a windmill to a tank sufficiently high to permit of its distribution to the second story of the buildings.

The station has in store seventy-five tents to be used in emergency. No fence or wall separates the grounds from the adjacent land. At the time of our visit the hospital was unoccupied and locked up, so that we were unable to inspect the interior, but were informed that it was supplied with iron bedsteads and the necessary bedding. There is no special disinfecting apparatus at the station, nor any adequate means of disinfection; but there was pointed out to us a wing of the hospital designed for a kitchen, consisting of a small room with two windows and a door communicating with the building, in which, it was said, fumigation with sulphur could be practised. The water in front of the station is shoal, large vessels being obliged to anchor within two hundred yards of the main channel. The Quarantine Officer and his assistant, both of whom are physicians, besides the crew of the tug, a male nurse, and a gardener, reside at the station during the quarantine season, which usually ends October 31st.

We also visited the place four miles nearer Baltimore, which was formerly used as the quarantine station. It is now unoccupied and fallen into decay. It consists of a tract of land about four hundred acres in extent and several dilapidated buildings, including eight one story wooden barracks. This establishment is occasionally used as a pest-house for smallpox cases from the city of Baltimore. It is now unfurnished and untenantable.

CONCLUSIONS.

It is evident that the quarantine establishments at Philadelphia and at Baltimore fail in the most essen-

tial requisites of the necessary number of properly equipped buildings for the isolation and observation of a large number of immigrants.

In regard to the station at New York, the buildings are sufficiently large and numerous, and have adequate arrangements for heating and cooking, but they are not divided into a sufficient number of small compartments to permit the strict isolation of the immigrants into small groups. The water-closets were not sufficiently numerous, nor were they all in good working order: neither were there enough bath-tubs. The pumps, by which the supply of sea water used for flushing these closets was obtained, were out of order, and a period of two weeks elapsed before the necessary repairs could be made. It is also worthy of note that the soil-pipes only reached the sea by the already mentioned series of angular turns.

The necessary use of the supplementary latrine we have described; objectionable in construction and situation, as it was, it constituted a menace to the safety of the immigrants detained upon the island, among whom new cases were from day to day occurring. The dangers of infection were still further increased by the fact that the immigrants could not, under the existing state of affairs, be prevented from defecating at any convenient spot.

There was no provision for the general washing of clothing by the authorities. As a result of this defect, there arose the exceedingly dangerous practice of the washing of clothes at the cisterns by the immigrants themselves. The existence of underground cisterns at a station of this kind is, in itself, highly objectionable. All water reservoirs should be inaccessible to the immigrants, and should be placed above ground in such a manner as to avoid all danger of accidental contamination.

The disinfecting chambers were sufficiently capacious, but the existence of windows in them was a fault of construction which would seem decidedly to impair their efficiency.

The lack of bedsteads, chairs, tables, and proper eating utensils, added to the hardships of the immigrants and to the dangers of infection.

The location of the room used as a temporary hospital, namely, directly opposite one of the water-closets, and the fact that patients, known to have cholera and placed in this hospital, were allowed to use the water-closets in common with others, constituted a serious danger, and suggested the advisability of the use, for this purpose, of a separate building provided with its own water-closets and system of drainage.

Your Committee feels called upon to comment upon the absence of a resident medical officer at this station, and of an adequate force of watchmen, patrolmen, and attendants. As a consequence of these defects of organization, the well-recognized requirements of a quarantine of observation as pointed out in paragraphs o, p, and q above, could not possibly be fulfilled. The possibility of occasional clandestine communication between the detained immigrants and their friends by means of small boats, constituted a danger to the country, difficult to estimate, and against which, so far as we could learn, there were no certain precautions.

There was, in fact, no official supervision of the personal hygiene of the detained, no compulsory bathing or washing. The absence of towels in the lavatory and of paper in the water-closets, was notable. Soiled hands and filthy clothing indicated habits which favored the transmission of the cholera infection from person to person, particularly as the custom of several individuals eating from a common dish, without knives or forks, was frequently observed.

One of the results of the absence of bedsteads was the promiscuous heaping together of the mattresses and blankets during the day, in order to make room for washing the floors with disinfectant solutions; the bedding was thus doubtless used on successive nights by different persons, constituting a very probable means of transmission of the disease if they should become soiled by dejecta or vomit. Furthermore, as there was an insufficient number of matresses, two or more persons must have, in many instances, occupied one bed.

The hospital building on Swinburne Island appeared to be excellently adapted to its purposes. The use of underground cisterns for the storage of water is, however, here also objectionable. As there were no less than nine cases of cholera in the wards, at the time of our visit, some of whom were desperately ill, your Committee noted with surprise the absence of a resident physician, a fact that demands no further comment. And it was a reversal of modern ideas to find male nurses in charge of female patients.

Your Committee was at a loss to understand why the clothing of patients was sent back to Hoffman Island to be disinfected, as there is a disinfecting chamber in connection with the hospital. We were informed that the convalescents were, as soon as they were strong enough to be about, returned to Hoffman Island, without having been previously bathed and disinfected.

The recent arrival of the "Britannia," another steamship of the same line, with a large number of Italian immigrants from the infected port of Naples, among whom, if press reports are true, cholera evidently made its appearance during the voyage, its existence being either not recognized by the ship's surgeon, or else concealed by the deliberate falsification of the ship's sanitary record, has already,

in the opinion of your Committee, seriously increased the present danger of the ultimate introduction of cholera into the country through the port of New York. It would seem that if the importation of immigrants directly from a European port notoriously infected, is not to be temporarily prohibited as a necessity of public safety, or if the treatment of these immigrants, after their arrival at the New York quarantine station, is not to be immediately and radically improved, our protection against an epidemic at the present time must rest mainly upon the fortunate circumstance of the near approach of a season in which the disease does not usually spread. The continuance of cholera among the passengers of the "Alesia" so long after their removal to the station of observation, in itself demonstrates the inefficiency of the measures which have been adopted and enforced for its extinguishment there. Although we have not yet heard of the development of the disease anywhere on the main-land, nevertheless, in view of the almost uncontrollable tendency of cholera to spread at times, and of the original insufficiency and the present faulty constitution of the police force on Hoffman Island, we feel impelled to believe that the immunity up to the present time has been owing to singular good fortune, rather than to good management.

Moreover, in our opinion, it is necessary that the personal effects of Italian immigrants directly from the infected ports shall be, in all cases, thoroughly disinfected before they are permitted to land, whether the word cholera makes its appearance in the ship's log and the sanitary record of the voyage or not. It is a well-known fact, established by numerous instances, that even when immigrants from an infected locality have themselves remained free from disease during the voyage, their baggage, packed before starting, has been the conveyer of the infection to their point of destination. The passengers of the steamship "Independente," most of whom were shipped directly from the infected port of Palermo, although it is stated that during the voyage no case of cholera developed, come under this category. The recent action of the Surgeon-General of the Marine Hospital Service, and the alarm of the health authorities of the cities of Chicago and St. Louis, seem, therefore, not without some just foundation.

It should be stated, however, that we have learned through the medium of the public press that an attempt has been made to remedy a few of the defects above pointed out. What has been done would appear, however, to be in the direction of improvement in minor matters, rather than in such radical changes as would insure the country against the dangers to which it is exposed.

In the conduct of its personal investigations, and in the preparation of its report, your Committee has dealt solely with patent facts and plain truths which would meet the eyes and occur to the minds of any unprejudiced and competent men charged with a similar duty. To lay the simple statement of these facts before physicians who are in possession of modern knowledge concerning the nature, cause, mode of production, and means of prevention of such a virulently infectious disease as Asiatic cholera, is to prove beyond rational dispute that the present quarantine, as a safeguard at the ports under consideration, is dangerously and essentially imperfect.

It is natural, after having made our comments on the defects of the quarantine stations we have described, that we should endeavor to point out their causes and probable remedy. There is one cause so prominent, that we may dwell on that alone. It is the great expense. Were it not for the question of money, there would have been physicians constantly in attendance at the New York station, and, consequently, better management and discipline would have been maintained, while at Philadelphia and Baltimore there would have been adequate establishments provided for the isolation and observation of large bodies of immigrants.

Municipalities and States are wont to scrutinize every dollar of their money appropriations, bringing their expenses down to the closest living limit. Quarantine in this country being, as a rule, enforced mainly against yellow fever and smallpox, a mistaken economy has caused no provision to be made for the more perfect establishments absolutely required for protection against cholera.

Philadelphia, Baltimore, and other ports of a more limited commerce, are unable to spend as much on their stations as is New York, with its large revenues from that source, yet an inefficient quarantine at any station exposes the whole country to the dangers of the importation of disease. But it is manifestly unfair that a single municipality or State should defray the expense of protecting the whole public.

How, then, can we have equally complete stations all along the coast? We believe that this can be effected by putting quarantine into the hands of the National Government. We know that there are legislative difficulties in the way; that quarantine partaking of the nature of police regulation, its exercise, it may be claimed, belongs to the local authorities. Yet, even if it be conceded to be a police regulation, its scope is not local, but extends over the whole country, and it would seem, in justice, that it should be exercised and paid for by the whole country. Objection is sometimes made to quarantine on the ground that commerce is unduly interfered with, or even destroyed. A modern quarantine, however, does not necessarily involve the detention of cargo, nor prolonged detention of

the passengers. It is now known that in the case of cholera the disease germs infest the persons, clothing, and surroundings of the passengers and crew, while the cargo, except in some rare instances, is free from infection. Non-infected vessels require no detention whatever, the health officer examining them in transit.

Not to speak of the danger which threatens the whole country, the exposure, suffering, and loss of life that have occurred among the passengers of the "Alesia" detained at the quarantine of observation on Hoffman Island, have been due to the imperfect manner in which the measures of quarantine have been there carried out. Had the details of isolation and disinfection set forth in the earlier pages of this report been immediately and effectually put in force, the passengers who were not already infected at the time of leaving the ship, and this includes the whole number with very few exceptions, might have been released from quarantine in eight days, without the slightest risk to the country.

The thanks of the Committee are due to the quarantine authorities of New York, Philadelphia, and Baltimore for courtesies extended to it in conducting the investigations upon which this report is based.

Your Committee offers the following resolution:

Resolved, that in order to secure concerted action among the medical societies of the United States looking to the early adoption of a uniform and efficient quarantine of all exposed ports, the Committee be continued and be authorized to issue an address to medical societies of the country, and seek their coöperation.

All of which is respectfully submitted.

J. C. Wilson, *Chairman.*
E. O. Shakespeare,
R. A. Cleemann.

Philadelphia, October 28, 1847.

CHOLERA AND QUARANTINE.

The report of the Special Committee appointed by the College of Physicians of Philadelphia to investigate our present sanitary defences, was presented to the College last evening, and it clearly shows that the quarantine arrangements of our coast are greatly insufficient for the accomplishment of the only object of their existence.

The establishments at Philadelphia and Baltimore are entirely inadequate for the proper treatment of even an emergency as has been present for the past month in the port of New York. While the plant of the New York quarantine establishment is altogether far superior to that of any other port in this country, yet in many respects it lacks the essential facilities for the handling of large numbers of immigrants under observation, in such a thorough manner as to prevent the spread of infectious diseases among them while under detention.

Whilst many of the shortcomings at New York are the natural consequence of parsimonious appropriations by the State or municipal authorities, yet the administration of affairs at the quarantine station appears, also, to be seriously at fault.

The absence of medical officers, and of an efficient corps of experienced attendants at Hoffman and Swinburne Islands, is, in our opinion, inexcusable.

The neglect to separate and isolate infected groups has had doubtless considerable to do with the continuance of cholera among the detained immigrants, and a failure to enforce habits of personal cleanliness, together with the insufficient supply of eating utensils, has greatly increased the means of disseminating the cholera poison.

The practice of promiscuous washing of clothing around the mouths of water cisterns, which no doubt occasionally supplied some of the people with drinking water, was, in the light of experience, exceedingly liable to spread the disease.

The carelessness with which the detained immigrants have been guarded is surprising. During the first weeks the number of the force was absurdly insufficient to prevent communication with the shore, and although it has been increased, yet the fact that all but one of the policemen were chosen from among the immigrants under detention, seems in itself to constitute a source of danger.

The present uneasiness created by the landing and transportation inland of the immigrants recently brought by the "Independente" from Palermo, after only twenty-four hours' detention at the New York Quarantine, is not without cause. Experience has shown that it is dangerous to place any great faith upon the statements and records of the ship's officers concerning its sanitary condition. Moreover, it is quite possible that the baggage could become infected in the localities whence these people migrated, and retain the infective agent while packed away and unused during the voyage, to become active in the production of the disease at any time subsequently when handled or washed.

It is, therefore, necessary to treat the baggage of all incoming immigrants from infected ports as if the disease had actually made its appearance on the ship. The passengers should be given a disinfecting bath and clothed in clean garments and then kept under observation until the expiration of the period of incubation of the disease—say, five days. It is needless to add that these precautions should be observed in the case of every ship arriving from an infected locality.

ORIGINAL ARTICLES.

THE TRUE PLACE OF MILK IN THE TREATMENT OF DIABETES MELLITUS.

BY JAMES TYSON, M.D.,

PROFESSOR OF GENERAL PATHOLOGY AND MORBID ANATOMY IN THE UNIVERSITY OF PENNSYLVANIA, ONE OF THE PHYSICIANS OF THE PHILADELPHIA HOSPITAL, ETC.

THE very emphatic declaration by Dr. Austin Flint, Jr, in THE MEDICAL NEWS of July 9, 1887, as to the harmfulness of milk in the treatment of diabetes mellitus seems to call for some reply from those who have been in the habit of regarding it with greater favor, and as I have published statements which distinctly commend its use under circumstances where Dr. Flint apparently directly condemns it, it appears not inappropriate that I should come forward and explain.

In the first place, I am not aware that any one, except Dr. Donkin, claims that milk is a specific for diabetes mellitus. My experience thoroughly sustains that of Dr. Flint, that "the so-called specifics for diabetes have little if any effect." Nor do I believe that a specific remedy for diabetes is likely to be discovered while its pathology is so ill determined as at present. There is reason to believe that we are able to influence the quantity of glucose in the urine of a given case by more than one drug. Thus, opium, and especially its alkaloid codeine, is well known to have this effect. In fact, codeine is by far the most active drug in this respect known to me. The bromide of arsenic, in the shape of Clemens's or Gilleford's solution, undoubtedly is influential. Ergot I have more than once seen reduce the quantity of sugar and urine. Salicylate of sodium in the hands of competent observers has been similarly credited. Finally, I have reason to believe, although my experience has as yet been too limited to justify any positive conclusion, that the treatment by lithium carbonate and sodium arseniate, recently announced by Martineau, but really originating with the late Prof. Rouget, may act similarly. Yet I am free to say that none of these remedies in my hands has ever cured a case, and I can cordially confirm Dr. Flint in the view that by far the most efficient treatment has been the dietetic.

And it is as a dietetic measure that I use milk, and always *skim milk*, in the beginning of treatment. It has happened to me time and again that glucose has completely disappeared from the urine and the quantity of the latter been rendered normal within a week after instituting the skim-milk treatment, and this, too, in cases where an antidiabetic diet, from which all kinds of bread were excluded, had failed to produce the same effect. On the other hand, it has happened to me, and I have now such a case, in which the use of milk without any drug was promptly followed by a reduction in the amount of glucose, which was not, however, permanent. The patient is an adult, male, aged thirty-nine years. The case is quite an acute one, in which the symptoms had set in but six weeks before he consulted me; at that time his urine contained fully eight per cent. of sugar. I immediately ordered him on an exclusive skim-milk diet. He himself much preferred buttermilk, and as I thought the treatment would be essentially the same I permitted it. Under this treatment the sugar rapidly declined until at the end of 20 days it amounted to but 0.9 of 1 per cent. One week later, however, it had risen to 3 per cent. I then withdrew the milk and placed him on Clemens's solution of bromide of arsenic, in three-drop doses, along with an ordinary diabetic diet including gluten bread. A week later the sugar had reached 4 per cent. I then ordered him to omit all bread and increase the Clemens's solution to 5 drops three times a day, and further to increase one drop daily. On the 25th, a week later, he was taking 21 drops of Clemens's solution a day and the sugar amounted to 6.75 per cent. By August 1st, nine days later, the sugar had been reduced to 2½ per cent. He was now taking 25 drops a day and there was slight puffiness under the eyelids. I reduced the dose to 5 drops three times a day, and in eight days made another analysis, discovering 3.6 per cent. Thus, the glucose, which on a buttermilk diet had fallen to less than 1 per cent., but had again risen to 3 per cent., and during the administration of bromide of arsenic and an antidiabetic diet from which all bread was excluded had again declined to 2½ per cent., again began to increase while the same treatment was continued.

I then placed him on the solution of lithium carbonate and sodium arseniate,[1] directing him to drink not less than one quart and not more than two quarts of the solution in twenty-four hours. After he had been on the treatment for three weeks a specimen of the urine had a specific gravity of 1.042 and contained 3.6 per cent. of glucose—that is, it remained at the same point as while he was taking the bromide of arsenic. Another analysis eleven days later gave precisely the same result while the quantity of urine had again increased 50 per cent. He complained also of severe pains in his feet and legs, and of obstinate constipation. I then added twenty grains salicylate of sodium three times a day together with an aperient pill of blue mass, comp. ext. of colocynth and hyoscyamus. Thirteen days

[1] In preparing the solution in this and other instances I directed simple non-carbonated water while the original prescription of Martineau's called for carbonic acid water. I have been unable to discover any difference in result whether carbonic acid water or non-carbonated water was used as the menstruum.

later the sugar had fallen to 1.4 per cent., while the pains in the feet and legs had disappeared, and the quantity of urine was normal. The pill had been efficient in regulating his bowels. I may add that in my experience the symptoms of true diabetes are invariably aggravated by constipation and torpor of the liver. Two weeks later the quantity of glucose had again risen to 4½ per cent., later to 5 per cent., but still later it had fallen to 4.2 per cent. for evening urine, the previous analyses being of morning urine.

It will be seen that in this case the use of buttermilk was followed by a decided reduction in the quantity of sugar, a reduction which exceeded that under any other treatment adopted. But it was not permanent. Nor was that under the bromide of arsenic and anti-diabetic diet more permanent. I cannot myself think that the substitution of buttermilk, which, if here permitted, could have altered the result. Indeed, on theoretical and practical grounds, one would expect the result to be even more satisfactory. For, in the first place, the fat is at least as much removed in the buttermilk as in the skim-milk, and in the second place, much of the sugar of milk of skim-milk is converted into lactic acid in buttermilk, while the experience of Cantani goes to show that lactic acid is an efficient remedy in diabetes.

Another striking instance of the effect of a pure skim-milk diet in diabetes mellitus is the following: A very active and successful business man, aged fifty-two, consulted me in June, 1884, with diabetes mellitus, which he had apparently had for three years. As is the case with so many at that time of life, he was so little inconvenienced by the symptoms, that he could hardly be made to realize its seriousness. When he came under my observations, he had, however, the thirst, dryness of mouth, and polyuria, and an analysis discovered 7½ per cent. of sugar with a specific gravity of 1.037. The treatment instituted was purely dietetic without milk, except a glass or two at meals. The effect was prompt. In a week the specific gravity was 1.031, and it contained 5 per cent. of sugar. The thirst and polyuria had diminished. In another eight days the sugar had declined to 4 per cent., and by June 30th, 2½ per cent.

The other symptoms were so totally relieved that I saw nothing more of the patient until January of the next year, when he reported with 2½ per cent. of sugar in his urine, which had a specific gravity of 1.027. He remained under my care on a diabetic diet, variously strict, and with a corresponding range in the sugar, which I note was at various times 7 per cent., 2½ per cent., 6.6 per cent., 4 per cent., 2½ per cent., 3.3 per cent., etc. Continuing actively engaged in large financial schemes he did not report until December, 1886, when he said that he had been pretty well all summer, except in the early part of July, when he had an attack in which he seemed to lose partially the use of his limbs. He continued to be able to walk, although with difficulty. This condition passed off in a few days. He continued well until the day before his visit, when a similar loss of power appeared in his hands and legs, especially shown in a difficulty in signing his name. The urine contained 3.3 per cent. of sugar, but there was no undue thirst, and he did not have to rise at night to pass water.

On January 1st, I was asked to meet the patient's family physician in the country. There had occurred total paralysis of the right arm, and partial loss of power of the corresponding leg. There was 2½ per cent. of sugar in the urine. He was immediately put to bed and upon a pure skim-milk diet. On the 5th the sugar was 2 per cent.; on the 9th there remained but ½ per cent., on the 13th a ¼ per cent., and on the 15th there was not a trace of sugar. Except a temporary return of a fractional part of 1 per cent. of glucose, the urine has remained entirely free, although the patient has long since returned to a selected diet of vegetables and meats, bread and the pure farinacea being alone excluded.

I could select from cases under my care others, all showing that glucose disappeared more rapidly and more thoroughly under a skim-milk, than under any other diet, while the practices of my friends, and notably that of Dr. Weir Mitchell, furnish similar results, and I now recall a case in which I was associated with Dr. Mitchell, which has been under observation for at least three years, where the patient is essentially well while limiting himself to a skim-milk diet, but who invariably has a return of symptoms when this diet is departed from, even though it be substituted by an anti-diabetic diet. As I have said elsewhere, it is not always necessary to restrict diabetics to a skim-milk diet, but when other measures fail I resort to it with more confidence than in any other measure.

A third case shows strikingly the difference in the effects of a skim milk and unskimmed milk diet. An army officer, aged forty-three, came under my observation March 1, 1887. Two years earlier sugar had been discovered in his urine. When he came under my care he was living principally on skim milk, with a quart of Vichy daily, and passing about five quarts in the twenty-four hours, with a specific gravity of 1.024. The quantity of sugar was 2.09 per cent. He had, however, no thirst, or other symptoms of diabetes. I directed a continuance of the skim milk, and by April 15th the sugar had fallen to less than one-half per cent., while the specific gravity of the urine was but 1.013. He was ingesting six and a half quarts of skim milk, one quart of Vichy, and passing seven quarts of urine a day.

We then began to substitute unskimmed milk, and during the week terminating May 23d, he used nothing but unskimmed milk. The urine sent to me for examination, although having a specific gravity of 1.028, contained 3.4 per cent. of glucose. His tongue was coated, and he had a very unpleasant taste in his mouth. During the week ending June 9th the specific gravity ranged from 1.040 to 1.045, and although no analysis was made, the sugar had evidently increased. During the following week he went upon a selected anti-diabetic diet of eggs, stewed kidney, beefsteak, sliced tomatoes, cottage-cheese, stewed okra and celery, drinking at the same time two quarts daily of the solution of carbonate of lithium, and arseniate of sodium, and from three to

five pints of skimmed milk. The specific gravity fell to 1.022, but there was no analysis. This large ingestion of liquid was accompanied by a corresponding increase of urine, which did not, however, exceed six pints. At the end of the following week under the same general methods, except that no skim-milk was taken, a portion of the twenty-four hours' urine, forty-six and a half ounces, had a specific gravity of 1.030, and contained but two per cent. of sugar. In consequence of the combined treatment, it is impossible to say to what the improvement was directly due, but the patient himself was inclined to ascribe it to the lithium carbonate and sodium arseniate solutions. The case shows, however, the inferiority, if not the harmfulness, of unskimmed milk as compared with the skim-milk. It is difficult to explain why this should be the case, as it is well known that the digested fats do not pass through the liver, but through the lacteal system, and, therefore, on theoretical grounds the fat of unskimmed milk should not embarrass the liver, at least until it comes round to the liver again by the hepatic artery. It is, nevertheless, true, that unskimmed milk, so long as the disease continues, is a diet which fails to produce the results of skimmed. It has, however, happened to me that the use of unskimmed milk is attended by a reduction in the amount of urine and sugar contained therein, especially if it be gradually substituted for the unskimmed.

It is true that Dr. Flint in his sweeping declaration does not draw any line between the effect of skimmed and unskimmed milk, and it may be that his conclusions are based upon the use of unskimmed milk only. To me it is quite inexplicable how any one who has tried the skim-milk diet at all, should have come to a different conclusion from so many others, as well as myself.

Note.—Since the above was written the continued use of the lithium carbonate and sodium arseniate solution has satisfied me that it is fully as efficient as Clemens's solution of bromide of arsenic, although far from having the specific effect claimed by Martineau. It should be remembered, however, that Martineau says the remedy is especially useful in cases with a history of arthritic symptoms, "either articular or in the form of biliary or urinary lithiasis." I do not think attention has been called to this by others who have referred to this treatment.

THREE UNUSUAL CASES OF DIPHTHERIA.

By F. C. FERNALD, M.D.,
of Washington, D. C.

Case I. *Membrane extending from throat to external ear; use of trypsin; recovery.*—Male, aged six and a half years, white; has Pott's disease of two years duration, affecting mid-dorsal vertebræ; has had discharges from ears since early infancy, and for past nine months. Whenever the ears were syringed, some of the fluid passed into the throat and escaped from the nose, indicating perforation of both membranæ tympani, thus permitting the injected fluid to impinge directly upon the fenestræ of the inner ear, in consequence of which the intralabarynthine pressure became altered and the patient was made dizzy and nauseated, sometimes vomiting. The left ear had not been discharging for about four weeks.

March 3, 1887. Patient began to complain of slight sore throat, but was not seen by me until two days later, when examination of throat revealed a deposit of doubtful character on the right tonsil; it was easily removed with a mop, except a small piece, size of a large pinhead; the tonsils and fauces were neither reddened nor swollen to any noticeable extent, and there was but very little enlargement of the submaxillary glands; very slight fever; pulse good. He was not in bed, but was subdued and disinclined to play; directed him to be put to bed at once, and isolated.

4th. Considerably prostrated; membrane now covered about one-third of right tonsil, and a deposit was beginning on the left one.

6th. Membrane has entirely disappeared, but the mucous membrane of the fauces and pharynx was much congested, dark red in color; considerable swelling and some tenderness at the angle of the jaws and upper cervical glands on right side; complains of severe pain in right ear; last night had a smart hemorrhage from the right nostril; no coryza or hemorrhagic discharge from nose to-day; very weak.

Up to this time the treatment had been two grains of calomel every two hours till bowels became loose, then every four hours; stimulants were also given. Henceforth the calomel was discontinued, stimulants increased in quantity, and a poultice ordered over the ear and neck.

7th. Passed a sleepless night on account of paroxysms of excruciating pain, which he referred to the middle of his forehead; right ear now discharges muco-pus freely; right parotid gland swollen and tender; no longer any pain in swallowing; general condition good; poultice to be continued; discharge from ear to be removed with absorbent cotton, boracic acid insufflations; stimulants.

8th. Tragus swollen and tender, mastoid slightly so; pain in head still persists with unabated severity; *no membrane* to be seen in the external auditory canal; treatment continued with the addition of morphia to relieve pain, and syrup of phosphates of iron, quinine, and strychnine.

9th. Dr. C. W. Richardson made the visit with me. We found the external auditory canal filled with a diphtheritic deposit which extended into the concha of the ear, covering the inner surfaces of the tragus and antitragus, and partially filling the incisura intertragica; the external surface of the former not covered by membrane, but swollen, injected, and painful to the touch. The membrane could not be dislodged without force; any attempt to do so was painful and caused the subjacent skin to bleed. In accordance with Dr. Richardson's suggestions, I directed the ear to be thoroughly syringed with a weak solution of boracic acid every hour, after which the external auditory canal and the concha were to be filled with a solution of equal parts of water and liquor calcis; this solution was to remain in contact for five or ten minutes, then powdered boracic acid was to be insufflated in the ear; poulticing was discontinued.

10th. General condition not so good; membrane

has extended over the entire concha; swelling of parotid and neck much greater; treatment continued as before. A mixture containing *trypsin* was prescribed:

R.—Trypsin . . . . . gr. xxx.
Sodii bicarb. . . . . gr. x.
Aq. destillat. . . . . ʒj.
S. as directed.

I directed the trypsin to be used in place of lime-water solution as soon as it could be procured. The mother was told to syringe the ear every half hour, then to fill the external auditory canal with the trypsin mixture and to paint it over the concha.

11th (A.M.) Trypsin had not been used as directed; only one drop each time had been put into the canal, but had been painted on faithfully. However, the *membrane has entirely disappeared from the concha*, leaving an excoriated surface. The trypsin was now directed to be warmed (which I had inadvertently omitted previously) and to be applied every fifteen minutes, the ear being thoroughly syringed beforehand. The external auditory canal is still nearly filled with membrane; at no time since it has been present has any of the fluid passed into the throat, nor has any dizziness followed syringing. (P.M.) Since last visit, the trypsin mixture has gradually passed into the throat, as if it made a passage for itself through the diphtheritic deposit. The membrane is said to come away in small flakes when the ear is washed out; the deposit is thinning, and extends less far toward the meatus. The parotid is much less tender. I directed the trypsin to be applied every two hours and twice in the night.

12th. Membrane is disappearing very rapidly; swelling of parotid and neck greatly diminished. Trypsin every two hours.

13th. *No membrane to be seen;* the entire external auditory canal is excoriated and reddened; swelling of tragus and neighboring parts entirely gone. Trypsin discontinued.

For the past few days, patient has been unable to retain anything in the stomach, so that it was necessary to resort to nutrient enemata; a mixture of bismuth and creasote was given by the mouth.

16th. Stomach no longer irritable; is hungry; wants to be dressed and get up.

From this date his convalescence has been rapid and satisfactory; no paralysis has yet occurred.

Remarks.—The extension of diphtheritic membrane to the external ear is such a rare accident that most otologists do not even mention it in their books. Those who do speak of it—*e. g.*, Politzer, think that it is almost exclusively in scarlatinal-diphtheria that it is found. Doubtless in my patient, the chronically inflamed mucous membrane of the middle ear afforded a very fertile soil for the diphtheritic deposit, and the previous perforation of the membrana tympani allowed its extension without hindrance to the external ear, where the parts were already irritated from the long-continued discharges.

It is interesting to note that the deposit in the throat was not at all extensive, and that the involvement of the ears seems to be an extension of the membrane from the naso-pharynx, where a fresh deposit took place after that on the tonsils had disappeared. The epistaxis and the sudden and marked increase in the swelling of the cervical glands appear to me to indicate plainly the very moment that the naso-pharynx first became affected.

On account of the accessibility of the external ear, both to observation and to treatment, I had hoped to decide definitively the value of trypsin as a solvent of diphtheritic membranes.

But just how much was due to the trypsin, and how much to the mere macerating effect of the watery solution in which it was suspended, and also to the natural tendency of the membrane to exfoliate, is very uncertain.

This much, however, was observed, that while under the lime-water treatment, the membrane was evidently extending, yet very soon after the trypsin began to be used this tendency to spread was checked, and within twenty-four hours the thinnest part of the deposit, namely, that in the concha, had disappeared and within three days not a vestige of membrane was visible in the ear. Moreover, after the first few applications, the trypsin mixture opened a passage for itself through the obstructed external auditory canal into the throat. On the whole, I am inclined to regard trypsin with favor, and shall certainly try it again at the first opportunity.

Case II. *Diphtheria, paralysis of the diaphragm; death.*—Female, æt. six years, colored. Illness began Oct. 5, 1886; was first seen by me four days later, when patches of diphtheritic membrane were found on both tonsils, and on velum palati, with moderate enlargement of submaxillary glands. During the next few days the membrane continued to spread and to increase in thickness until on the 11th of Oct. it covered the whole of both tonsils, the pillars of fauces, the uvula, and the velum palati; the neck was enormously swollen. Eight days later the membrane had entirely disappeared, and the neck was of natural size. The voice, however, had been noticed to have a nasal intonation for a few days previously, and there was slight difficulty in swallowing, liquid coming back through the nose; during the entire attack there was but little fever; the prostration was excessive.

The treatment was tincture of chloride of iron and chlorate of potassium, and the following gargle:

R.—Liquor. sod. chlorinat. . . ʒiv.
Aquæ menth. pip. . . . ℥ss.
Glycerine . . . . . ad ʒiv.

This gargle was not distasteful to the patient, and controlled the fetor completely. Brandy was given freely. Oct. 21. Syrup of the phosphates of iron, quinine, and strychnine, and syrup of iodide of iron were substituted for all other medication. She improved slowly but progressively, and as I did not anticipate any further trouble, I ceased my visits on Nov. 2d.

About a week afterward I was summoned to see her again. She had been seized suddenly the night before with very high fever and vomiting. In the interval between my last visit and this time, paresis had developed in both legs, and in the muscles of the neck also, to such a degree that the head drooped forward upon the chest. She could

raise her head, however, but could not hold it erect for more than a few seconds; there was a good deal of trouble in deglutition, as the velum palati was now paralyzed completely. I prescribed a simple febrifuge. The next day found her about the same, except that the fever was much less. Prescribed $\frac{1}{24}$th grain of strychnine in suppository three times a day. On the following morning she was extremely weak, wholly unable to swallow, could not rid the pharynx of mucus, which was very abundant and tenacious; respirations were labored, but not accelerated; examination of lungs negative. Strychnine continued; nutrient enemata with brandy ordered. In the afternoon the embarrassment of respiration was greater; the breathing was almost entirely costal, the abdomen scarcely moving. Strychnine continued.

11th. (A. M.) Could swallow liquids more readily, but they caused coughing. (P. M.) Seems brighter and stronger; great quantity of mucus in pharynx. Administered $\frac{1}{32}$d grain strychnine hypodermatically.

12th. (A. M.) Passed a very restless night, but there were no toxic symptoms from the strychnine. Rids the pharynx of mucus with less trouble. (P. M.) General condition unchanged; almost no action of the diaphragm, as shown in the act of coughing, particularly. Strychnine suppositories continued.

13th. Lividity of nails and hands; respiration exceedingly labored; paralysis of diaphragm now complete, being shown by the fact that the epigastrium and the hypochondria were drawn inward during inspiration instead of being curved outward, as normally. Moreover, the protrusion produced in health by the descent of the diaphragm could not be felt. The lower ribs, during inspiration, were raised excessively and with a heaving motion. The cervical accessory respiratory muscles being already paralyzed could not be brought into action, hence there was but very little motion of the upper part of the thorax. Strychnine continued; mustard plasters applied to back of neck and to chest, and heat to extremities.

14th. (A. M.) Much to my surprise, could now swallow milk and brandy without the least trouble; otherwise her condition was the same. Gave $\frac{1}{16}$th grain strychnine, hypodermatically. (1 P. M.) Much worse; hypostatic congestion of lungs had now developed; mucus accumulating rapidly in trachea and bronchi. Gave $\frac{1}{16}$th grain of strychnine and four minims of tincture of digitalis and tincture of belladonna, hypodermatically. (8.45 P. M.) In my absence patient died very quietly, having become very cyanotic. There was no evidence that the strychnine had produced its toxic effect.

REMARKS.—Paralysis of the diaphragm is mentioned in our text-books as one of the rarest among the sequelæ of diphtheria, but when it does occur, the case, as a rule, terminates fatally. It seems very odd that this child should regain the ability to swallow so completely, and yet be so near to death. Whether the strychnine was of any service, or whether it did harm, it is impossible to say. At first I hesitated to employ it on account of the elevation of temperature, which, however, was never above 101.5° after I began to use it. The sufferings of the patient were dreadful to behold, and the utter inability to relieve them by any therapeutic measures was profoundly impressed upon me.

CASE III. *Diphtheria with extensive disturbance of sensation.*—Female, æt. ten years, colored. When I first saw her she was three weeks convalescent from a moderately severe attack of diphtheria. The only trouble she complained of at this time was great difficulty in walking (not so much from weakness, as from unsteadiness of gait), and slight difficulty in swallowing, fluids returning in part through the nose. I found that she was analgesic in legs and arms, but for lack of time deferred making a thorough examination until several days subsequent. Prescribed $\frac{1}{12}$th grain strychnine in solution, three times a day, and syrup of iodide of iron.

The following are my notes of what was discovered at the next visit: Nasal intonation of voice; paralysis of velum palati; gait ataxic, worse when the eyes were closed; inability to stand steady with the feet together and eyes closed; patellar reflex absent; some muscular weakness of legs, especially the right one, and of the right arm; complete loss of sense of smell as far as could be detected by spirits of camphor, cologne water, and kerosene; sense of taste absent over entire tongue; says she cannot taste salt, pepper, or strychnine, which I applied; hearing apparently normal; she has been very short-sighted for several years, but thinks she cannot see as well as formerly; no satisfactory test of sight could be made; complete analgesia was found over nearly the entire body, including the face and head, the exceptions being a circumscribed space in the palms of both hands, and in the soles of both feet, also along the sides of the spine in the dorsal region, but even in these parts the sensation of pain was much diminished. At any of the analgesic parts a pin could be thrust entirely through a fold of skin without the least pain to the patient. The mucous membrane of lips, mouth, and tongue, also, could be pricked as hard as possible, without producing the least pain. There was great diminution of the tactile sensibility. This was tested by means of a rough æsthesiometer in the shape of a pair of carpenter's dividers, with very sharp points. Nowhere could she detect that she was being touched with more than one of the points, even if they were four or five inches apart. She was also unable to distinguish heat from cold. For this test, two vials, one filled with hot water, the other with cold water, were used.

Several other physicians examined the patient subsequently, and found the same condition that I did, so that there was no deception; the girl was unusually intelligent, and very willing to submit to examination. There was no evidence of hysteria, either now or in the past.

The strychnine was continued in the same dose ($\frac{1}{12}$th grain) for several weeks without any upleasant effects, except for the first two or three days, during which there was slight stiffness of the jaws and neck, and a feeling of general uneasiness.

After one week of treatment she began to complain of the bitterness of the medicine; could taste

other things also, her gait was improved considerably. Two weeks later, could smell for the first time, and was able to swallow without difficulty. She continued to improve, and, in about six weeks from my first visit, all the abnormal conditions had disappeared, and she was perfectly well.

REMARKS.—It is not infrequent to find more or less disturbance of sensation preceding or accompanying diphtheritic paralysis, but usually confined to the paralyzed parts. I have not been able to find any case reported in which the disturbance of sensation was so great and so extensive, as in this patient. Such cases are, probably, quite rare, but I believe not so rare as one would at first suppose, for my patient was quite unaware of her condition, which would have escaped unnoticed without the very careful examination that was made.

USTILAGO MAYDIS.

A STUDY OF THE DRUG WITH REFERENCE TO ITS EMPLOYMENT AS AN OXYTOXIC.

BY W. A. N. DORLAND, M.D.,
RESIDENT PHYSICIAN AT THE PHILADELPHIA HOSPITAL.

THE group of the Ustilagineæ, or smuts, of the natural order Fungi, as classified by Fischer de Waldheim, embraces a large number of species which are scattered throughout the various known countries of the globe, the United States laying claim to over twenty distinct varieties. Included in this number are some which have especially attracted the attention of scientists, and of these the ergot of corn, Ustilago maydis, has of late attained a prominent position.

Ustilago maydis, corn ergot, or corn smut, as it is variously known, is the parasitic fungus which is found infesting the young ears and tassels of the common maize or Indian corn. It appears as irregular swellings of a bright steel-gray color, which become darker as they increase in size, and as they mature are filled with a brown-black powder, the spores of the growth.

Strange as it may appear, this fungus, though inhabiting what may be called the American staple of food, and though known to botanists[1] for over a century, has never been thoroughly studied as to its chemical analysis and therapeutic properties, though from time to time, since its first introduction to scientific notice, it has received a limited degree of attention from pharmacists and physicists.

In one of the earliest papers on the subject, Mr. Crissler[2] reported as the result of his investigations in the analysis of the growth, the discovery of secalin, propylamin, and other minor constituents of the ergot of rye, and suggested that the drugs, being chemically similar, might be possessed of like therapeutic values. This invited investigation, and since then various reports and monographs on the drug have been published, especially within the last four or five years.[3]

It is not the object of the present article to discuss at large the results of the labors of the different investigators. After careful deliberation they have variously recommended its employment in the treatment of all maladies in which the use of ergot would be indicated. This paper, however, will be confined entirely to a consideration of the main therapeutic value of the drug, namely, as an oxytoxic.

The attention of the medical profession was first turned to this property of ustilago by the fact that pregnant cows fed on corn infested with this parasite, almost invariably threw off their young within a week's time. This created considerable interest as to whether a like effect would be produced in other cases, and bitches and other pregnant animals were treated to the drug, all promptly aborting. By reasoning from analogy, naturally the question arose as to whether the drug would not be valuable in parturient women when there was marked uterine inertia or persistent post-partum hemorrhage, the old stand-by, ergot, having frequently failed to perform its rôle in such cases. Certainly, all the indications seemed to tend in this direction.

Once suggested, it was not long before scientific practitioners tested the practicability of the logical conclusions which had been arrived at. In 1877, Estachy[2] records the successful employment of ustilago in a case of suspended labor pains, and in the same year Dr. C. Henry Leonard[3] reports similar cases, in which he had used the drug with marked success. These results have from time to time been confirmed by others, who have strongly advised the adoption of the drug as a substitute for ergot in like conditions.

During the past three months, May to August, while serving as resident obstetrician to the maternity wards of the Philadelphia Hospital, the writer enjoyed the opportunity of testing the efficiency of Ustilago maydis in those cases in which the parturient pain had either almost or entirely died away after complete dilatation of the os uteri had been accomplished—that is, during the second stage of labor. Through the kindness of his friend and colleague, Dr. M. J. Donohoe, he was also given the privilege of employing the drug in similar cases under his charge. The record was as follows:

CASE I.—Frances C., colored, age twenty-three, III-para, R. O. P. Labor began 7 P.M., May 3d. At 11 A.M., May 4th, the pains had considerably subsided, though the os was fully dilated and the occiput had descended in the parturient canal midway between the superior and inferior straits.

11.52. Pains feeble. Administered twenty minims ustilago.

12.12 P.M. Pains very powerful and effective. Rotation of the occiput now accomplished.

12.15. The membranes ruptured.

[2] National Dispensatory, Mitchell and Stillé, 3d edition.

[3] Am. Journ. of Pharm., 1877.

12 24. Delivered of a healthy male child, weight seven pounds.

CASE II.—Mary J., age thirty, II-para, L. O. A. Labor began 3 A.M.

9.05 A.M. Os fully dilated, head engaged. Pains weak and inefficient. Gave 15 minims ustilago.

9.30. Pains more severe. Membranes ruptured.

9.37. Pains weaker; gave 15 minims ustilago.

10.05. No increase in the force of the pains; gave 20 minims ustilago.

10.40. Still no noticeable effect; gave 30 minims ustilago.

11. Pains stronger, more frequent, clonic in character.

11.30. Delivered of healthy male child, weight 7⅞ pounds.

CASE III.—Eliza H., age eighteen, I-para, L. O. A. Labor began 4 A.M. Pains weak and inefficient from the first.

2.27 P.M. Os dilated, head engaged. Gave 20 minims ustilago.

2.50. Pains much stronger and increasing in force.

3.50. Delivered of healthy male child, weight 5¾ pounds.

CASE IV.—Sophia K., age forty, II-para, R. O. A. Labor began 9 A.M., May 13th. Continued at irregular intervals throughout the day and night.

9.05 A.M., May 14th. Pains every fifteen minutes, weak and without effect. Gave 3j ustilago.

9 25. Pains stronger and occurring every minute and a half.

9.56. Pains growing weaker. Gave 3j ustilago.

10.50. Still weak. Gave 3j ustilago.

11.10. Pains stronger, clonic in character.

11.20. Delivered of healthy female child, weight 5 pounds 15 ounces.

CASE V.—Anna W., colored, age thirty, I-para, R. O. A. Labor began 12 P.M., May 21st. Admitted to the wards 2 A.M., May 23d.

4 A.M. Pains entirely subsided. Gave 3j ustilago.

4.35. Slight pains. Gave 3j ustilago.

4.45. Pains increasing in severity.

5.12. Delivered of a healthy female child, weight 7½ pounds.

CASE VI.—Ada C., colored, age twenty-two, II-para, L. O. A. Labor began 8 P.M, May 31st. Pains continued throughout the night and morning of June 1st, when, the head being fully engaged, they gradually died away, ceasing during the afternoon.

11.31 P.M. Gave 3j ustilago.

12. Pains strong and natural. Head advancing.

12.30. Delivered of a healthy male child, weight 9¼ pounds.

CASE VII.—Mary H., age twenty, I-para, L. O. A. Labor began 8 P M., June 5th. Pains were strong and frequent during the dilatation of the os uteri, and continued throughout June 6th at irregular intervals. Complete dilatation accomplished at 4.30 P.M.

7 P.M. Head engaged. Pains becoming weaker.

9.10. Administered 3j ustilago.

9.30. Strong, efficient pains. Head advancing.

9.47. Delivered of a healthy female child, weight 8 pounds.

CASE. VIII.—Elizabeth T., age twenty, II-para, R. O. A. Labor began 11 P.M., June 13th.

6 A.M. Pains quite weak. Patient sleeping during the intervals.

7 A.M. Pains entirely suspended. Gave 3j ustilago.

7.35. No pains as yet. Gave 3j ustilago.

8. Slight pains, increasing in force.

9. Pains strong; head advancing.

9.25. Delivered of a healthy male child, weight 9½ pounds.

CASE IX.—Mary T., age twenty-three, II-para, L. O. A. Labor began 11 P.M., July 4th. Though the patient had a stout physique, the pains throughout were extremely feeble.

10 A.M. Head resting on the perineum. No pains for fifteen minutes.

10.25. Still no pains. Gave 3j ustilago.

10.50. No effect noticed. Gave 3j ustilago.

11.20. Has occasional weak pains. Vomited some, part of the ustilago in the ejecta.

11.45. Weak pains at long intervals.

11.54. One severe pain. Delivered of a healthy female child, weight 9 pounds.

The above comprises all of the cases within the three months in which it was deemed necessary to employ the drug to shorten the duration of labor. Before proceeding, it may be as well to state that the patients were all in good physical condition, that all were at term, and that all made a rapid and complete recovery.

Having, now, this record before us, let us endeavor by a careful examination of the cases, to group the results of our experiments, that we may the more clearly ascertain the value of the drug. Three or four points seem to stand out prominently, demanding our consideration.

1. *The toxicology and physiological action of the drug.*

No cases of poisoning in man by the drug are on record. That it is, however, possessed of toxic properties in large doses has been proved by Mitchell.[1] He found that in the lower animals, in large doses, it acted violently upon the spinal cord, paralyzing first the sensory, later the motor tracts, finally involving the motor and probably also the sensory nerves. Like ergot, then, it is probable that the chief force of the drug, in toxic doses, is expended upon the nerve centres, producing a toxic paralysis.

As may be understood, our studies on the physiological action of ustilago were necessarily limited. After the administration of the drug in three instances, notably in Case IX., there was considerable nausea, followed in the latter by vomiting of the ustilago, together with the other contents of the stomach. This nausea seems to be of a similar nature to that produced by the ergot of rye, and calls for no further discussion.

The action of ustilago upon the uterus has been more carefully noted. After the ingestion of a sufficient amount, in from twenty minutes to half an hour, the pains, if present, are increased in severity, in frequency, and in duration, presenting a marked *clonic* character, following each other in frequent

[1] Dr. James Mitchell, Inaug. Thesis, Univ. of Pa., 1883

succession, with a decided intermission between each. In this respect it differs decidedly from the action of ergot, which, in full doses, produces one continuous, *tonic* spasm of the uterine muscle. It is this property of ergot which has, when administered before the delivery of the placenta, produced in so many instances the irregular contractions of the uterus, of which the hour-glass is a well-known example. The employment of ustilago seems to be entirely free from such unpleasant complications.

In addition to being a valuable adjuvant in stimulating weak uterine contractions, ustilago seems to possess the property, which some years ago was ascribed to quinine, namely, of exciting uterine pains when entirely suspended— see Cases V., VIII., and IX.). This has been noticed by Leonard and others.

As to the time required for the action of the drug to become apparent, it may be said that it differs in different cases, depending, undoubtedly, upon the rapidity with which it is absorbed from the gastro-intestinal tract and carried into the system. In the above record, in only two instances (Cases VIII. and IX.) did it require over thirty-five minutes before the ustilago acted upon the uterine tissues, and in the latter case it will be remembered that most of the drug was ejected by emesis. In the remaining seven cases the average time required was twenty-five minutes.

The effect produced by ustilago upon the other unstriped muscular tissues of the body has not been inquired into. Probably it produces the same increase of intestinal peristalsis and the same rise in the arterial pressure due to vaso-motor spasm as is produced by ergot. This is yet open to investigation.

2. *The indications for the employment of the drug.*

It may be noticed that in all the above cases the ustilago was not administered until complete dilatation of the os had been accomplished. Whether or not a disastrous effect would be produced by the administration of the drug prior to the commencement of the second stage of labor cannot be stated. As yet, that question has not been decided. From the study of the physiological action of ustilago, we should think all danger of the irregular contractions of its compeer, the ergot of rye, would be precluded, and that if there were any possibilities of the exigencies of the case demanding its use, it might be employed with impunity during the first stage of labor. At present, however, we shall consider the first indication for its use to be the failure of the pains, with *complete dilatation of the os uteri.*

In none of the cases was the drug employed until the pains of labor had either become so weak that they were inefficient to accomplish the expulsion of the fœtus, or until they were entirely suspended. This, then, we consider the second indication for its use, namely, the *inefficiency or entire suspension of the parturient pain.*

After the ustilago had been taken, it may also be noticed that in no case was there the slightest tendency toward a post-partum hemorrhage. In each case, after the expulsion of the placenta, the uterus remained in a state of firm contraction. While, during the three months the great majority of the remaining cases, in which the customary ergot had been employed, showed no tendency whatever toward this alarming accident, however, in two instances was there such an occurrence demanding prompt attention. The third indication, then, for the employment of ustilago we shall consider to be *a condition of uterine inertia threatening or producing post-partum hemorrhage.*

3. *The dose and mode of administration.*

The preparation of ustilago employed in all reported cases, as well as in our own, was a good fluid extract. The dose of this varies from one-half to two drachms, one drachm being a fair average. This may be repeated at intervals as required. Should it be necessary, it may be used hypodermatically in doses of from five to fifteen minims.

Finally. *The advantages of ustilago over ergot.*

Dr. Frank H. Potter in a paper on the "Proper Use of Ergot in Obstetrical Practice,"[1] closes his article with a series of ten conclusions. In these he states that when administered during labor the action of ergot is uncertain, producing irregular contractions, rigidity of the os, with interference of the placental circulation, or too rapid expulsion of the fœtus, jeopardizing the maternal tissues. He also asserts that the life of the child is endangered through absorption of the oil of ergot, and that indirectly the drug may prove a cause of puerperal septicæmia by preventing the removal of every portion of the placenta and membranes. His last conclusion is as follows: "The proper use of ergot in obstetrical practice is limited to those cases in which, after the expulsion of the placenta, the uterus refuses to contract, or having once contracted, shows a tendency to secondary relaxation. Even in these cases reliance should not be placed upon it alone, but its action should be supplemented by the other means used to provoke uterine contraction."

When compared to this formidable array of objections the employment of ustilago seems much to be preferred to that of ergot. It does not produce irregular contractions with all the consequent complications and sequelæ; containing but two and a half per cent. of fixed oil, while ergot contains from twenty five per cent. to twenty-eight per cent., the dangers of absorption are reduced to a minimum; and, finally, as it can be procured at a cost of fifty per cent. less than that of ergot, it seems to be on a fair highway toward the supplanting of the latter in obstetrical practice, should the results of the investigations thus far be confirmed by subsequent researches.

Philadelphia Hospital.

SPIRILLUM, FINKLER AND PRIOR, IN HEPATIZED LUNG-TISSUE.

By THEOBALD SMITH, M.D.,

of the Bureau of Animal Industry, Department of Agriculture, Washington, D. C.

The invariable presence of a specific microbe, the so-called comma bacillus, in the intestinal tract of cholera patients was first demonstrated by Koch.

[1] Buffalo Med. and Surg. Journ., Sept. 1886, quoted in Therapeutic Gaz., Nov. 15, 1886.

The interest which after the publication of his investigations attached itself to forms resembling this comma bacillus led to the more careful study of two other microbes closely resembling this. One, found by Finkler and Prior in the stools of patients affected with cholera nostras, gave rise to much discussion at the time as to the real value and significance of Koch's discovery. Careful observation, however, of the growth of this second form in culture media showed well-marked and constant differences between it and Koch's comma-bacillus. Moreover, its presence in cholera nostras has been demonstrated in a few instances only, and it has been found by W. D. Miller in a tooth cavity and by another observer in the cæcum of a man who committed suicide.[1] A third form found by Deneke in cheese was likewise differentiated from Koch's comma-bacillus by means of cultivation, so that the latter still remains to be found in localities other than the intestines and dejecta of cholera patients.

Recently these comma-bacilli have been classed as spirilla. Although there may be some doubt as to the strict propriety of this nomenclature, it is certainly the best at our disposal, and in this paper they shall be so denominated.

Several months ago, in examining cultures from hepatized lung-tissue of a cow, the result of pleuro-pneumonia, I found in every one of twelve tubes several kinds of bacteria. Among others, a spirillum was present in almost every tube, the close resemblance of which to the spirillum of cholera and to the others mentioned above was of sufficient importance to warrant a more careful examination. Various media, including nutrient gelatine and agar-agar, blood serum and beef infusion had been inoculated by adding a minute bit of recently hepatized tissue (red hepatization) to each tube. The various microbes, chiefly bacilli, which had multiplied in the cultures after one or two days, had, very probably, found their way into the lung-tissue shortly before or after death and multiplied there. The heat was very great at the time and no special precautions had been taken by those removing the lungs from the body to keep foreign bacteria away. The source of the spirillum cannot, therefore, be inferred. It may have come from the ice which had been placed upon the lungs during transportation. After the rather laborious process of isolating it from several liquefying bacilli various culture media were inoculated in order to observe its mode of growth. Through the kindness of Dr. E. O. Shakespeare I was enabled to compare it with cultures of the three spirilla thus far discovered. By making cultures of all at the same time and exposing them to similar conditions of temperature, relative alkalinity, and concentration of culture media, accurate comparisons could be made.

The spirillum under consideration resembles the spirillum Finkler and Prior so closely that it may be regarded as a slightly modified variety of this microbe. For the sake of brevity it will be denominated spirillum β, the original spirillum of Finkler and Prior, spirillum α. The spirilla mentioned above have been very carefully described in many publications by writers on cholera, so that the reader will be spared any unnecessary repetitions.[1]

In tubes and on plates, spirillum β liquefies the commonly used 10 per cent. gelatine *much more rapidly* than spirillum α. At a temperature of 22° to 24° C. the plate containing colonies of the former was completely liquefied on the third day, that containing colonies of the latter only partially so. The colonies[2] of these two forms do not differ in any other way. Before liquefaction sets in, they present a homogeneous, circular disk with sharp, regular margin and a darker central nucleus which appears on the second day.

In tubes spirillum β liquefies the gelatine twice as rapidly as spirillum α during the first two or three days. Later on, both microbes seem to experience the same difficulty in the downward liquefaction of the gelatine, and after the first week they look alike.

On boiled potato spirillum α grew best at 20°–24° C. Spirillum β multiplied very slightly at this temperature. A feeble growth may appear at 35° C., which then resembles that of spirillum α in color and consistency. In general the latter grows far more vigorously on potato than the former.

In liquid media such as simple beef infusion, or beef infusion containing 1 per cent. peptone, both made slightly alkaline with sodium carbonate, the multiplication of this organism and of the other spirilla deserves some attention. The employment of liquid media as an accessory means of distinguishing them from one another, has not received any attention whatever, although it is of considerable value as the following shows: If the spirilla of Koch, Finkler, and Prior, and Deneke, be added to beef infusion and the tubes placed in a temperature of about 35° C. the following changes may be seen after twenty-four hours. The tube inoculated with Koch's spirillum will be clouded and the surface of the liquid covered with a delicate, but complete membrane. Beneath this the upper strata will be quite turbid from the very abundant massing of spirilla. The infusion inoculated with the Finkler and Prior spirillum is barely opalescent, without any trace of a surface membrane. The third tube inoc-

[1] Flügge: Die Mikroörganismen, 2d ed., p. 385.

[1] Very good descriptions will be found in Flügge (l. c.).

[2] In studying these it is very important not only to know the concentration of the gelatine employed, but to keep it in as uniform a temperature as possible, since both of these conditions have a marked influence upon the characters of the colony in its development. It is exceedingly difficult to realize a uniform, low temperature, both in summer and winter. In summer, the temperature in this climate is above the melting point of 10 per cent. gelatine for weeks and months. In winter a thermo-regulator usually fails within the narrow limit between the average temperature of the laboratory and that at which it is desirable to maintain the gelatine. A given per cent. of gelatine at a low temperature is equivalent to a larger per cent. at a higher temperature. The density, in other words, is increased when the temperature falls. We know, for instance, that the most important diagnostic feature of the cholera spirillum is the peculiar appearance of its colonies on the gelatine plates—a certain irregularity of outline combined with a marked refrangibility as of "particles of glass." The writer has, however, seen these very colonies present smooth, sharply outlined disks, differing from those of the other spirilla only in size. This loss of characteristic features was due to an abnormally low temperature at the time. A few days later, another plate growing in a higher temperature presented colonies of the usual type.

lated with the Deneke spirillum remains permanently clear. These differences have reappeared with each succeeding test, so that they may be regarded as constant; the same is true of beef infusion containing 1 per cent. peptone.

That the spirillum of Koch has a tendency to rise to the surface in culture media and there form a membrane, is not a new fact. It has been made use of by investigators Schottelius, Büchner, Gruber, in demonstrating the presence of this microbe in cholera stools. A minute portion of the latter is added to beef infusion and the whole allowed to stand in an open vessel in a warm place. After a few days, sometimes only after five or seven days (Gruber) the spirilla will be found on the surface. It must be borne in mind that by this process a number of bacteria are introduced into beef infusion at the same time with the spirilla, which may interfere more or less with the growth of the spirilla at the surface. That the three spirilla may be thus readily distinguished in pure beef-infusion cultures has not yet been suggested, so far as I know. It should not be lost sight of in endeavoring to identify the spirillum of Koch in cases of suspected Asiatic cholera.

The spirilla *a* and *3* entirely agree, so far as their growth in liquids is concerned. In a few cultures of *3*, a membrane has appeared, but only after standing undisturbed one or two weeks.

In milk kept at 22° C. there is for nearly two weeks no microscopic change. At the end of this time, however, spirilla *a* and *4* have caused precipitation of the casein. The precipitate contracts into a very firm mass at the bottom of the culture tube, and a layer of acid watery fluid, equal in bulk to about one-half the original volume of milk, rests above the coagulum. A parallel culture of the spirillum of Koch shows even at the end of three weeks no change. When placed at 35° C. the process of precipitation and settling sets in in four or five days with the spirilla *a* and *3*, while no change is observed in cultures of the spirillum of Koch after two weeks.

The microscopic examination of the various culture media reveals organisms not differing appreciably in size or form from the other comma-bacilli. It is, in fact, quite impossible to distinguish them by this means alone, especially when we bear in mind that all very slightly curved rods or spiral form according to the composition of the culture medium and the age of the culture. The short comma form always predominates. In older cultures, particularly in beef infusion, numerous perfect spirilla are found consisting of from one to very many complete revolutions of the spiral body. When dried on cover glasses and stained in an aqueous solution of fuchsin prepared from an alcoholic solution these longer spirals are, as a rule, resolved into commas, and the true spiral form is more or less obliterated. The comma forms are exceedingly active in their movements, even when the cultures are two or three weeks old. They dart to and fro with great rapidity, or revolve about one of their extremities as a fixed point. The spirilla whose movements are slower show very well the corkscrew-like revolution about their long axis as they move across the field.

This spirillum was destroyed by a ten minutes' exposure to 58–60° C. When taken from gelatine cultures and dried on sterile cover glasses, it was incapable of infecting beef infusion after four hours, indicating that in cultures four to five days old no resistant spore-state had been formed. No inoculation or feeding experiments were made upon animals.

The rather tedious and laborious work of identifying this microbe has led to the following results: A comma bacillus or spirillum not distinguishable from the spirillum of Koch under the microscope was found in hepatized lung-tissue. After isolation and cultivation in different media it resembled the spirillum Finkler and Prior very closely, and, was, therefore, easily distinguishable in this way from Koch's cholera spirillum. It differs from the former only in liquefying gelatine more rapidly and in growing more feebly upon boiled potatoes. The name, spirillum of Finkler and Prior *3*, is provisionally suggested.

The conclusion which was reached by Koch that the spirillum found by him is exclusively associated with Asiatic cholera is not modified but rather confirmed indirectly by these results. They throw no light, however, on the supposed relation between cholera nostras and the spirillum of Finkler and Prior.

CASE OF ACUTE ERGOTISM OCCURRING AFTER THE INGESTION OF A FLUIDOUNCE OF THE FLUID EXTRACT OF ERGOT.

BY LAURE HULME, M.D.,
OF WEST CHESTER, PA

TAKING into consideration the widespread use of ergot, cases of acute poisoning from the drug are of very infrequent occurrence—in fact, almost unknown, and when met with are ascribed either to an idiosyncrasy on the part of the patient or to some impurity of the preparation.

On the other hand, epidemics of a peculiar nature, due undoubtedly to the continued ingestion of large quantities of ergotized breadstuffs have occurred in Europe and have been described by the various writers on the subject.

Single cases of chronic poisoning from the long-continued use of ergot, resulting in gangrene of the extremities, etc., are occasionally seen. In Caspar's *Vierteljahrschr. H.* Bd. xiv., S. 46, the following record of experiments with ergot is given:

"A quantity of bread which contained sixty grains of ergot, eaten at once, produced a burning sensation in the stomach and unconsciousness. These symptoms appeared after half an hour and continued in some people from 10 A.M., until 3.30 P.M. In another experiment, sixteen grains of ergot in bread were given at one time. This produced increased warmth in the region of the stomach, increased flow of saliva, nausea and headache. In the course of an hour all these symptoms disappeared. The action of large doses of ergot, mixed with bread and eaten for a length of time, depends, as found by experience, upon the constitution of the individual, the age, mode of life, etc. Ten grain doses can be taken for a considerable time."

The following case well illustrates the acute toxic effects of the drug in a mild form: Mrs. M., aged

forty-eight years, married twenty-eight years, two children, youngest fourteen years old, has suffered for several years from the presence of fibroid tumors of the uterus, causing menorrhagia. One of these tumors, being pedunculated, was removed two years ago by the ecraseur. One submucous nodule of about the size of a hickory-nut was allowed to remain. The patient recovered from the operation without any bad symptoms. The menorrhagia was lessened for several months, but again increased. She had had hot vaginal injections in connection with the remedies usual in such cases, with little benefit from any. On the second day of the menstrual period, the flow being excessive and proving more uncontrollable than usual, at 10 A.M. I administered one small teaspoonful of Squibb's fluid extract of ergot, and left the patient quite comfortable. On returning, less than forty minutes afterward, I found her in a half fainting condition. The countenance was swollen, pallid, and denoted great anxiety; the respirations were shallow and frequent; the extremities were swollen, and the hands increased about one-fourth in size. The abdomen was also much enlarged. Pulse was frequent, weak and irregular. The pupils were equally dilated and vision indistinct. She complained of great dizziness and nausea. The flow continued as before and no signs of uterine contraction were evident; she had no pain.

I administered whiskey f3j, and aromatic spirits of ammonia, gtt. x, every half hour, until at 2 P.M. she felt stronger and her pulse was normal in frequency (although very full and quick). The pupils were still widely dilated and vertigo prevented the patient from leaving the bed. The swelling of the face and extremities continued to increase until 7 P.M. In twenty-four hours the symptoms began to decrease and gradually subsided, the dizziness and indistinct vision being the last to disappear and lasting several days.

One of the most interesting points in this case was the absence of all evidence of uterine contraction, unless the nausea can be referred to this cause, as it is by Dr. Keating in a case mentioned in Ringer's *Therapeutics*, when the nausea attendant upon the administration of ergot in a case of fibroid tumors was much increased by the introduction of the finger into the os; and also in a case which came under my own observation where the introduction and dilatation of a sea-tangle tent caused little pain, but great and constant nausea and vomiting until the dilatation was complete, when all symptoms ceased entirely.

As to what to ascribe the deleterious effects of the drug in this case, I am at a loss to determine. The preparation was freshly procured from a reliable druggist, and has not caused any disagreeable symptoms in the patients to whom I have administered it since. The patient had frequently taken ergot on former occasions and in as large a dose.

In reference to the frequency of acute ergot poisoning, Dr. H. C. Wood remarks: "Although I have given the fluid extract in ounce doses, I have never seen it cause distinct symptoms. Fatal abortion has several times been produced; but I know of but two instances of decided poisoning in a non-pregnant person." (Wood's *Therapeutics*.) According to the U. S. Dispensatory, "But one fatal case of poisoning has occurred, except when abortion has been produced." In a case occurring in the practice of a medical friend, Squibb's fluid extract was given to arrest a persistent discharge of blood after an abortion, and although its use was kept up for over a week (ten ounces were given in nine days) there was no perceptible effect of any kind whatever that could be traced to the drug.

In an article in *Med. Times and Gaz.*, vol. ii., 1879, entitled "Acute Poisoning by Ergot, followed by Tolerance of the Drug," a very interesting account is given of a case under the care of Dr. Meadows, in which, after the removal of a fibro-cystic polyp from the anterior wall of the uterus, a half a drachm of powdered ergot was given to remove any shreds of growth which might remain; this did not only cause decided toxic effects, such as "marked depression, nausea, headache, swelling of the hands, etc.," but it set up powerful uterine contractions, which lasted for two hours, when upon vaginal examination there was found presenting a tumor the size of an orange. The same toxic effects in an exaggerated form followed the administration of the drug in the same dose a week later. About two weeks after this second administration of ergot it was again given; but three half-drachm doses at intervals of six hours produced only slight toxic effects and no evidence of uterine contraction. In this case there was a "weak dilated heart, with marked systolic murmur."

Dr. John M. Keating (*Medical Record*, 1880) reports a case of labor in which "there were placental adhesions of great firmness, and consequently more than the usual amount of hemorrhage," and in which there was given by the doctor before leaving, f3ij of the fluid ext. of ergot, and subsequently, through a misunderstanding on the part of the nurse, a drachm every half hour; the amount given altogether being half a fluid-ounce. In this case there were alarming symptoms of poisoning, which, however, yielded to prompt treatment addressed to stimulation of the circulation.

Dr. S. J. Radcliffe, in commenting upon Dr. Keating's report, says that he had reported a case in which he ordered a drachm of Squibb's fluid ext. of ergot every half hour, and the patient took in twelve hours one and a half ounces without injurious effect. Never having had a case of ergot poisoning in his own experience, he is rather of the opinion that the "placental adhesions of great firmness, and in consequence more than ordinary amount of hemorrhage," in Dr. Keating's case were prominent factors in producing the symptoms described.

Dr. M. F. Leary, of Gayloid, Kansas, writing to Dr. J. M. Keating, says (*Ibid.*, Dec. 4, 1880):

"Some two years ago I had about the same experience with ergot that you have described. The case was one of miscarriage in which half an ounce of Squibb's fluid ext. of ergot was given by error (one drachm every half hour), followed by symptoms much resembling those in your case. In my case, I am satisfied that there was neither hemorrhage, shock, nor idio-

syncope at work, but that it was purely a case of poisoning by ergot."

One of the most interesting cases of acute ergot poisoning on record is that reported by Dr. G. S. Oldright (*Canada Med. Journal*, 1870): in this case there were first symptoms of spasm of the arterioles and diminished heart action, dizziness, syncope, coldness of the surface, followed by reaction, shown by most intense congestion of face and head, which latter condition very slowly subsided.

A CASE OF PERICHONDRITIS OF THE CRICOID CARTILAGE.

BY LOUIS JURIST, M.D.,

LECTURER ON LARYNGOLOGY, JEFFERSON MEDICAL COLLEGE, FELLOW OF THE COLLEGE OF PHYSICIANS, PHILADELPHIA.

Mr. H., æt. thirty-seven, married, of good habits and good family history, was treated by my friend, Dr. De Young, for a mild attack of bronchitis, limited to the upper lobes, from Sept. 9 to Sept. 12, 1885, inclusive. He again presented himself on Sept. 19th, complaining of huskiness and some cough without expectoration. There was no dysphagia, no pain, no external swelling, but considerable fever. The following day he remained much the same; his cough, however, inducing vomiting. On the 21st improvement began, cough diminished, the voice cleared up, and on the 22d, after a friendly chat with his physician, he expressed desire to follow his usual clerical work. This he was cautioned not to do, but disregarded the admonition and left for his place of business the following morning. He remained at his books until evening, and on his way to take a street-car home, noticed dyspnœa marked enough to necessitate resting several times while walking a block. At 7.45 P.M., he was suddenly seized with a suffocative attack. Dr. De Young, living in the immediate neighborhood, was at once summoned, and finding his circulation good, and no cyanosis present, considered his symptoms due to spasm. Shortly after he appeared easier and expressed a wish to sleep.

Dr. De Young having hastily sent for me, we reached him at 9 P.M., and found that he had just ceased breathing. An immediate laryngotomy and artificial respiration failed to restore him.

Post-mortem fifteen hours later, limited to the thoracic cavity. Lungs crepitant and pale; the right bound down by old adhesions. Heart normal, pale, filled with fluid blood, and clots. Contrary to expectation, laryngeal œdema was conspicuous by its absence. The laryngeal surface of the epiglottis was crimson in spots; there was arborescent injection of both arytæno-epiglottidean folds. Both ventricular bands, bright red. Vocal bands, particularly the right, reddened and infiltrated. About one-third of an inch below the right vocal band, there was a gangrenous patch of mucous membrane about one-third of an inch in diameter; on the left side, at a point exactly corresponding to this, a very much smaller spot of gangrene was also noticeable. The trachea was slightly red in patches. On splitting the larynx from behind, which should not have been done, the knife slipped into an irregular cavity on the right side, from which about half a teaspoonful of thick pus exuded. This cavity extended under the gangrenous patch above mentioned, and showed a curious condition of the cricoid cartilage, and loss of perichondrium. There was also a well-marked plate of ossification. On the other side, a similar but much smaller cavity was found, by carefully following a minute opening in the gangrenous mucous membrane.

The incomplete post-mortem permitted, together with the absence of a more extended history of the patient, make the determination of the etiology, as well as the exact mode of death in this case, almost impossible. The condition of the larynx and the lungs excludes tuberculosis. Acute primary perichondritis, running a rapid course, or a late syphilitic infiltration of the cricoid perichondrium, seem to be the only explanation. In the absence of the patient's history, and an ante-mortem laryngoscopic examination, this point must remain undetermined. As there was no extrusion of any portion of the cartilage, nor an amount of pus sufficient to cause suffocation, death was apparently due to prolonged laryngeal spasm. The case is interesting not only from the pathological standpoint, but as illustrative of a possible, though rare form of sudden death.

839 N. Broad Street.

HOSPITAL NOTES.

PHILADELPHIA HOSPITAL.

Service of Barton C. Hirst, M.D.

TUBAL PREGNANCY; RUPTURE OF THE CYST DOWNWARD; FORMATION OF A RETROUTERINE, EXTRAPERITONEAL HÆMATOCELE; RECOVERY WITHOUT OPERATION.

(Reported by Richard C. Norris, M.D., Resident Physician.)

A. N. was brought in ambulance to hospital July 19th with the following history: Æt. thirty-eight years, II-para, youngest child five years of age. After two days of hard work as a washerwoman, she was attacked with sudden, cramp like pain in the hypogastrium, increasing in severity until she fainted. Partial recovery, with profuse sweating, great prostration and alarm were followed by two successive fainting spells and the discharge of blood from the vagina. This occurred six weeks subsequent to her last menstrual period.

Abdominal palpation disclosed a tumor in right iliac region. Vaginal examination showed an upward and forward displacement of the cervix behind the symphysis, with an elastic, fluctuating, and tender tumor occupying the posterior vaginal wall, and extending in the direction of the right broad ligament. The tumor became firmer and tense after two or three days. A close watch was kept for any discharged shreds of membrane, but none was found, and there was no history of any before coming to hospital. When admitted the temperature was 99°, and for sixteen days ranged between 98.5° and 100.5°, once rising to 102°, but quickly falling after being catheterized. The pain and tenderness largely disappeared three days after admission. On the twelfth day the tumor rose slightly above the pelvis, the pain and tenderness returned, lasted about one week and again disappeared, without subsequent recurrence.

The patient was allowed to get up two weeks after admission and was practically well, serving in the capacity of a ward assistant until September 12th, when she was granted a few hours liberty and did not return to the hospital.

At the last vaginal examination, made a few days before she left, the uterus had almost regained its normal position, the tumor was apparently solid and considerably contracted, although not to the extent expected from the length of time it was under observation.

MEDICAL PROGRESS.

Oil of Turpentine in Diphtheria.—Roese, of Hamburg, treated 58 cases with a mortality of 3 (5 per cent.), as follows: oil of turpentine was given in teaspoonful doses three times daily; it was mixed with spirits of ether in proportion of four minims of ether to the teaspoonful of oi of turpentine. In addition a tablespoonful of a 2 per cent. solution of sodium salicylate was given every two hours; externally an ice bag was used, and locally gargles of 1 per cent. warm solution of potassium chlorate. The results were.

1. Rapid diminution in pulse rate and temperature.
2. The subjective symptoms were rapidly alleviated.
3. The duration of the illness was shortened.
4. An exacerbation of the local process was not observed after the first dose of oil of turpentine.
5. Danger of suffocation occurred but once, when tracheotomy was done.

Roese considers pencilling the throat to be generally futile as done in private practice. He exercised great caution in pushing oil of turpentine in anæmic individuals and those having diseased hearts. Excessive heart action, from any cause, was carefully treated. The nourishment given was bouillon, old port wine and milk; to quench thirst ice and aërated fruit juices were used. As soon as the patient was free from fever turpentine was discontinued. In ordinary cases from 3 to 5 drachms sufficed; as much as 15 drachms were sometimes used. No intoxication was observed. Paralysis occurred once, and recovery followed the use of potassium iodide. — *Therapeutische Monatshefte*, October, 1887.

Antifebrin as a Disinfectant.—Dr. S. A. van Leer has been prosecuting a number of researches in the Hygienic Laboratory at Groningen on the antiseptic properties of antifebrin (acetanilide). When added to milk, so as to saturate it, acetanilide prevents it from turning sour; similarly, albumen can be kept from becoming putrid. It does not, however, seem a suitable substance for dressing wounds, as it does not easily dissolve or become moist, and irritates the surface of wounds. Dr. van Leer examined the effects of solutions of antifebrin of various strengths on several kinds of bacilli, and found that the development of many of them was not by this means prevented; consequently he does not think that the suggestion of Leube to employ antifebrin for surgical dressings is likely to prove of any advantage.—*Lancet*, October 15, 1887.

Saccharin.—In addition to the formula of Fischer (The Medical News, October 22, 1887, p. 480), the following are convenient modes of administering this substance:

Liqueurs may be sweetened with saccharin in the proportion 1 to 8000. A saccharin syrup may be made with

Saccharin	30 parts.
Carbonate of soda	11 "
Water	100 "

Saccharin and quinine may be given as follows:

Saccharin	1 part.
Carbonate of soda	1 "
Water	100 parts.

With this fluid mix thoroughly one part of sulphate of quinia, and drink at once.—*Therapeutische Monatshefte*, October, 1887.

Avulsion of Ingrowing Nails under Hypnotism.—Dr. S. L. Trivus, of St. Petersburg, relates a case in which he removed an ingrowing nail from the great toe of a cook after a hypnotic state had been induced in the patient. The operation lasted about twenty minutes. At first the woman occasionally moved her foot about, but when the author had suggested to her that no more pain was to be inflicted, and that the foot must be kept at rest, she sat quite quiet until the matrix of the toe was incised. At that point of the operation she shrieked out, and when questioned about the cause, stated that "a dog had just bitten her." After applying the dressing, Dr. Trivus woke her up, and asked her whether she would consent to the operation. She hesitated a little, and then said, "Yes, go on." On his pointing to her bandaged foot, however, she at once guessed that all was over already, and burst into laughter followed by hysterical sobs. No pain was felt until the next day, when she became somewhat lame. Dr. Trivus also relates an instructive case in which a man of twenty-five, after having been hypnotised for the sake of experiment and subsequently awakened, could not return to his normal state for several hours: when left alone, he was seized with a kind of hypnosis, and on his way home fell into a deep swoon in the street.—*British Medical Journal*, October 15, 1887.

The Effect of Iodoform Vapor upon the Cholera Germ.—Buchner, of Munich, has made a series of experiments to determine the effect of iodoform upon Koch's comma-bacillus. He found that when iodoform, in powder, was placed in tubes containing culture material infected with bacilli, there remained an upper zone where the bacilli did not develop. After several days the iodoform was removed, when the bacilli at once invaded the zone. It was evident that the bacilli were not destroyed, but that their action was inhibited. Pure iodine was substituted for iodoform, when no such inhibitory action resulted. Other volatile antiseptics, among them carbolic acid, were inert. Buchner considers the value of iodoform to consist in its power of penetrating, by its vapor, the deeper tissues, where it increases their resistance to bacteria, and inhibits bacterial growth. It is, then, an indirect antiseptic. We are, therefore, in therapeutics, not to rely upon the direct action of the drug. As a contrast,

Buchner uses tuberculin, whose effect upon the tissues is direct and intelligible.—*Münchener medicinische Wochenschrift*, No. 25, 1887.

THE CAUSE OF TYPHOID FEVER.—Investigations made by Brieger, Pasquet, and others, seem to have demonstrated that a ptomaine produced by the typhoid bacilli when injected into animals may cause a disease resembling typhoid fever. The ptomaine was discovered by Brieger, and named by him "typhotoxine." It is this substance, and not the germ directly, which is the cause of typhoid fever in man, according to the most recent theory. The *London Medical Record*, in commenting on these researches, draws the following conclusions from them: "1. The symptoms and alterations observed in animals in which cultures of typhoid bacilli had been injected are due to the toxic substances secreted by these bacilli. 2. The noxious germs, which secrete typhotoxine, are reproduced in the intestinal canal. From these the ptomaine is taken up by the circulation, and carried to all the organs liable to be affected by this poison. 3. It is most probable that the same takes place in abdominal typhoid fever of man. 4. A first infection induces immunity against the injurious effect of a later infection, even of large quantities of the toxic substance. 5. Further experiments and careful clinical investigations are necessary in order to establish a scientific support of the theory of immunity from infections of sterilized cultures containing not more than a determined quantity of typhotoxine. 6. In case this theory be an ascertained fact, the reproduction of the same immunity in man would be justified by commencing with very minute doses of typhotoxine, which would be gradually increased according to the results obtained."

A CHEMICAL TEST FOR THE CHOLERA BACILLUS.—BUJWID, in the *Zeitschrift für Hygiene*, describes a chemical test for the detection of the presence of the cholera bacillus. He adds to a bouillon-culture of the bacillus from five to ten per cent. of ordinary muriatic acid. In a few minutes a rose-violet color appears, which increases in intensity for half an hour. It remains unchanged for several days. This reaction occurs in bouillon-cultures ten to twelve hours old, and in gelatine-cultures after twenty-four hours. The coloring is increased by heat. It is claimed by Bujwid that this color is characteristic of the bacillus of Asiatic cholera, and distinguishes it from all others.

CLINICAL POINTS REGARDING ERYSIPELAS.—LINDÉN believes that there is no relation between the severity of an operation and the liability to erysipelas afterward. The number of patients and number of wounds under treatment have no bearing on the frequency of erysipelas. Meteorological conditions have no influence on the prevalence of erysipelas, excepting sudden changes in atmospheric pressure and temperature. The occurrence of erysipelas after operations is less dependent on the severity of the operation than on the infection of the wound with foul discharges.

The duration of erysipelas depends on its extent; it is least prolonged when upon the head and upper extremities, and most prolonged when on the lower extremities. Erysipelas endures longest in weak patients. Post-operation erysipelas is more prolonged than that occurring without an operation. Scar tissue and integument subject to irritation are more favorable to the spread of erysipelas than healthy integument. The first attack is generally most severe. After seven or eight months a recurrence is as severe as an original attack. Hypodermatic injections of alcohol and antiseptic dressings are the best treatment.—*Deutsche medicinische Wochenschrift*, October 13, 1887.

FORMULÆ FOR THE USE OF STROPHANTHUS.—ZERNER and LOEW have used tincture of strophanthus and Merck's strophanthine in Bamberger's wards in Vienna. They observed nausea and vomiting as occasional unpleasant after-effects. Their prescriptions were:

℞.—Tinct. strophanth. . . . ♏ 23 to 45.
Aquæ destill. . . . . ℥ss
Syrup simpl. . . . . ℥ss to ʒss.

The whole to be taken during twenty four hours. Subnitrate of bismuth was given when diarrhœa occurred. Also:

℞.—Strophanthin (Merck) . . gr. $\frac{1}{50}$ to $\frac{3}{50}$.
Aquæ destill. . . . . ℥ss
Syrup. simpl. . . . . ʒss.

For use during twenty-four hours.—*Gazette Médicale de Paris*, October 15, 1887.

THE TREATMENT OF PULMONARY TUBERCULOSIS BY FINELY POWDERED BORAX.—FEROGLIO, of Cagliaro, has treated five cases of phthisis by inhalations of compressed air laden with finely powdered, carefully dried borax. When reported, the treatment had persisted but fifteen days. The effects were an improvement of all the symptoms presented by the cases.—*Centralblatt für die medicinischen Wissenschaften*, October 8, 1887.

TREATMENT OF GONORRHŒA IN WOMEN.—SINCLAIR, in the *Medical Chronicle* for October, 1887, advises the following method of treatment, which has been introduced by Schwarz, of Halle:

"First of all, the vulva and vagina are thoroughly cleansed from the adhering secretion by means of a 1 : 1000 sublimate solution, then with the help of a Simon's speculum, the vagina and vulva, including every fold and recess, are energetically swabbed with a pledget of cotton-wool soaked in a one per cent. solution of the sublimate, and rubbed with it for several minutes, so that the superficial layers of the epithelium containing the gonococci are removed. The Simon's speculum, or some other with separable blades (such as Bozeman's, etc.), is essential for the purpose in view; by this means it is possible to distend the folds of the vagina to their utmost extent, and to obtain a complete controlling view of the whole process, so as to avoid missing any of the diseased patches. Special care is taken with the introitus, which contains numerous folds.

"The next step is copiously to dust over the vagina and vulva with iodoform, which is still more effectively applied by rubbing it into the mucous membrane with the tip of the finger.

"To complete the process, the vagina is with moderate firmness packed full of iodoform gauze.

"If the treatment is very painful, a thing which depends upon the intensity of the disease process, and the idiosyncrasy of the patient, a narcotic or anæsthetic must be administered.

"The process is of value only when thoroughly carried out, but then it is certain to succeed.

"If, as is usual in rubbing the vagina, there occurs extensive capillary hemorrhage, it is only a favorable sign, inasmuch as it shows that at the bleeding points the diseased epithelial covering is for the most part removed, and, at the same time, a large number of the superficial, perhaps diseased, capillaries are destroyed.

"The iodoform gauze is permitted to remain for three or four days, and then the whole process is repeated with the same thoroughness, and over the same area.

"After four or five days more the gauze is finally removed, and then, for eight to fourteen days, the patient carries out a copious irrigation of the vagina with a sublimate solution of 1 in 2000."

This process was hardly ever known to fail. The vagina is red and raw after the second tampon has been removed, and there is usually a copious purulent discharge, "but the gonococci are annihilated, and have for ever vanished."

Acid Solutions of Sublimate as Disinfectants.—Laplace has made a study of the effects of acid solutions of corrosive sublimate as disinfectants, and concludes as follows from his work, which was done in Koch's laboratories, at Berlin: Sublimate, with tartaric acid in solution, can be recommended as a surgical disinfectant dressing for the following reasons:

By combining the action of tartaric acid, we obtain the full action of sublimate in fluids and surfaces containing albuminoids. Infected wounds should be irrigated from ten to twenty minutes daily; a single thorough cleansing is enough for fresh wounds, after which a dressing of tartaric acid-sublimate gauze is applied.

Tartaric-sublimate gauze does not interfere, in any degree, with iodoform and the other substances commonly used in surgery. It gives in the laboratory and in practice better results than sublimate alone. It does not irritate wounded tissues. Sublimate dissolves better in solution of tartaric acid than in water alone. The compound solution does not decompose in the tissues or dressings, and is cheap.

Solutions may be made after the following formulæ:

Corrosive sublimate . .	1 part.
Tartaric acid	5 parts.
Water	1000 "

for irrigation.

For the preparation of dressings:

Corrosive sublimate . .	5 parts.
Tartaric acid . . .	20 "
Distilled water . . .	1000 "

may be used, in which dressing material should soak two hours, after which it may be wrung out and dried.

Laplace's investigations consisted of experiments in Koch's laboratory, and in von Bergmann's and Fehleisen's clinics. He had previously demonstrated that the efficiency of sublimate and carbolic solutions as germicides is greatly increased by the addition of hydrochloric acid. — *Deutsche medicinische Wochenschrift*, October 6, 1887.

Tea-drinking and Pharyngitis Sicca. — Dr. Downie reports, in the *Practitioner* for October, 1887, that "Some three years ago I pointed out to students a form of dry pharyngitis occurring in badly fed, anæmic women, which I then in great part ascribed to the excessive use of cheap, and, therefore, inferior, tea. On inquiry it was found that those women had tea with almost every morsel of food of which they partook, and the tea, of a rank odor, was not simply infused, but literally *stewed*.

"For a time, in addition to proscribing the use of tea (recommending the substitution of cocoa or milk), I advised the liberal use of farinaceous food with milk, and prescribed a chalybeate tonic, under which the patients rapidly recovered. After a time I prescribed no medicine, directing the change of diet indicated alone, with the same beneficial results; but patients are never thoroughly satisfied unless they get a bottle, and as preparations of iron materially assist in the cure of the accompanying anæmia, I have returned to my former prescription. Those patients when asked if they use much tea confess to it freely, but add that since the throat became so dry they have quite lost taste for it—have 'turned against it.'

"Now in all such cases I look upon this form of dry pharyngitis, which does not involve the naso-pharynx as in *pharyngitis sicca*, as in great measure due to the gastric derangement—the dyspepsia—induced by the constant use of stewed tea shortly before, with, or immediately after meals, as well as to the local effect on the pharynx itself of this frequently-applied astringent and irritant lotion. And just as we forbid the use of tobacco in certain inflammatory conditions of the mouth and fauces, so the total abstinence from tea should in all cases be rigorously enjoined."

Tests for the Purity of Antifebrin.—Yvon has found the following tests reliable, in studying the properties of the drug in the laboratory of Dujardin-Beaumetz:

1. It should possess no odor.
2. It should be perfectly white.
3. Heated on a platinum foil, it should give a colorless liquid.
4. When thus heated, it should be entirely volatilized, leaving no residue.
5. It ought not to give with hypobromite of sodium an orange-yellow precipitate.

This last reaction, which is very delicate, is obtained whenever acetanilide retains any traces of free aniline. — *Therapeutic Gazette*, Oct. 15, 1887.

Antifebrin in the Feebile Diseases of Children.—Hidowitz is quoted as follows on this point by *The Archives of Pediatrics* for October, 1887.

The author reports the use of antifebrin in fifty-three cases, including four of scarlatina, eleven of measles, eleven of measles with subsequent pneumonia, two of measles with tuberculosis, two of facial erysipelas, four of croupous pneumonia, two of lobular pneumonia, two of pleuro-pneumonia, four of bronchitis, three of tuberculosis, four of follicular tonsillitis, three of gastricismus, one of acute intestinal catarrh. An interesting fact is that at the end of ten or twenty minutes after the medicine was taken the temperature began to decline, and con-

tinued steadily until it reached its lowest mark. After remaining at this point for a short time it began to rise again. The rapidity with which the temperature declined seemed to depend not so much upon the size of the dose as upon the peculiarity of the child and of the disease. Another observation was the very favorable effect upon the general condition of the children. Those who had previously been restless and fretful became quiet and soon fell asleep. In several instances the severe symptoms connected with collapse were quickly relieved after the ingestion of the medicine. Scarlatina and erysipelas were more rebellious to the antipyretic action of the drug than any of the other diseases in which it was used, the temperature falling only a few tenths of a degree. In pneumonia occurring as a complication of measles, in croupous and lobular pneumonia, in measles complicated with tuberculous affections of the stomach and intestines, the antipyretic action of the drug was prompt and energetic. The pulse became fuller, its frequency being diminished, though not always in proportion to the decline of the temperature, the respiration became deeper and more quiet. The drug was given in the form of powder, and in doses of 1½ grains to children three or four years of age. To older children, 3 or 4½ or even 7½ grains were given. Small doses usually sufficed for poorly nourished children, the reaction being much more energetic than in more robust children. As much as 30 grains were given in the course of a day. The antifebrin never produced any perceptible effect upon the duration of the disease. In some cases of croupous pneumonia its use was accompanied by profuse perspiration, with cyanosis of the face and the ends of the fingers.

FORMULÆ FOR PURGATIVE MIXTURES.—In obstinate constipation:

Ol. ricini	ʒ ss–i.
Syrup. rhei.	ʒ ss.
Alcohol.	ʒ ss.
Essent. menth. piper.	gtt. ii.

In one dose or two as needed.

As podophyllin is insoluble in water, a chemist has prepared a "liquor of podophyllin," containing one-sixtieth of a grain to fifty minims. This may be prescribed as follows:

Liquor of podophyllin	ʒ ss to 3.
Decoction of aloes	ʒ ss.
Tincture of capsicum	gtt. 5.

An agreeable purgative powder or mass results from the combination of the following ingredients:

Rad. jalap. pulv.	1 part.
Sennæ fol. pulv.	1 "
Sacchar. albæ.	1 "
Tamarind. pulp.	6 parts.

which may be partially dried and made into chocolate-covered tablets.—*Revue de Therapeutique*, October 1, 1887.

STAB-WOUND OF ABDOMEN AND COLIC ARTERY; RECOVERY.—DR. JENKINS, of Henderson, Kentucky, reports the following case in the *Annals of Surgery* for October, 1887:

There was a cut in the meso-colon, involving about two-thirds of its thickness, situated about midway between its fixed border and the transverse colon. The cut was about three centimetres long, transverse in direction, and evidently made by the point of the knife. The clot being rubbed out of the cut, it began bleeding in a weak diffused jet. The bleeding vessels had retracted into the tissues of the mesocolon and could not be caught by forceps until the peritoneum on the superior surface was scissored up. The severed arteries were the main right branch of the arteria colica media and a branch thereof. Ligated proximal and distal ends with sublimatized catgut. Iodoformed wound. This part of the operation was most difficult, owing to the poor flickering light; several candle-moths also fell upon the peritoneal field of operation. Digital exploration of the wound in the wall of the belly was made beneath the guts. It was found to be transverse in direction, a little to the right from middle of the epigastric region, about five centimetres long, slanting inward to the right, the right rectus abdominis entirely severed, the circumference of the wound tightly strangulating the expressed bowel (thus probably preventing lethal hemorrhage from the arteria colica media). Systematic reduction was attempted in narcosis but failed. The wound was then enlarged by an incision extending from its inner angle to the umbilicus, after which restitution was effected. The peritoneum of the extrusion had become glazed and opaque from the long action of the carbolic acid. The various peritoneal apartments were sought out, particularly Douglas's sac and the recessus duodeno-jejunalis, and wiped with sublimate gauze; only light blood staining, serum seemed in excess. Air expressed, wound closed with eight deep silk sutures, snowed external wound under with iodoform, sublimate gauze dressing. The only bad symptoms that followed were decided intestinal tympany on third day with slight abdominal pain (no morphia used). His temperature on that day registered the highest—101°. He left hospital apparently well.

A NON-IRRITANT ANTISEPTIC LIQUID.—LÉPINE, who has studied the combination of various antiseptic substances, has found the following an efficient and non-irritant compound:

Corrosive sublimate	gr. $\frac{1}{10}$.
Carbolic acid	gr. 1½.
Salicylic acid	gr. 1½.
Benzoic acid	gr. ¾.
Chloride of lime	gr. ¾.
Bromine	gr. $\frac{1}{6}$.
Hydrobromate of quinia	gr. 3.
Water	ʒ 25.

This fluid may be used by parenchymatous injection or in dressing wounds.—*Journal de Médecine*, October 9, 1887.

RAPID ANÆSTHESIA.—DR. CORNING has used the following device, which he describes in the *New York Medical Journal* of October 22, 1887, as follows:

A strong, flat elastic tourniquet was secured around each of the patient's thighs, so as to arrest both the arterial and venous blood-flow in the same. By this procedure each limb was converted into a species of receptaculum for a considerable proportion of the total blood-mass, or, as a distinguished friend of mine who

was present put it, "about one-third of the man was cut off," and consequently it was only necessary to saturate the remaining two-thirds (of the total blood-mass). The ligatures being in place, the ether cone was applied over the mouth and face of the patient, and in about three minutes by the watch the patient was anæsthetized. On the completion of the operation, the ligatures were removed and the patient recovered from the effects of the ether instantly. This rapid recovery from the effects of the anæsthetic created considerable comment from the medical gentlemen present, and was certainly a very interesting phenomenon from whatever physiological standpoint one chooses to view it.

The Life of the Teeth Independent of the Roots.—Rose, in a recent work published by Hirschfeld, of Leipzig, concludes, from the study of necrosis of the jaws, that teeth can continue to live after their roots have been entirely destroyed by resection of the bone, if the alveolar membrane and teeth are allowed to remain *in situ*.—*Deutsche medicinische Wochenschrift*, October 6, 1887.

Creolin versus Carbolic Acid.—Dr. E. von Esmarch, assistant in the Royal Hygienic Institute of Berlin, has made a series of experiments with creolin, a new disinfectant, which has been highly spoken of by Professor Fröhner, of the new Veterinary School of Berlin. Dr. von Esmarch made a number of comparative observations with carbolic acid on the disinfecting, deodorising, and antiseptic properties of creolin. Amongst other observations, he noted the effects of the two substances on fluids containing cholera, typhus, and anthrax bacilli. As a rule, creolin appeared to be much the more active. Similarly the offensive smell of various putrefying liquids was controlled much more readily by creolin than by carbolic acid. Creolin soap, too, showed itself more active as a disinfectant than corrosive sublimate soap.—*Lancet*, October 15, 1887.

Useful Applications for "Toothache."—The following may be inserted into a carious tooth:

Camphor,	
Chloral	ää 5 parts.
Cocain. hydrochlorat.	1 part.

An oily liquid results from the mixture.

Experience with cocaine has shown that in many cases it irritates the nerve to which it is applied, and that oil of cloves is more efficient.

Beginning superficial periostitis of the jaws may be promptly checked and the pain cured by painting with tincture of aconite and tincture of iodine, equal parts: the application should be entrusted to a physician only. —*Revue de Thérapeutique*, October 1, 1887.

The Histology of Reunited Intestines.—Bishop concludes, from micro-photographs of sections made of intestines after suture:

First, that there are three distinct stages in the process of intestinal union, namely, primary, or peritoneal union; secondary, or the stage of contraction; and tertiary, or cellulo-fibrous union. Secondly, that each is complemental to the others, and that the process cannot be considered complete until the whole three have been passed through. Thirdly, that in considering the action of sutures upon the wall of the intestine, and in forming any judgment as to the best method of using them, regard should be had to each and all of these three stages.—*Medical Chronicle*, October, 1887.

Treatment of Diphtheria by Oxygenated Water.—Hofmokl has used the following in diphtheria, by the gastro-intestinal tract or locally:

Oxygenated water (2 per cent. solution)	℥ 50.
Glycerine	ℏ 45.

A teaspoonful may be given every one or two hours.

This may be given by inhalation. The effects of the medicine are an abundant salivation: the false membranes have in some cases been rejected in three or four days, and in others in six or nine days.

The medicine is a tonic against anorexia.—*Journal de Medecine*, October 9, 1887.

Salol.—Bielschorvski, of Breslau, treated 27 cases of rheumatism with salol, of whom 19 were promptly cured; 2 resisted salol and yielded to salicylic acid; the remainder became chronic. Relapses occurred eight times, but yielded to salol. The drug was given in capsules, in doses ranging from 30 grains to 2 drachms in five hours. The smallest quantity which effected a cure was 3¼ drachms; the greatest quantity taken was 11 drachms. The disease was generally checked in three days; 1 case resisted treatment for ten days. In 4 cases mild affection of the heart were present, which disappeared. The urine showed the presence of carbolic acid, and gave a violet color with ferric chloride.

Rosenberg, of Berlin, was not so successful. After the use of 90 grains to 2 drachms in twenty-four hours, a prompt effect was produced, but complications were frequent. One case resisted salol, but yielded to sodium salicylate promptly. Rosenberg also observed all the unpleasant effects caused by salicylates after the use of salol. The smallest dose which produced an effect was 1 drachm, given during twenty-four hours. Rosenberg considers salol a "masked salicylic acid."

Feilchenfeld, of Berlin, obtained good results from 30 to 45 grains of salol daily, in cystitis and pyelitis, in acute cases, and also in hypertrophied prostate. Strangury followed the use of the drug in one case; in the others no ill effects were observed.—*Centralblatt für klinische Medicin*, October 15, 1887.

Five Years of Gastric Surgery.—Maydl reports forty gastrostomies in five years in Albert's clinic in Vienna. There were thirty operations for carcinoma of the œsophagus, and ten for other œsophagea stenoses. Twenty-one patients recovered. Mortality fifty-seven per cent. Patients suffering from carcinoma perished sooner or later. Three patients were permanently cured of stenoses from other causes. In these cases the stricture was dilated by passing bougies from the mouth and emerging in the wound. Maydl considers gastrostomy a much more valuable operation for stricture of the œsophagus than œsophagotomy. He would perform it, if occasion offered, for recent injuries to the œsophagus. Two resections of the pylorus were performed; one patient recovered, and one died of peritonitis.—*Internationale klinische Rundschau*, Nos. 3–22, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE . . . . . $5.00.

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in registered letters.

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, NOVEMBER 5, 1887.

THE CONTROL OF QUARANTINE.

Recognizing the paramount importance of preventing the importation of cholera into the United States, we published on Oct. 29th, in an extra issue of THE NEWS the Report of the Committee of the College of Physicians of Philadelphia to investigate the efficiency of our quarantine arrangements for the exclusion of cholera and other epidemic diseases. The report contains an exhaustive relation of the state of affairs existing at the ports of New York, Philadelphia, and Baltimore. It discloses many startling facts which cannot be regarded as less than highly disquieting, and which will doubtless even excite alarm in the minds of some, and we are forced to admit that it will not be entirely groundless. As the testimony of thoroughly competent and independent observers, a committee of one of the most conservative and respected medical bodies in America, it carries with it the weight of conviction, and conclusively proves the urgent necessity of a radical reform in our method of guarding the country against devastating epidemics with which we are, through foreign communications, from time to time threatened.

The quarantine establishments at Philadelphia and Baltimore are entirely unprepared and insufficient to prevent the spread of cholera, should either of them have the misfortune to be called upon to deal with a large number of immigrants with this disease among them, or its germs infecting their baggage. In the language of the report "there is no reason to believe, from the published official descriptions, that the conditions of the other ports of entry upon our Atlantic and Gulf coasts are in any respect superior," and indeed the same may, with equal justice, be said of the various ports along the lakes, through which thousands of immigrants annually reach the West, by way of Quebec and Montreal.

This country has been exposed to the introduction of cholera into one or more of her ports for the last four years. From the Mediterranean, from both coasts of South America, and from the eastern coast of Asia, this scourge might at any time during this period have been spread among us by the arrival of immigrants and baggage from infected places. Yet with all this warning and time for ample preparation, we find ourselves at last surprised by an attack which, because of its very tardiness, seems to have been entirely unexpected. The suspicious continuance of the disease among the immigrants, so long after their arrival and detention at the New York quarantine station, prompts an investigation, and a state of defences at New York, Philadelphia, and Baltimore is revealed, which, even if local interests alone were involved, can be characterized as nothing else than deplorable. Should, however, the germs of cholera finally escape or be permitted to pass beyond quarantine, they may not limit their onslaught to the nearest city, but may spread over the land and ultimately carry sorrow and loss to homes hundreds and even thousands of miles distant from the port where they entered.

The case of the "Independente" well illustrates how this may happen. A few days after their arrival and detention at New York for twenty-six hours, immigrants brought by this steamship from infected ports in Italy and Sicily reach Philadelphia, Baltimore, Syracuse, Chicago, and pass through St. Louis *en route* for Colorado, without any warning whatever from the quarantine officer of the port of entry. If they were not themselves affected with cholera, they carried with them baggage which had certainly been packed in infected districts, possibly in houses where cholera had raged. It has been stated that at least some of this baggage was not disinfected at New York, and it is safe, in consideration of all the circumstances, to affirm that none of it was effectually disinfected, even if the attempt had been made during the detention of twenty-six hours, inasmuch as neither the baggage nor the immigrants were, removed from the ship until all were landed at Castle Garden.

The chief value of the work of the Committee will be improperly appreciated by those who are most interested, namely, the public at large, if it does not lead to an earnest effort to bring about an immediate and satisfactory improvement in the provision and proper administration of the means of protecting the health of the country. The abuses and the faults of an exclusively local quarantine, such as at present exists, are so natural and intrinsic

that we should by this time acknowledge the absolute need of a national protection of the general welfare by a national maintenance and administration of quarantine.

ACETPHENETIDINE.

In the *Centralblatt für die medicinische Wissenschaften*, No. 9, p. 145, 1887, Kast and Hinsberg call attention to the antipyretic influence of this compound, which is chemically very closely allied to antifebrin. In appearance it is of a reddish-black color, insipid, odorless, and sparingly soluble in water and glycerine, very soluble in warm alcohol, but insoluble in acid and alkaline liquids, especially in the gastric and pancreatic juices.

When 45 to 75 grains of the drug were administered to a dog it produced rapid respiratory movements, somnolence, and vomiting, with uncertainty in walking. These symptoms continued for three hours and were accompanied by a cyanosis of the buccal mucous membrane. The blood was also darker in hue than normal, due to the presence of methæmoglobin. In the course of a few hours more, however, these signs passed away and complete recovery took place.

Reasoning from these experiments that the drug was only capable of producing harmful results when given in very large doses, these observers turned to the bedside for the clinical information which was the ultimate object of their research, and found that in cases of phthisis from 3 to 7½ grains decreased the bodily temperature two degrees without much effect upon the pulse, but with a moderate amount of perspiration. There was no disturbance of the appetite, no nausea, and no vomiting. These writers, therefore, believe the drug worthy of further trial and the attention of the profession.

Still other tests as to its value have been made by Kohler, of Vienna, assistant to Bamberger, the records of which may be found in the *Wiener med. Wochenschrift*, Nos. 26 and 27, 1887. This observer used the drug in fifty cases of different diseases associated with fever, consisting of pulmonary phthisis (11 cases), croupous pneumonia (10 cases), typhoid fever (7 cases), and in puerperal septicæmia, pleurisy, pyæmia, and cerebro-spinal meningitis. The doses ranged from 3 to 7½ grains according to the age and susceptibility of the patient. He believes that its innocuousness is established, and he would not hesitate in pushing it strongly if need demanded it. Kohler also failed to discover any disagreeable effects produced by its ingestion, but evidently found more profuse sweating after its use than did Kast and Hinsberg.

The drug is eliminated by the kidneys, and changes the color of the urine to a dark-yellow hue, which becomes red on the addition of the perchloride of iron; and care must be exercised that the copper test be not used in testing for sugar, since the urine after the ingestion of acetphenetidine reduces a copper solution very strongly.

ON THE INCIDENCE OF ALBUMINURIA AMONG THE SICK.

We have still much to learn about the condition under which albuminuria occurs, and the significance of this extremely common symptom. In the *British Medical Journal* of October 15th, there is a valuable contribution to the question by Grainger Stewart, who has investigated the incidence of albuminuria among the sick of all classes, with the following results: In 150 private patients, 36 showed albumen, of whom only 13 had Bright's disease. Of 150 indoor patients, in 74 the urine contained albumen, and of these 26 had Bright's disease. Of 100 outdoor patients, 19 responded to the tests, of whom 8 had Bright's disease. Of 50 cases in the Children's Hospital, 7 had albumen, only 1 of whom had morbus Brightii; of 50 cases in the Fever Hospital, 33 showed albumen; of 25 patients in the Maternity Hospital, the urine of 18 contained albumen. In 40 cases of alcoholism, acute and chronic, 19 were albuminuric.

Albuminuria is certainly more common in disease than is usually supposed. Some of the inferences drawn by the author from the facts stated are that Bright's disease does not account for one-half of the cases of albuminuria met with in practice; but it accounts for more than any other individual cause. The changes in the renal circulation due to cardiac and other maladies, and accidental cases due to admixture of blood and pus in the urine, rank next in order. Dietetic, cyclic, and simple persistent albuminurias are rare. The albuminuria of Bright's disease is more abundant than in that due to other causes, though at first in the waxy and cirrhotic forms it may be so slight in amount as to be shown only by picric acid, by which reagent alone in some of the digestive and nervous cases, and in those due to high temperature the slight amount of albumen may be detected.

Professor Stewart makes no attempt to explain the albuminuria of the various conditions, but is content, for the present, with the statements above noted, which, it is hoped, may direct anew the attention of practitioners to the important fact that the presence of albumen in the urine does not necessarily mean the existence of Bright's disease.

THE EXPOSURE OF THE STENOCARPINE FRAUD.

For the last month or six weeks there has been a growing suspicion that gleditschine or stenocarpine was not what it purported to be, and that a gross fraud was being perpetrated on the profession, which

is always alert to try a new drug without, perhaps, question as to its source or previous history.

In The Medical News of last week Dr. Marshall, of the University of Pennsylvania, published the results of a careful investigation, carried out by him, on the solution sold in the shops as stenocarpine, in which he found a large amount of cocaine, and a smaller quantity of atropine, or an alkaloid of the same group, there being no distinctive tests between it, duboisine, and daturine. Articles also appear in the *Pharmaceutische Rundschau* for November by Nooy, of Ann Arbor, and in *The Medical Age* of the 25th ult., by Thompson, in which results identical with those of Marshall were reached. One of the New York firms which have been selling the substance has, too, within the last week published a disclaimer in which it pleads ignorance of the source of the alleged drug, and states that it has merely acted as agents of the manufacturers.

Moreover, it has been shown that the Gleditschia triacanthus possesses in none of its parts an alkaloid capable of allaying the functional activity of sensory nerves. The fraud does not stop here, however, for the solution is labelled as being of the strength of two per cent., while analysis proves the presence of over seven per cent. of solid matter, of which six per cent. or more is cocaine. This so-called two per cent. solution is retailed to physicians at one dollar and twenty-five cents a fluid drachm, and its ready sale has, therefore, netted a handsome profit to its manufacturers.

An esteemed New York contemporary three months since, first called the attention of the profession to the remarkable properties of this alleged new anæsthetic, and but a month ago, with its accustomed enterprise, laid before its readers an elaborate botanical description of the tree from which it was obtained, with beautiful illustrations of its leaves and branches to aid in its identification. Unfortunately, however, this has only tended to increase the harvest of those who, in duping our contemporary, have sought to impose this fraud on the profession.

In this connection we cannot but express the hope that in the future greater discrimination will be exercised by our journals as to the reliability of the statements to which they give currency, in order that they may protect their readers from, rather than expose them to grossly fraudulent imposition.

There are other features about this subject, which are of even greater importance than the mere discovery of the imposition, and are far from agreeable to the medical man who prides himself on the mental power and scientific conservatism of his profession. Lessons taught by such incidents as these, generally make their influence felt for a considerable length of time, and we hope that this one will, at least, teach physicians to look with distrust on any new drug, the history of which is shrouded in mystery.

Words cannot condemn with sufficient force the persons who have knowingly and deliberately carried out, with all its nicety of detail, this scheme. We do not know on whom the blame may be justly placed, but we do know that the momentary influx of dollars will never repay the men who have perpetrated the fraud.

Prof. Heneage Gibbes, of London, has been appointed to the Chair of Pathology in the University of Michigan. It is understood that Dr. Gibbes will accept the position, and will begin his work in February. With Dr. Klein, Dr. Gibbes constituted the English Cholera Commission to India, in 1884. Koch pronounces him one of the foremost of English bacteriologists.

The Medical Faculty of the University of Michigan have been so much gratified by the attendance upon the three years' courses of nine months each, that they have unanimously petitioned the Board of Regents to establish an optional fourth year course, which shall be given in Detroit, and shall consist wholly of clinical specialties.

The new laboratories of histology and physiology are now being occupied, while the hygienic laboratory is in process of erection. But the Department of Hygiene has been established, and for the present year the work will be done in rooms in the chemical laboratory. Dr. Vaughan has been relieved of his work in Materia Medica, and has been made Professor of Hygiene and Director of the Laboratory. Mr. F. G. Nooy has been appointed Instructor in Hygiene. Dr. Conrad George has been appointed to the Chair of Materia Medica. The new laboratory of hygiene will not be ready for occupation before October, 1888. It will contain rooms for chemical analysis of foods, water and gas analysis, bacteriological work, a disinfecting chamber, and a cold room.

On Sunday, October 23d, Dr. John G. Jay, Professor of Anatomy and Operative Surgery in the Woman's Medical College of Baltimore, performed the Cæsarean section upon a negro woman, aged twenty-seven years. The woman was not a dwarf, but was of good external development; internal examination, however, revealed an infantile pelvis, with a great narrowing of all the pelvic diameters. The antero-posterior diameter of the superior strait was estimated to be from one and three-quarters to two inches; hence it was deemed proper to perform the section rather than craniotomy. The operation was

done according to the method of Sänger, with three rows of sutures for the uterine wound, and a resection of the muscularis of the uterus. The child was born alive, but soon died. The mother is now in the seventh day, has had almost no fever, not much pain, no unusual lochia, and seems to be on the high road to recovery. The further report of this case will be awaited with interest.

The medical men of British Columbia have obtained an act of Legislature of that Province requiring that every physician who wishes to practise there, shall pass an examination before the Provincial Medical Board. So, now, three of the provinces, Ontario, British Columbia, and Quebec, have raised around them a Chinese wall of protection, for the liberal profession of medicine. There is to be no reciprocity.

John Murray Carnochan, M.D., died in New York, October 28th, aged seventy years. His death by apoplexy was very sudden, he had been in his usual good health two hours previously. He was a native of Savannah, Ga. His predilections for surgery were early marked, and were fastened for life by his entering the office of Dr. Valentine Mott as a medical student. In 1847 he began practice in New York, and three years later was appointed surgeon-in-chief of the Emigrant Hospital, a position held by him for nearly twenty years. He was Professor of Surgery for many years in the New York Medical College (now extinct), and was the author of several works on operative surgery. He was Health Officer of the port of New York, from 1870 to 1872. His name is identified with the bold operation, first done by him in 1856, of exsecting the second branch of the fifth pair of nerves for facial neuralgia, and with a large and original experience in the field of arterial surgery.

REVIEWS.

Druitt's Surgeon's Vade Mecum. Edited by Stanley Boyd, M.B., B.S. Lond.; F.R.C.S. Eng.; Assistant Surgeon to the Charing-Cross Hospital; and Surgeon to the Paddington Green Hospital for Children. Twelfth edition. 8vo. pp. xvi. 985. Philadelphia: Lea Brothers & Co., 1887.

An admirable edition of an old favorite. Few books have enjoyed a wider or longer sustained popularity, or have more fully come up to the ideal of a vade mecum than Druitt's *Surgery*. No less than 50,000 copies have been sold in England alone, while in this country the book has had extensive collegiate recommendation and Federal patronage. Mr. Boyd has revised, and, in great measure, rewritten the book, adding sections on surgical diagnosis, and giving greater prominence to pathology. The chapter on diseases of the eye has been omitted, and one on injuries of the orbit and its contents inserted instead. A large number of new, and some of them admirable illustrations, have been added, and the latest and best authorities are relied upon for the statements made, and the rules of practice laid down. Although Mr. Boyd says he has attempted to keep down the size of the book, from the enlarged field of modern surgery, and the additions to which we have referred, the volume has very considerably expanded in comparison with the "Druitt" of our youth. We have no hesitation in saying that the book is abreast of the times, and desirable for students, and especially for those practitioners who wish their book for surgical reference to be in the most condensed form.

Syphilis. By Jonathan Hutchinson, F.R.S., LL.D., Consulting Surgeon to the London Hospital and to the Royal London Ophthalmic Hospital; Vice-President of the Royal College of Surgeons. With 8 chromo-lithographs. 16mo. pp. xii. 532. Philadelphia: Lea Brothers & Co.

A valuable addition to the series of clinical manuals of its publishers, by an expert and accomplished writer, moderate in tone, judicious in spirit, and yet expressing the decided convictions of one whose experience entitles him to speak with authority, the student, no matter what may be his age, will find in this compact treatise a valuable presentation of a vastly important subject. It is in every respect abreast of the present state of our knowledge, and is well entitled to full confidence as the work of one who has made a lifelong study of the disease. The chromo-lithographs are very good illustrations of choroiditis and keratitis, of vaccination syphilis, of erratic chancres, and the changes produced in the tongue, teeth, and nails. Altogether we know of no better or more comprehensive treatise on syphilis, which at the same time is condensed into the small compass so much desired by the busy men of the present day.

SOCIETY PROCEEDINGS.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, October 26, 1887.

Charles McBurney, M.D., in the Chair.

EXSECTION OF THE ELBOW FOR TUBERCULOUS DISEASE.

Dr. Gerster presented a patient with the following history:

Rudolph B., aged twelve, was admitted to the German Hospital, having tuberculous osteitis of the right olecranon, with two large abscesses and a fistulous opening leading into the joint. On March 30th, a partial exsection of the elbow was performed, and a sequestrum was removed from the olecranon, a shell of bone being preserved, to which was attached the triceps tendon. No drainage tubes were inserted, but the joint was closed and put up in the semi-flexed position. On April 12th, the dressings were removed, primary union having occurred. The elbow was then put up at a right angle, and passive motion was employed every three or four days, in spite of the fact that it caused some pain and swelling. During one of the exercises the cicatrix was ruptured, and bloody serum exuded; after that,

there was a persistent serogarulent discharge. Later, exuberant granulations appeared about the fistula, so that it was necessary to scrape it out two or three times.

On June 10th, complete excision was performed, as ankylosis seemed to be inevitable. The soft parts showed gelatinous infiltration, especially around the head of the radius, while there was a cheesy focus between the ulna and radius. About an inch of the humerus, radius, and ulna were removed, and the joint was put up in a semi-flexed position, the dressings being left undisturbed for five weeks, when they were removed and *active* movements were made. The boy began to use his joint almost from the first, and has continued to improve ever since; it has not been necessary to use the ordinary apparatus with lateral hinges. There is now considerable mobility, flexion and extension being normal; while pronation and supination are fair and will improve. The speaker stated that he had reported the case in order to call attention to the fact that a good result might be obtained by a secondary operation after partial excision had proved to be unsatisfactory.

DR. SANDS thought that the result was quite good, since the arm could be flexed and extended very well in one plane. He assumed that no one questioned the advisability of performing the partial operation only when it would be likely to effect the desired result. He had presented a patient to the Society a year before, in whose case he had removed a portion of the ulna and condyles, there being a cheesy focus limited to one condyle. There was better motion subsequently than after complete excision. He no longer performed the complete operation when the partial one was sufficient. He had sometimes removed the synovial membrane alone, leaving the healthy cartilage. This practice was the reverse of the old rule, which prescribed complete excision in every case. The advantages of partial excision were conspicuous when operating for tuberculous disease of the knee in young subjects, as in many cases the parts affected could be thoroughly removed without serious disturbance of the epiphyseal cartilage, the destruction of which would interfere with the growth of the limb.

DR. GERSTER said that he desired to lay particular stress upon the fact that passive motion had been entirely withheld, and active movements had not been begun until the swelling had subsided. The old teaching was to commence "early" movements after the operation; but this meant in from six to eight weeks, because formerly there used to be abscesses around the joint, so that manipulation had to be delayed. He believed that he had often begun to make movements too soon, as a result of which he had caused ruptured of the connective tissue and effusion, thus retarding the healing. It was better to wait until the swelling had entirely subsided, and then to try active movements only.

DR. WEIR thought that the tuberculous deposit is more commonly found in the ends of the bones, when partial excision is more likely to be successful. Moreover, when the disease is confined to the synovial membrane and capsule, it may be sufficient to remove this alone, although the results of the operation, the arthrectomy of Volkmann, had not been very satisfactory in the hands of other surgeons. But, when the bone and the capsule were both affected, complete excision should be performed at once.

DR. STIMSON said that he had excised the capsule five or six times for disease which was apparently limited to it, and in three cases he had been obliged to perform complete excision subsequently. The subject had been discussed at a meeting of the Society a year before, and at that time other members had reported similar results. He thought that pronation and supination would always be imperfect in the case of the patient shown, for they were then effected by rotation of the ulna upon the humerus.

DR. GERSTER, in reply to a question by Dr. Abbe, said that the ends of the bones had originally been placed in apposition, but that they had become separated half an inch, as a result of lifting weights.

REMOVAL OF TUMOR (?) FROM THE BRAIN.

DR. MARKOE presented a patient and read the following report of the case:

Sidney McLowrie, aged twenty-five, England, gives the following history: In the year 1879, he fell from a height of about eight feet, striking on his head. He was stunned by the blow and remained unconscious for a certain time. Brain fever followed, from which he gradually recovered, until about two months from the time of the accident, when he had his first convulsion. Convulsions now recurred at irregular intervals for about two years, sometimes becoming as frequent as three or four in a night. These attacks gradually became less frequent, and at the end of two years ceased altogether. He had then regained good health and was able to attend to his daily duties as a clerk. There was no renewal of epileptic seizures until about a month before his admission to the hospital, January 15, 1887. At that time, while taking a bath, he accidentally struck his head, receiving rather a severe blow. No marked effects followed the blow, but within a week after a convulsion occurred, which was repeated at intervals more or less frequently, until they became as frequent as four during the night.

On admission he was anæmic and thin, but nervous and excitable, and quite intelligent. He had perfect possession of all his faculties, both mental and physical, and at no time had had any symptoms which could be referred to a cerebral lesion, except pain and the convulsions above mentioned. The head was irregular in shape, the frontal region prominent, the right parietal region bulging markedly, while the corresponding region on the left side was as markedly depressed. In the centre of this flattened area was a marked depression over a space as large as a half dollar. Has had continual dull pain referred to the depressed spot. He had lately suffered a good deal of pain in the head, which had almost always been referred to, and had radiated from this same point, though at times the pains had been felt on the right side. He was ordered to keep his bed, to be put upon light diet, and to have bromide of sodium, thirty grains, three times a day.

On the third day after his admission, he had his first convulsion, which was followed by two more before morning. There was no aura, and no cry, nor did the muscular spasm begin at any single point. The spasm took the form of opisthotonos, alternating with extreme flexion, and followed by sleep.

January 21. No convulsions until last night, when he had five.

25th. Number of fits increasing. Bromide increased, and ordered six leeches over the region of pain. Violent, almost maniacal, excitement follows some of the convulsions. No diminution in the number of fits.

An operation was determined upon, and performed January 27th. The point of operation selected was the centre of the depressed portion of the left parietal bone, which corresponded quite accurately with the region of greatest pain, and which was on a level with, and about an inch and a quarter in front of, the left parietal bone. The operation was done after Victor Horsley's method, with a semicircular flap of the scalp, and a large trephine, one and a quarter inches in diameter. On removing the disk of bone, the dura mater did not bulge, but nevertheless presented a decided sense of fluctuation. Between the dura mater and the brain a firm, hard surface was felt, which the finger reached after pressing through perhaps two lines of fluid. The dura mater was now opened by a semicircular incision, one line within the edge of the saw-cut. When it was turned back, a surface was exposed of a bluish-white color, as if it were the surface of a thin, semi-transparent sac, containing fluid. The sac being opened, gave issue to some thin, pellucid fluid, in quantity at least a drachm, and revealed the contents to be two unequal bodies, of a rounded shape, lying close together, forming a mass about an inch in diameter as looked at from above. These masses did not present the appearance of the normal cortex, but were more grayish in color and of a distinctly granular appearance, and to the touch they were firmer than the normal surface of the brain. Without the use of any force, the handle of the scalpel passed easily around the mass, and turned ou of the areolar bell in which it had lain. This removal showed the walls of the cyst to be continuous around the periphery of the tumor, and that the whole had been buried deep in the cerebral substance, pressing it down more than half an inch.

As I turned the mass out of its bed, I was not aware that I had divided any portion of cerebral matter, but, on studying the cyst wall after the mass had been removed, I saw a portion of exposed cerebral matter a: the anterior margin of the opening, and, though I examined it with care, I could not decide whether this was a point at which the tumor had been continuous with the convolution, or whether it was merely the surface of the convolution accidentally bared. This spot of exposed brain matter was about two lines in diameter. No hemorrhage took place during or after the enucleation. The dura mater was brought together with two or three catgut sutures, and the scalp-flap was accurately approximated in the same way. Light antiseptic dressings were applied, and two or three threads of large-sized catgut were left in the wound for drainage. Moderate reaction followed the operation. Some mental excitement, with amnesic aphasia was noticed during several days after the operation, with some paresis of the right arm. These symptoms, however, never reached a serious degree and subsided during the second week entirely. The wound healed *per primam*, and he was discharged well on the 19th of February, no convulsions having occurred since the operation twenty-three days previous.

The following is Dr. Prudden's account of his examination of the mass submitted to him.

"The small fragment of brain tissue which was sent to the laboratory was ellipsoidal in shape, measuring about 1½ by 1 cm. It consisted of white, and gray brain matter normally arranged." The ganglion-cells lying, as usual, in layers, are nearly all considerably swollen and prominent. The intercellular substance is somewhat cracked and fissured, which might be due to the hardening in alcohol. The most marked departure in structure from the normal was an accumulation of small spheroidal cells in the lymph-spaces around the ganglion-cells. Sometimes as many as six or seven of these small cells lay crowded around the ganglion-cells. This accumulation of cells in the lymph-spaces has been described as occurring under a variety of conditions. The appearances are figured in Virchow's *Archive*, Bd. 69, in connection with an article by Herzog Carl von Bayern on the condition of the cortex in abdominal typhus. The microscopic appearances do not throw much light on the peculiar conditions which you found at the operation, and I am entirely at loss to account for them, except on the hypothesis of an aberrant fragment of brain tissue which had developed at the seat of operation."

October 26. From the time of his discharge from the hospital, up to the present moment, his health has been perfectly good, No abnormal sensation about the seat of the wound, and no pain in the head. The only exception to be made to this statement is an attack of pain rather severe, intermittent in character, and seated in the region of operation. He himself is disposed to consider the attack as the result of unusual devotion to work, he having undertaken to acquire the art of shorthand writing, and having given every evening to that study. The attack lasted only three days and then entirely subsided. This seizure came on rather suddenly, about the first week in October. His habits have been perfectly correct in all respects, and with the exception mentioned above, he has been able to attend regularly to his duties.

This case was of some interest as throwing light confirmatory of the views now entertained with regard to cerebral localization. The tumor, while undisturbed, gave no indication as to the locality. After removal, however, the slight inflammatory action set up in its areolar bed was sufficient to produce aphasia and paresis of the right arm. The position of the tumor corresponded very nearly to the centres for the arm and for speech.

NEPHRECTOMY BY LAPAROTOMY FOR ADENOMA OF THE KIDNEY; RECOVERY WITH VENTRAL HERNIA.

Dr. Weir presented a patient from whom he had removed a tumor of the kidney as large as the two fists, and weighing twenty-one ounces. This tumor was shown to the Society last January, and the history of the case was then related in detail. (The Medical News, March 12, 1887.) The prognosis given by Dr. Peabody, after a microscopical examination, was not favorable, since he was inclined to look upon the growth as having a strongly malignant tendency. Nevertheless the patient was in good health, having gained forty pounds in weight, and was able to pursue his laborious occupation as a butcher, being only troubled by a her-

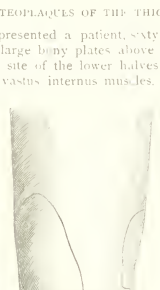
nial protrusion at the site of the incision; this was supported by a bandage. The incision was made at the outer edge of the rectus, according to Langenbuch's method, and in closing it the transversalis fascia had been sutured separately, as were the muscles also, in order to counteract the tendency to hernia which resulted from abdominal incisions. After the removal of the tumor, the cut edges of the peritoneum originally covering the kidney were brought together over the stump, and an opening was made posteriorly for drainage. Although there was considerable hemorrhage during the operation, the spouting vessels were readily secured with compression forceps through the anterior incision, which could have been done only with great difficulty through the lumbar incision.

DR. WYLIE, and other surgeons, suggested the advisability of performing a secondary operation for the cure of ventral hernia after laparotomy, the peritoneal cavity being opened and the peritoneum and transversalis fascia being sutured separately.

DR. WYETH said that he had been called to assist Dr. Wylie in an operation for the cure of ventral hernia following laparotomy, in which a good result was obtained. The peritoneum was united separately, and a series of deep sutures were carefully passed through the muscle and fascia. The speaker had adopted this method of closing the wound after laparotomy and believed that he had in this way prevented the subsequent formation of hernia.

OSTEOPLAQUES OF THE THIGH.

DR. ABBE presented a patient, sixty years of age, showing two large bony plates above the left knee, occupying the site of the lower halves of the vastus externus and vastus internus muscles. The internal



one measured six and one half by four inches, and had an estimated thickness of an inch. They were freely movable. They represented the amalgamation of numerous bony nodules in the muscle, first observed as long as forty years ago. They had been watched by him for three years, and had changed but little. The flexing of the knee was partially restricted and painful intervals the joint became painful and a little swollen when overtaxed.

DR. WEIR stated that he had seen the patient in 1884, and learned from him at that time that he had first noticed a number of small, hard nodules, which subsequently coalesced.

DR. STIMSON believed that the bony mass on the outer side had developed in the lateral ligament of the patella, and that its inner surface was in contact with the interior of the joint, as evidenced by crepitus on manipulation. On the opposite side the upper portion of the osteoplaques was evidently embedded in the muscle, while the lower portion appeared to occupy the capsule of the joint.

DR. WEIR said that he had seen a case in Schede's wards, in Hamburg, in which the nodules were confined to the muscles of the back and upper extremity. The pathology of the affection was obscure, only one autopsy having been made. *Myositis ossificans* (of which there were only about twelve or fifteen recorded cases) usually began in early life, and might follow inflammatory processes. It was sometimes thought to be of nervous origin, although the autopsy alluded to showed no nerve lesion. It was noted that in these cases the earthy phosphates in the urine were usually much diminished.

DR. BRIDDON said that he recalled the case of a patient who was presented at the Pathological Society several years before. He was a boy ten or twelve years of age. The osseous plates were confined to the trapezius muscles, and were unquestionably intramuscular.

EMPYEMA FOLLOWING STAB-WOUND OF THE PLEURA; RECOVERY AFTER EXSECTION OF PORTION OF A RIB.

DR. WYETH presented a patient, whose history was as follows: A man, aged thirty-five, was stabbed four or five times in the left side, three years ago; the lung was said to have been wounded. Considerable hemorrhage into the pleural cavity occurred, and a quantity of blood and serum was removed with a trocar and canula. The operation was repeated twice during the following two months, when the fluid was found to be purulent. Septic symptoms developed, and an incision was made to promote free drainage.

Dr. Wyeth saw him for the first time one year ago last May, and found that he was wearing a rubber drainage tube, which was closed by the pressure of the ribs between which it passed. Two inches of the seventh rib were exsected, and as much of the cavity as could be reached by the index-finger was thoroughly scraped out. The wall of the abscess could not be felt in a posterior direction, although the finger penetrated to its entire length. Two stiff rubber drainage tubes were introduced. The patient's convalescence was retarded by his dissipated habits, so that it was nine months before he could remove the tubes. The cavity was first washed out every third or fourth day (but later in the management of the case daily injections were made) with a solution of bichloride, beginning with a 1 : 3000, and gradually increasing in strength up to 1 : 500. Fifty or sixty injections of the latter were given without causing any symptoms of bichloride-poisoning. A weaker solution was always injected immediately after the strong one, in order to wash out any excess of the sublimate. The lung on the affected side was now collapsed, but on the other side the respiratory movement was good, and the patient was fully restored to health.

DR. SANDS thought that the case illustrated clearly

the value of a free opening in cases of purulent effusion into the chest. He had seen several cases in which, from the neglect to perform an operation early, the lung had been so bound down that it was impossible to effect a cure, even by removing portions of ribs. In one instance, at Roosevelt Hospital, he had exsected three inches from two ribs, but without curing the patient. If an opening was made early, Estlander's operation might be unnecessary. Dr. Wyeth's case also showed that it was not always necessary to remove much of the rib when the lung was remote from the chest-wall.

DR. WYETH, in reply to a question by Dr. Weir, said that he had not measured the contents at the time of the operation, but a few weeks after the cavity would hold about half a pint of fluid.

DR. WEIR said Estlander's operation had not given as good results as had been expected; it was often necessary to repeat it two or three times. Even after removing portions of ribs, the surgeon was often obliged to scrape out the cavity, to employ stimulating injections, or even to make a counter-opening. Sometimes the empyema-cavity could be further lessened at the performance of Estlander's operation by fracturing some of the ribs posteriorly.

DR. WYETH said that the most important point was to secure perfect drainage from the bottom of the cavity, and to wash it out frequently. He used tubes of stiff, white rubber. In reply to Dr. Sands's statement that he always used two tubes, side by side, the speaker said that he had omitted to mention that he had also employed two tubes in the same manner.

DR. POORE asked if a simple incision was not sufficient in most cases of empyema, without exsecting a piece of rib.

DR. WYETH replied in the affirmative.

DR. BRIDDON cited the case of a patient upon whom he had operated at the Presbyterian Hospital, removing portions of five ribs. Although the cavity was diminished in size, it still contained three ounces of pus when the patient left the hospital. A second operation was proposed and declined.

OSTEOMA OF THE UPPER JAW; REMOVAL OF THE SUPERIOR MAXILLA, WITHOUT MAKING AN INCISION THROUGH THE CHEEK.

DR. WYETH presented a patient from whom he had removed an osseous tumor of the left superior maxilla, involving almost all of this bone (the specimen was shown). He was a German, æt. twenty-eight, who at the age of fourteen had noticed a small swelling on the left upper jaw. It grew slowly, and was examined by a prominent German surgeon, who pronounced it to be a benignant growth. The speaker saw him for the first time six months before; the tumor was then increasing in size, and caused considerable deformity, so that an operation was advised. It was readily removed through the mouth, *without an incision being made through the soft parts of the face*, by the subperiosteal method. The growth involved the antrum, the whole of which was removed. Goodwillie's gag proved of great assistance during the operation. The periosteum was sutured with silk, and the patient left the hospital on the fourth day after the operation. The bone had been largely restored.

CORRESPONDENCE.

STROPHANTHIN VS. DIGITALIS.

To the Editor of THE MEDICAL NEWS,

SIR: Referring to your editorial note on the use of ergot in combination with digitalis, in a late issue of the journal, permit me to add a few words to your friendly criticism on the methods advised by Rosenbach.

Accepting as true, your statement, "that aortic insufficiency is, of all the valvular lesions of the heart, the very one which rather contraindicates the use of digitalis, in that it not only prolongs diastole, but likewise increases the ventricular capacity, thereby permitting a greater opportunity for regurgitation into the ventricle," I would go a step further, and point out the objectionable effects of digitalis in cases of this character, by reason of its pronounced influence upon the bloodvessels. I fully agree with you as to the undesirable action of ergot, its effect being to increase the expenditure of force on the part of the heart in overcoming the resistance in the arterioles; but how shall we meet a similar objection to digitalis?

The first centennial anniversary of the introduction of digitalis into medicine has lately been noted, and yet its therapeutical position is still indifferently understood. When we take into consideration that digitalis may be given to the extent of preventing the blood from passing through some of the bloodvessels, while the heart still continues to act, then do we begin to appreciate the conditions attending its so-called cumulative action, although I have lately been disposed to regard this so-called cumulative action as a misnomer, if not a myth. In cases of poisoning from the cumulative action of digitalis, we are taught that the heart is paralyzed and stops in diastole. Professor Bartholow says: "When, after the administration of large doses, the pulse is much reduced in the recumbent posture, on rising, the heart is suddenly found unequal to maintaining the circulation in the face of the increased resistance in the arterioles and against the force of gravity." It is evident, then, that digitalis is a remedy which diminishes the calibre of the arterioles, and acts on the cardiac muscle at the same time, but not in equal proportion on both, else there would be no loss of compensation.

Had we a remedy which would increase, say, two or three times the power of the heart, and act less energetically on the arterioles than digitalis, and thus equalize the compensation, it would be an acceptable addition to our *armamentarium*. A remedy which would act principally upon the heart, and slightly upon the bloodvessels, which, like digitalis, would produce diuresis and reduce temperature, would be suitable for exhibition in cases of "aortic insufficiency," and in cases of "idiopathic dilatation of the heart with alterations in the elasticity and contractility of the bloodvessels," instead of digitalis and ergot, as advised by Rosenbach. Such a remedy we have in strophanthus hispidus, first introduced by Pelikan in 1865, and studied thoroughly by Professor Fraser, of Edinburgh, who, twenty years later, placed the drug, with its physiological action and therapeutical indications, before the British Medical Association. As compared with digitalis, its

action on the heart is more than twenty-five hundred times greater; while on the bloodvessels its action is less than one-tenth that of digitalis.

Let me quote, in conclusion, and in support of the above statement, from Professor Fraser's paper (*Brit. Med. Journ.*, Nov. 14, 1885): "Solutions of digitalis, 1 part in 4000, passed through the separated frog's heart by means of Williams's apparatus, produced characteristic changes in the heart's action, but were not sufficiently strong to kill it within two hours; while a solution of strophantin,[1] 1 part in 10,0000,000, produced characteristic changes in the heart's action, and killed the heart. A solution of 1 part in 6,000,000 was sufficiently strong to cause complete stoppage of the heart in extreme systole in about twenty minutes. Taking the same preparation as had been used upon the heart, and passing solutions through the bloodvessels, it was found that digitalin, 1 part in 20,000, produced, in six or seven minutes, such extreme contractions of the vessels as practically to prevent the solutions from passing any longer; while but a temporary effect, which was soon recovered from, was produced when the solution of strophantin was increased to 1 part in 2000." It would seem, therefore, that in the diseases mentioned above, strophantin, as respects the heart, is twenty-five hundred times more efficient, while in respect to the bloodvessels, its use is followed by less than one-tenth the activity of digitalis, thus presenting a material contrast between the two remedies. Whether the position of strophanthus will be settled finally as being *twenty-five thousand* times more valuable than digitalis, I leave for physiologists of a mathematical turn to determine.

Very respectfully yours,

JOHN AULDE, M.D.

4719 Frankford Ave., Philada.,
October 29, 1887

[1] Prof. Bartholow regards *tin* as the proper termination.

AID FOR THE MEDICAL COLLEGE AT SHANGHAI.

To the Editor of THE MEDICAL NEWS.

SIR: Allow me to ask your aid on behalf of the medical department of St. John's College, Shanghai, China. We have in Shanghai, hospitals for natives with about 230 beds; we have out-patient departments, treating some 23,000 or 24,000 individual out-patients every year. Our facilities for clinical teaching are good. These institutions are supported by their own earnings and by local charity. We do not need any money for them. We own the land and a building for the medical school; we have the nucleus for a medical library and a medical museum, and we hope that this museum will—by contributions from all parts of China—become a most important and valuable institution. Shanghai is the business centre of China, most easy of access from all parts of the empire. Our medical school has four lecturers and one tutor, and we have a small class of medical students. Candidates for medical instruction undergo a preliminary examination; after admission they study three months, when they have to pass another examination. Should they not show aptitude for the study of medicine they are required to leave the class. If proficient they sign an agreement to remain and study for four years. The first two and a half years they are in the medical school, the last year and a half they act as internes at St. Luke's Hospital. They then pass their eighth final examination, and are free to go out and practise medicine. While our hospital is independent, needs no help, we need about $800 a year, for a few years to come, to enable us to keep the medical school going. When our graduates begin to earn a living as doctors, we shall have so many applicants for medical instruction that we shall become self-supporting. Can you lay these facts before the medical profession of this country and ask them to help us? The smallest contributions will be thankfully received. We hope that medical authors will donate copies of their works to our library, that the medical book publishers will give us books for our library, and that the medical profession of the United States will help us to give the benefits o modern medical science to the people of this great nation, and thus help, on a grand scale, to alleviate the vast amount of human suffering among the three hundred millions of people in China. Any contributions in money or donations of books, can be sent to Rev. Dr. Wm. S. Laryford, Secretary of Board of Missions, 22 Bible House, N. Y., and they will be forwarded to China. I remain,

Yours, faithfully,

H. W. BOONE, M.D.,
Vice-President Medical Missionary Association of China; Lecturer on Surgery,
Med. Dept St John's College, Shanghai, etc.

PHILADELPHIA, October 26, 1887.

THE DISCUSSION ON CHOLERA AND INTERNATIONAL LEGISLATION AT VIENNA.—In the discussion on cholera in the Third Section, PROF. MAX GRUBER, of Vienna, speaking of certain experiments which he had made, in Austria, in 1885 and 1886, as to the spread and prophylaxis of cholera, concluded his remarks by saying that Koch's vibrio was the specific agent in Indian cholera, and that it was propagated by patients suffering from the disease or by infected clothing, linen, etc. In his (the speaker's) opinion, it had not been proved that cholera could be transmitted by drinking-water. It was quite evident that the spread of cholera depended on seasons and weather. The etiology of cholera had still to be determined. The prophylactic measures which had been adopted in Austria to prevent the spread of the disease by patients suffering from it were, nevertheless, fully justified, and if they had not been as successful as might have been wished, that was due to the difficulty, or rather impossibility, of carrying them out with adequate strictness. It was necessary that sanitary organization should be improved, and particularly that proper instruction in hygiene should be given in the public schools. Dr. Shiba-Saburo Kitatair, member of the Ministry of the Interior of Japan, reported on the cholera epidemics which had visited Japan, first in 1822, and afterwards in 1877, 1879, 1882, 1885, and 1886, and stated that the disease had always been imported into Japan from China by English or French ships. In its method of dealing with epidemics Japan was, according to the speaker, fully abreast of the most enlightened countries.

The suggestions made by Mr. Shirley Murphy, which were almost identical with those made by the other reporters, were as follows: 1. The appointment of a sanitary authority at every port, whose duty it should be to keep himself informed as to the sanitary condition of the port, and the health of the passengers and crews of vessels arriving at or leaving the port. This information should be placed at the disposal of the Consuls of the countries to which the vessels are bound. 2. Every country to have a central office, to which reports should be sent of the number of cases of specified epidemic disease occurring in every large town and port during each week, immediate notice being sent of cases of cholera. This information should also be placed at the disposal of the governments of other countries. 3. Precautions must be taken by the sanitary authorities and officers of vessels as already indicated, to prevent the embarkation of persons or articles infected with cholera. 4. A station should be established on the Suez Canal for the purpose of obtaining information as to the health of passengers and crews of vessels bound for Europe, but not for their detention for more than the time necessary for procuring this information. 5. This information should be placed at the disposal of representatives of the different governments. 6. Every vessel arriving at a European port should be dealt with in accordance with the manner determined on by the government of that country.—*British Medical Journal*, October 22, 1887.

Gleditschine.—F. A. Thompson, Ph.C., reports as follows to Messrs. Parke, Davis & Co., at whose request he analyzed a sample of the substance called "gleditschine:"

My conclusions, subject to further analysis, which I hope may identify the exact constituents, are:

1. That the solution claimed to be a two per cent. of gleditschine, is not what it is represented, and that those introducing it as such are guilty of fraud.

2. That the solution likely contains some coloring agent, differing from that obtained from the drug in which the alkaloid is isolated, or that the color may be due to the presence of an alkaloid, or the substance supposed to be in combination with the cocaine.

3. That the peculiar action of the extracted alkaloid to chemical tests, appearance, taste, and odor, suggest it to be none other than cocaine.

4. That the presence of chloride and sulphate indicates positively that a sulphate of one alkaloid and a muriate of another are present; and the presence of cocaine being established, which is without doubt in the form of muriate, the sulphate can be accounted for only by assuming that it is in combination with *atropine*, or some other mydriatic alkaloid, such as *duboisine*.

5. The solution contains 6.85 per cent. of alkaloid, calculated as cocaine muriate, instead of 2 per cent. of gleditschine (!) as stated on label.

6. That the dilatation of the pupil of the eye was thought to be more lasting than from cocaine, and less so than from atropine, indicating the possible presence of some myotic, modifying the action of the mydriatic. Experiencing no dryness of the throat or any hallucinations from the hypodermatic injection of the solution, it is possible no *mydriatic* except cocaine is present.

7. That the statement made, that the salt was not permanent, and finding the salt of the alkaloid in this solution quite so, leads one to suppose that this *is not the reason for making such an assertion*.

8. That having had placed at my disposal through the firm of Parke, Davis & Co., several pounds of the leaves, from which I am unable to produce, as yet, but a trace of alkaloid giving precipitates with the usual alkaloidal reagents, and which, applied to the tongue, produces no sensation whatever, and the existence of a volatile consituent very probably, and a large amount of resinous-like substance having strong astringent properties being present, I question the existence of an anæsthetic or mydriatic alkaloid in Gleditschia triacanthus.—*Medical Age*, October 25, 1887.

Gleditschine Again.—Mr. Nooy, of the Hygienic Laboratory of the Michigan University, also states in the *Pharmaceutische Rundschau* for November, 1887, that the so-called gleditschine or stenocarpine is nothing but a mixture of cocaine and atropine, and that the 2 per cent. solution which is on the market is nothing but a 6 per cent. solution of cocaine hydrochloride and ½ of 1 per cent. of atropine sulphate, to which has been added ½ of a per cent. of salicylic acid to act as a preservative.

The Washington Obstetrical and Gynecological Society has elected the following officers for the ensuing year:

President—Samuel C. Busey, M.D.

Vice-Presidents—D. W. Prentiss, M.D., and W. W. Johnston, M.D.

Treasurer—George Byrd Harrison, M.D.

Recording Secretary—Samuel S. Adams, M.D.

Corresponding Secretary—G. Wythe Cook, M.D.

The Health of the Crown Prince.—The *British Medical Journal* of October 22d, states "plainly and without any diplomatic reserve or ambiguity," that, according to the best authority on the subject, the Crown Prince's condition is, up to this morning, highly satisfactory. There is no recurrence whatever of the growth; the functions of the parts are not interfered with in the slightest degree, except that the voice is still rather weak; there is no appearance or sensation in the throat that need cause either alarm in the present or well-grounded apprehension as to the future.

Sir William Gull is reported to be progressing favorably. Power of action in the affected extremities has been regained, and sensation is returning.

The buffalo has been recently utilized for the propagation of vaccine virus, with excellent results. The experiment was performed in India.

Stricker's Electric Microscope.—The *British Medical Journal* of October 8, 1887, thus describes a recent invention of this distinguished histologist, as exhibited at the recent Congress of Hygiene at Vienna:

A very interesting feature of the programme on Wednesday, September 28th, was the demonstration of Stricker's electric microscope by the Professor himself. The lecture-room of the famous histologist was crowded to overflowing, and a large number of visitors

could not find places. Among those present were the following: Archbishop Corrigan, Herbert Spencer, Wells, Sir John Thomas Mirault Erichsen, and many others. Professor Stricker began by showing a transverse section of the spinal cord; he alternately used projecting lenses of an increasing power, and was able to demonstrate the constituents of the spinal cord, the ganglion cells, and the nerve fibres so distinctly, that even the faintest outlines of the microscopic details could be distinctly seen by all present. The wall on which the microscopic objects were projected was at a distance of six metres from the electric microscope. Among the preparations there was also a transverse section of the spinal cord, taken from an individual who had been executed some time ago. Professor Stricker succeeded in demonstrating, particularly by means of this specimen, the details of the structure of the spinal cord in a very distinct manner. After Professor Stricker had also demonstrated a number of other specimens, he showed the utility of the reflected light in his microscope. He succeeded in projecting, with a 25-fold linear augmentation, specimens of bones so distinctly, that the minutest constituents could be quite distinctly seen from the furthest part of the room. Lastly, he showed the movements of the heart of a turtle as projected by his electric microscope. The evening which the members of the Congress passed in Professor Stricker's lecture-room was one of the most interesting during the whole session of the Congress, and the demonstrations were all received with the most enthusiastic applause.

THE BEST SOLDER FOR CANS CONTAINING FOOD.—Mr. T. P. White, in a communication to the Chemical Society, gives a decidedly negative answer to the question whether the acids of canned fruits may not form poisonous salts with the tin. He reports, as the result of his experiments, that "tin is entirely devoid of danger when taken internally in any form that might arise from being in contact with fruits or vegetables." He believes that the cases of accidental poisoning attributed to tin were due to solder or other impurities—arsenic, copper, or lead. Prof. W. Mattieu Williams says that that there need be no lead in the solder—that it is only put in for cheapness' sake, and that tin makes a superior solder to any alloy. Therefore, all danger may be obviated by prohibiting the use of any other solder than pure tin.—*Popular Science Monthly*, October, 1887.

COBALT AN ADULTERANT FOR MILK.—Cobalt blue has been used to give a bluish tinge to yellow milk, and is dangerous on account of the arsenic which it contains as an impurity.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY, FROM OCTOBER 25 TO OCTOBER 31, 1887.

GREENLEAF, CHARLES R., *Major and Surgeon.*—Will proceed from this city to the places hereinafter named, in the order in which they are named, for the purpose of investigating the methods of examining the recruits at the depots and rendezvous located thereat, and of instructing recruiting officers in matters pertaining to such examinations: Baltimore, Md.; Philadelphia, Pa.; Camden, N. J.; New York City and David's Island, N. Y.; Boston, Mass.; Portland, Me.; Albany and Buffalo, N. Y.; Cleveland, Ohio; Detroit, Mich.; Chicago, Ill.; Milwaukee, Wis.; St. Paul, Minn.; Jefferson Barracks and St. Louis, Mo.; Cincinnati and Columbus, Ohio; and Pittsburg, Pa.—*S. O. 249, A. G. O.*, October 25, 1887.

CLEAVE, J. A., *Major and Surgeon.*—Ordered to proceed from Fort Hancock to Fort McDowell, and report to the commanding officer for duty as Post Surgeon.—*S. O. 111, Department of Arizona*, October 18, 1887.

ADAIR, G. W., *Captain and Assistant Surgeon.*—The leave of absence for seven days, granted on the 27th instant, by the commanding officer, Fort Brady, Michigan, is extended twenty-three days.—*S. O. 231, Division of the Atlantic*, October 28, 1887.

MUNN, CURTIS E., *Captain and Assistant Surgeon.*—Relieved from duty at Fort Canby, Washington Territory, and ordered for duty as Post Surgeon, at Fort Klamath, Oregon.—*S. O. 251, A. G. O.*, October 28, 1887.

BYRNE, CHARLES B., *Captain and Assistant Surgeon.*—Ordered for temporary duty at Fort McHenry, Maryland.—*S. O. 231, Division of the Atlantic*, October 28, 1887.

BROWN, PAUL R., *Captain and Assistant Surgeon.*—Leave of absence extended one month.—*S. O. 250, A. G. O.*, October 27, 1887.

BURTON, H. G., *Captain and Assistant Surgeon.*—Ordered from Plattsburg Barracks, New York, to Watervliet Arsenal, New York.—*S. O. 249, A. G. O.*, October 26, 1887.

MERRILL, J. C., *Captain and Assistant Surgeon.*—Ordered from Watervliet Arsenal, to Frankford Arsenal, Pennsylvania.—*S. O. 249, A. G. O.*, October 26, 1887.

RICHARD, CHARLES, *Captain and Assistant Surgeon.*—Granted leave of absence for one month, to take effect when his services can be spared by his Post Commander.—*S. O. 247, A. G. O.*, October 22, 1887.

JARVIS, NATHAN S., *First Lieutenant and Assistant Surgeon.*—Ordered from the Department of the Platte to the Department of the Missouri, for duty in the field.—*S. O. 249, A. G. O.*, October 26, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING OCTOBER 29, 1887.

BATES, N. L., *Medical Inspector.*—Ordered to hold himself in readiness for orders to the "Trenton."

HESLER, F. A., *Assistant Surgeon.*—Ordered to examination for promotion.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, FOR THE THREE WEEKS ENDING OCTOBER 29, 1887.

BALLIACHE, P. H., *Surgeon.*—To proceed to Buffalo, N. Y.; Erie, Pa.; Ashtabula, Cleveland, Sandusky, and Toledo, Ohio, as inspector, October 4, 1887.

FESSENDEN, C. S. D., *Surgeon.*—Detailed as Chairman of the Board for the Physical Examination of Cadets, Revenue Marine Service, October 15, 1887. To proceed to Cape Charles Quarantine Station, as inspector, October 26, 1887.

SAWTELLE, H. W., *Surgeon.*—Detailed as Chairman of the Board for the Physical Examination of Officers, Revenue Marine Service, October 27, 1887.

IRWIN, FAIRFAX, *Passed Assistant Surgeon.*—To inspect unserviceable property at Boston, Mass., and Portland, Me. To proceed to Vineyard Haven, and New Bedford, Mass., as inspector, October 8, 1887.

MEAD, F. W., *Passed Assistant Surgeon.*—Detailed as the Recorder of the Board for the Physical Examination of Cadets, Revenue Marine Service, October 15, 1887.

WHITE, J. H., *Passed Assistant Surgeon.*—Leave of absence extended four days, October 21, 1887.

CARRINGTON, P. M., *Assistant Surgeon.*—Detailed as the Recorder of the Board for the Physical Examination of Officers, Revenue Marine Service, October 27, 1887.

FAITIC, J. B., *Assistant Surgeon.*—Granted leave of absence for seven days, October 28, 1887.

PETTUS, W. J., *Assistant Surgeon.*—When relieved at Savannah, Ga., to proceed to Galveston, Texas, and assume charge of the service, October 17, 1887. Granted leave of absence for thirty days, October 21, 1887.

KINYOUN, J. J., *Assistant Surgeon.*—Granted leave of absence for fifteen days, October 19, 1887.

AMERICAN PUBLIC HEALTH ASSOCIATION.

FIFTEENTH ANNUAL MEETING.

THE ANNUAL ADDRESS.

Delivered Tuesday, November 8, 1887.

BY GEORGE M. STERNBERG, M.D.,

PRESIDENT.

GENTLEMEN: I am sure that all of the older members of the American Public Health Association feel, as I do, that our meeting this year has a special interest due to the locality in which we meet. We feel that the good city of Memphis is, in a manner, a protégé of our Association, because in her hour of distress she appealed to some of our most distinguished members for sanitary counsel and acted upon the advice given; and we recognize the fact that in more than one way our relations to this city are exceptional.

It was due to the yellow fever epidemic of 1878, in which Memphis was the chief sufferer, that steps were taken at our meeting of that year in the city of Richmond, to urge upon Congress the importance of a National Board of Health. Recognizing the fact that epidemics do not respect State boundary lines, and that an efficient sanitary service in times of emergency requires a liberal expenditure of money and unity of action on the part of sanitary officials, we urged the formation of a central health board, and for a time it seemed as if our well-meant plans would be crowned with success. Indeed, they were crowned with partial success, for all must recognize that in the early days of its existence the National Board of Health accomplished much good. It is unnecessary for me to refer to the various circumstances which conspired to paralyze the effective energy of this Board. Unhappily it is a thing of the past, and the hopes which we had founded upon this our bantling are but a memory of the past. But we should not be discouraged that our first effort has failed. A careful consideration of the circumstances which led to this failure may enable us to mature a better plan. Such a plan, endorsed by the judgment of the experienced sanitarians here assembled, and properly presented to our national legislators, could not fail to receive respectful attention.

One thing appears to me to be clearly demonstrated by the experience of the past, namely; that a central health board, to be efficient, must be attached to one of the departments of the government now in existence, so that it may be under the protection of a Cabinet officer. It would be useless to ask at the present time that the sanitary interests of the country may be represented by an additional Cabinet officer, a minister of public health, although there can be no doubt that the interests involved are sufficiently important to justify such an innovation. But we may at least demand that the sanitary interests of the people of the United States shall receive the same consideration from the National government that is accorded the educational interests, the agricultural interests, etc. We may, at least, ask for a bureau of public health, with a Commissioner at its head, and with the necessary secretaries and clerical force to make it efficient; and attached to such a bureau should be a well-equipped laboratory in which expert bacteriologists, chemists, and sanitary engineers should be employed in the experimental investigation of unsettled sanitary problems: such as the natural history of disease germs: the best methods of destroying them; protective inoculations against infectious diseases; problems in sanitary engineering, such as the disposal of sewage, domestic sanitation, etc.; food adulterations; and a variety of other questions of equal importance, which will readily occur to you. I do not approve of the plan of having a central Board of Health composed of members located in various parts of the country. Such an organization is cumbersome, and it cannot be expected that a Board which is only assembled at long intervals, and of which the members are occupied by various pursuits which claim their time and best thought, will render the most efficient service. On the other hand, by diversity of opinions they may greatly embarrass their executive officer, who must necessarily be located in Washington. Nor, in my opinion, would a Board composed of officials at the head of various departments in Washington, such as the Surgeons-General of the Army, the Navy, and the Marine Hospital Service, as has been suggested, be much better. These officials are fully occupied with the duties pertaining to their office, or at least have not sufficient leisure to undertake the executive work of a central health bureau. I would, therefore, expect better results from the untrammelled action of a single Commissioner who would be responsible directly to the Cabinet officer to whose department his bureau was attached, and would necessarily be controlled by the law defining the nature of his duties. In this case it is evident that the good accomplished would depend largely upon the fitness of the man selected for the special duties entrusted to him, and that a political appointment in the first instance, or the removal of a suitable man for party reasons, would entirely defeat our object.

We may, however, ignore this possibility, and trust to the good judgment of the Chief Executive, and the growing public sentiment in favor of retaining efficient bureau officers without respect to party changes.

In connection with the bureau of public health, it would certainly be desirable to have an *Advisory Board of Health*, to which the Commissioner could refer questions for consideration, or which could advise him of new measures, or desirable changes in his regulations, which after full discussion commended themselves to the judgment of the Board. Such a Board should have no executive power, and the members should receive

no pay, beyond their actual expenses in attending the appointed meetings. I would suggest that such a Board should consist of the Surgeon-General of the Army, the Navy, and the Marine Hospital Service, and of the Presidents of State Boards of Health. One annual meeting in Washington would probably answer the purpose for which a Board would be constituted, except in case of an actual or threatened epidemic, when it might be convened by order of the President of the United States, or the suggestion of its President or of the Commissioner of Health.

I request your careful consideration of the plan here suggested, and if it meets your approval would urge the importance of taking such action at the present meeting as will insure its being properly brought before the Congress of the United States.

My reference, at the outset of my address, to the Richmond meeting of this Association, will recall to those of you who were fortunate enough to be present at that meeting, the very great interest which attached to the reading of reports upon the epidemic of that year; and especially will you recall the scene when our lamented colleague, Dr. Samuel M. Bemiss, of New Orleans, occupied the platform. Surrounded by diagrams showing the typographical features of the towns in the great Mississippi Valley, which had suffered most from the epidemic, and with tabular statements of population, mortality, etc., Dr. Bemiss, with the clearness and precision which characterized his delivery, passed in review the terrible record of the devastating pestilence. His genial and rugged face, aglow with humanitarian zeal, and an intelligent appreciation of the sanitary lessons conveyed by the stern facts which he presented to us, made an impression upon my mind, which will not soon be effaced. Alas, that he is not here with us to congratulate the good citizens of Memphis upon the favorable change which has occurred in their sanitary surroundings since the date of which we are speaking.

Sanitarians recognize the fact that epidemics are often blessings in disguise, just as great fires may be in badly built cities. Certainly not a blessing for those who suffer directly from the scourge; but the traveller who sees broad and well-paved streets, substantial and well-ventilated dwellings, and a healthy-looking population, where formerly narrow, filthy streets, and crowded tenement houses occupied the ground, may be excused for looking upon the conflagration which cleared the way for such improvements as a blessing. So, too, sanitarians, recognizing the fact that in many instances nothing short of an epidemic will arouse the people to take action with reference to sanitary improvements, cannot fail to see that the benefits which result from an epidemic of cholera, or of yellow fever, in the long run, may more than compensate for the distress and loss of life which attend them. A cholera epidemic which decimates the population of a town without sewers or proper water supply, will prove a blessing in the end if it leads to the introduction of an ample supply of pure water and of a system of sewerage by which the mortality from typhoid fever and other endemic diseases is greatly reduced. But this mode of obtaining sanitary improvements is an expensive one, and rather hard on the victims of the epidemic.

The members of this Association, therefore, actuated by a humanitarian spirit, desire to secure these benefits for every town in this broad land if possible, in advance of the scourge which is sure to come some day, if the warnings and the lessons of past experience do not suffice to arouse the inhabitants of insanitary towns to a sense of the risks they run. It is a remarkable fact that in matters of this kind individuals and corporations are slow to profit by the experience of others, and that it is commonly only when the fatal results of neglect are brought under their immediate observation, that they are ready to apply the remedy, which is necessarily more or less expensive. We all remember how promptly the people of Memphis responded when the epidemic stimulus was applied, and we have heard much of the sanitary improvements which have been made in this city since the memorable year 1878. Many of us are here for the first time, and, as I have said, this meeting possesses special interest for us, because it enables us to see for ourselves what has been done and what remains to be done, in order to put Memphis in a state of defence in the event of another yellow fever epidemic in the Mississippi valley.

Do not allow yourselves to fall into a state of inaction and false security, because, for several years our foe has been kept at bay. Although it is now evident that yellow fever is not endemic in any portion of our land, and we have learned by recent experience that by proper measures it is possible to exclude it for a series of years even from the city of New Orleans, yet there are so many possibilities of its introduction, in spite of the vigilance of those who have charge of the gateway of the Mississippi Valley, that it would be folly to neglect those local measures of sanitation which remove the vulnerability of cities in the presence of the germs of pestilential diseases. Shutting the door is of prime importance, and while the keys are in the hands of our energetic and able colleague, Dr. Holt, we may feel comparatively safe. But the efficient President of the Louisiana State Board of Health cannot guarantee that all avenues of approach are securely guarded, inasmuch as some of these avenues are quite beyond his control. This is exemplified by the Biloxi epidemic of 1886. Local outbreaks such as that at Biloxi, and the epidemic at Key West, and at Tampa during the present year, show that the conditions upon our Gulf coast are no less favorable to the prevalence of yellow fever than they were in former years, and that our immunity depends solely upon the exclusion of an exotic germ. Unfortunately, also, the Biloxi epidemic illustrates the very greatest liability of physicians to fall into error with reference to the diagnosis when yellow fever unexpectedly makes its appearance at a place outside of its habitual range. History repeats itself in this particular. The early cases in an epidemic, which are often mild, are pronounced to be malarial fever, and this diagnosis is often sustained by those who have committed themselves to it, when no reasonable doubt remains in the minds of unprejudiced physicians as to the nature of the malady.

The question whether it is practicable to make a city which lies within the area subject to invasion, proof against epidemics of yellow fever and cholera is one of very great importance. At the International Sanitary Conference of Rome, the delegates from England and from India opposed all quarantine restrictions as unnecessary, and pointed to the fact that for years there

has been constant and free communication between cholera-infected ports in India and the seaport cities of England, but that cholera has not effected a lodgement in that country, Dr. Thorne Thorne, of the Local Government Board, a delegate to the Conference, ascribed this immunity to the sanitary improvements which have been carried out in England during the past ten or twelve years. He stated that during the period included between the years 1875 and 1884, an amount exceeding six and one-quarter millions sterling per annum had been expended in England "under private and public Acts mainly of a sanitary character." Dr. Thorne Thorne, in his report of the proceedings of the Conference referred to, says:

"Lastly, I would note that I took occasion to explain to the technical Commission, that expenditures such as I have referred to, are, with only very trivial exceptions, voluntarily incurred in the interests of public health.

"I then went on to show, in connection with this expenditure, that the average annual mortality for England and Wales was now only 19, as opposed to 22 per thousand in the decennial period 1861–70, and this notwithstanding the increase in population of some five millions; and taking the continued fever mortality of this country as that which, in point of causation, most nearly resembled cholera, I point out that whereas in the five years 1865–69, this mortality was at the rate of 934 per million living, it had steadily fallen to 428 per million during the period 1880–82, and that it was now only 307 per million."

In a later communication published in the *Practitioner* for October, 1887, Dr. Thorne Thorne gives fuller details of the English system of protection against cholera as follows: "Having deliberately abandoned the system of quarantine, we began, many years ago, to organize the system of medical inspection with isolation. The medical inspection comes first into operation on our coasts. The customs officers board the vessel coming into our ports, and they at once communicate to the sanitary authority the occurrence of any case of cholera, choleraic diarrhœa, or suspected cholera. A vessel so affected is detained until the medical officer of health has examined every member of the crew and passengers. Those actually sick with cholera or choleraic diarrhœa are at once removed to the port sanitary hospital, and any person certified to be suffering from any illness which that officer suspects may prove to be the cholera, is detained for a true period of observation, not exceeding two days. The medical inspection is thus followed by isolation of the sick. Unlike a quarantine system, this process does not interfere with the healthy, or expose them to risk by herding them together with the sick, but the names of the healthy, and the places of their destination are taken down, and the medical officers of health of the districts in question are informed of the impending arrivals. This part of our system has been named our first line of defence, but it would be of little value if we stopped there. Our main trust is in the promotion of such local sanitary administration in every part of the country as shall rid us of the conditions under which alone cholera can spread. In periods of emergency, as during the past three years, a special medical survey of such districts as are most exposed to risk is organized under the supervision of the medical officer of the Local Government Board, and, where needed, the sanitary authorities are urged to action. Important as have been the results of the recent survey, they would go for little, were it not for the steadily maintained work of sanitary authorities and their officers throughout the kingdom; and we who have been taunted abroad for opposing quarantine because its restrictions touched our commercial interests and our pockets, may justly feel proud that in England and Wales alone, the people have, during the past ten years, of their own accord, and apart from government dictation, spent by way of loan or in current expenditure, over eighty millions sterling, for purposes mainly of a sanitary character. And we may fairly ask whether any corresponding expenditure has in other countries given evidence of real faith in a quarantine system."

Without denying the value of the sanitary improvements which have been carried out in England, and the possibility that her immunity from cholera is largely due to them, the delegates from more exposed countries, such as France and Italy, demanded a quarantine station on the Suez Canal, and pointed out the fact that their seaport cities were not in such a sanitary condition that they could hope to escape the ravages of the pestilence in case of its introduction, and that to place them in such a state of defence would require time and the expenditure of large sums of money. It was noticeable that those countries, such as Turkey, Egypt, and Spain, where sanitary improvements have made the least progress, were the most exacting with reference to quarantine restrictions. They evidently looked upon these as their only hope, and were advocates of the old-fashioned time quarantine, which, as carried out in these countries, has often been attended with barbarities which are intolerable for civilized nations. Self-preservation is, indeed, the first law of nature, but it is barbarous to sacrifice the life of another to save our own, and in guarding the lives of a community, we are bound to show due consideration for the health and comfort of those who are believed to be the possible bearers of disease germs.

Recognizing this humane principle a majority of the delegates to the Sanitary Conference of Rome were anxious to effect a compromise between the old-fashioned time quarantine and the English practice, which they could not rely upon for the countries of Southern Europe. It was believed that such a compromise was practicable, and that the plan agreed to by a majority of the delegates present was more reliable than a simple quarantine of detention. I must refer you to the published transactions for the details of this plan; but, in brief, it consisted of a sanitary supervision of ships at the port of departure, when this was an infected port, or in communication with an infected locality; in the sanitary supervision of ship and passengers while in transit by a properly qualified physician upon all passenger ships; and in such detention at the port of arrival as might be necessary for the disinfection of the ship, the personal effects of passengers, etc. If one or more cases of cholera should appear on board during the voyage, they were to be isolated and rigid measures of disinfection carried out, and the action of the health authorities at the port of arrival was to depend largely upon how effectively this had been done. In short, the treatment of the vessel and its passengers was not to be

determined in advance by arbitrary rules, but was to be governed by an intelligent consideration, by an expert, of all the circumstances relating to the sanitary history of the ship from the date of its departure from the infected port. This rational quarantine service, which is far less burdensome to the commerce of a country than the arbitrary time-quarantine of former days, has proved itself to be also more effectual in accomplishing the end in view. This is amply proved by recent experience in our own country, where, to a large extent, the principles indicated control the action of the health officers of our principal seaports. Look at the city of New Orleans, where epidemics of yellow fever were formerly so frequent as to lead to the belief that the disease was endemic, and a necessary evil appertaining to the situation of the Crescent City. Happily, under an efficient quarantine service she has now a record of seven years' exemption from the dreaded pestilence.

It is, perhaps, too soon to speak with confidence with reference to the action taken by the sanitary officials of the port of New York upon the recent arrival of two cholera-infected vessels from the Mediterranean, but we have good reason to hope that the measures taken will prove sufficient, and that this pestilential disease, which has for several years been threatening us from a distance, has not effected a lodgement upon our shores.

Whether it would be practicable to put our seaports in such a state of sanitary defence that it would be safe to open the door and defy the foe is extremely doubtful. I have never believed that yellow fever was excluded from New Orleans, in 1862 and 1863, by the sanitary regulations enforced by General Butler, as has been claimed. The exemption from this disease enjoyed by the unacclimated soldiers of the North, who filled the hospitals in that city at the time mentioned, was due, in my opinion, to the absence of commerce during the military occupation of the city and the rigid enforcement of quarantine restrictions.

But I do believe that this and other cities similarly located can be preserved from such devastating epidemics as have too often occurred in the past, and that by the carrying out of needed sanitary improvements, and the constant supervision of expert sanitary officials supported by an enlightened public sentiment and sufficient appropriations, the ravages of pestilential diseases may be restricted within very narrow limits.

As regards cholera, the system of local defence is even simpler than in the case of yellow fever. Ample evidence demonstrates that the epidemic extension of this disease depends largely, if not exclusively, upon the water supply. Where this is subject to contamination by the discharges of the sick, there cholera is liable to become epidemic. On the other hand, cities like Rome, in Italy, which have an ample supply of pure water, drawn from a source not liable to be contaminated, seem to be cholera-proof, notwithstanding the filth and squalor in which a considerable portion of the population live. The same thing is seen in Naples, which, in 1884, suffered terribly, but which, since the completion of its new system of water-works in 1885, has enjoyed a comparative immunity, notwithstanding the fact that cholera still prevails in Italy, and that we have evidence of its presence in a malignant form in the city referred to. When I was in Naples in 1885, the Mayor of the city invited a number of the delegates to the Sanitary Conference to the municipal palace, for the purpose of conferring with them in reference to projected sanitary improvements, and especially with reference to the best system of sewerage for the city, which, up to the present time, remains destitute of sewers, and which, I may add, is a noted stronghold of typhoid fever. In the course of the conversation I suggested to the Mayor Colonel Waring's American system, which has been tested with such favorable results in this city. My recommendation was sustained by the distinguished German bacteriologist, Dr. Robert Koch, who was one of the delegates present. I may remark that I have recently received a letter from Dr. Koch asking me to give him full particulars with reference to the details of this system as carried out in the city of Memphis.

I am not willing to leave the subject of quarantine, to which I have briefly referred, without placing myself upon record with reference to a matter in connection with it, which I consider one of the greatest importance. The practice which has come down to us from former times, when questions relating to abstract justice and individual rights had but little consideration in face of a danger to the community, of taxing commerce for the support of quarantine establishments, I consider one that is wrong in principle and unjust to those who are required to bear the burden. It seems to me to be evident that the people protected should pay the cost of such protection, and that quarantine establishments should be supported at the expense of the National Government, or of the States in which our seaports are located, and not by a tax upon the shipping entering these ports. I am not so much concerned, however, with the unjust tax upon ship-owners as with the gross injustice to passengers, practised at many ports in various parts of the world, when they are so unfortunate as to be detained at a quarantine station. Humanity demands that a sick person who is detained for the protection of a community should receive the best possible care, and justice requires that both sick and well, while detained at a quarantine station, should be well fed and well lodged without expense to themselves. Moreover, at a quarantine establishment which is supported by a tax upon ships and upon the passengers detained, an unscrupulous official may add to the hardships of passengers, the barbarity of an unnecessary detention from a venal motive. I trust that such things do not happen in our country; but to show how unjust the principles of taxing the passenger for his support while under detention in quarantine is, I will mention a circumstance which recently fell under my own observation:

When I left Brazil, in the month of August last, smallpox was epidemic both in Rio de Janeiro and at Para. Our ship touched at Para and five days later at Barbadoes. A passenger for this port was not allowed to land, because of the prevalence of smallpox in Brazil. Proceeding to St. Thomas, less than two days' sail from Barbadoes, our passenger was again refused permission to land, except to go to the quarantine station for a certain number of days. This was all right; but the conditions upon which he would be received seemed to me to be all wrong. Either he himself or the ship must guarantee the payment of the quarantine fees, which would be $3 a day for his board and $5 a day to the quarantine physician if he were alone. If others were at the station at the same time, this fee would be divided

between them. One can easily imagine what a hardship such a tax would be for a person of limited means, who had only provided himself with funds for the journey he had undertaken. The agent of the ship refused to take any responsibility, and our passenger had no resource but to submit to the imposition or to come to New York, paying his passage to that port.

As another illustration of the evils arising from the present system of supporting quarantine establishments, I will mention a circumstance which occurred upon our arrival at the port of New York. With the Deputy Health Officer who boarded our ship came a man with a jug. I was informed by one of the officers of the ship that he was to disinfect the vessel. Being somewhat curious to know the method of disinfection employed, I asked the ship's surgeon to go with me to inspect, when, after a detention of less than one hour, we had started from the quarantine station for our wharf. We found that the man with the jug had lowered a bucket by means of a rope through one of the hatches between decks. Upon pulling up this bucket, I found that it contained two or three pounds of some powder which had been wet, probably with an acid solution, and which gave off an odor of chlorine. No doubt, when first lowered between decks, there had been a considerable evolution of chlorine, but in the vast space to be disinfected it was so diluted that, at the end of an hour, I did not detect the odor of chlorine gas when I lifted the hatch, and it was only by approaching my nose to the bucket that I was able to ascertain what disinfectant had been used. The most curious part of the story is that I was informed that the bucket had been lowered between decks to disinfect a quantity of hides which were stored in the hold. What was the object of this "disinfection"? Evidently not to disinfect, for no one at the present day would think of maintaining that the hides in the hold had been disinfected by the procedure of the man with the jug.

The only object that I can conceive of depends upon the fact that there is a fee for disinfecting, which must be paid by the agents of the ship; at least I was so informed by one of the officers of the ship.

Gentlemen, we cannot control the action of sanitary authorities abroad, and, if we are ever so unfortunate as to be thrown in a lazaretto in one of those countries where the rights of the individual are counted as nothing, God pity us, for the fact that we are American citizens will be of no avail. But we can at least correct abuses, if such exist, at our own seaports, and set an example to other nations of an enlightened policy, which will not only redound to our credit, but will directly benefit our languishing commerce.

The most enlightened nations of Europe recognize the importance of a uniform system of quarantine administration, based upon past experience and recent progress in sanitary science, and this has been one of the principal objects in view in the assembling of expert delegates from the various countries interested for international sanitary conferences.

The first International Conference was that of Paris, in 1852. A second Sanitary Conference assembled in the same country in 1859, for the purpose of revising and simplifying the conclusions adopted in 1852; the next Conference was that of Constantinople, in 1866, and this, like the last Conference assembled in Rome in 1885 at the call of the Italian Government, followed immediately after an epidemic of cholera, and had special reference to the restriction of this disease. The Conference at Vienna followed in 1874, and that of Washington in 1881. The latter, following after our yellow fever epidemics of 1878 and 1879, had the special object in view of establishing an international system of notification of the appearance of epidemic disease in all parts of the civilized world, and of the sanitary condition of seaport cities, and especially of ships sailing from infected ports.

Unfortunately, all attempts to establish an international code of quarantine regulations have thus far failed, owing to the very diverse opinions held by the delegates from the several nations who have been assembled for this purpose, and to the conflicting interests of some of the great powers. While, as a nation, we have taken part in these sanitary conferences, and have advocated an enlightened and uniform policy of quarantine administration, and international notification of infectious diseases, we have as yet no uniformity in the quarantine regulations of our own seaport cities, and no central health bureau. Gentlemen, it is well for us to consider these matters, and to point out to our legislators the present unsatisfactory condition of affairs with reference to the subjects referred to.

(To be concluded.)

INJURIES OF THE FŒTUS DURING LABOR.[1]

By THEOPHILUS PARVIN, M.D.,
PROFESSOR OF OBSTETRICS IN JEFFERSON MEDICAL COLLEGE, PHILADELPHIA.

Though injuries of the child during labor are not frequent, probably they are much less rare than commonly believed. In many instances they are not recognized immediately after delivery, and they may spontaneously disappear, and in some their consequences are attributed to erroneous causes. Some of these lesions may happen in spontaneous labor, and others in artificial, whether the interference be manual or instrumental. It is impossible to classify them according to their causes, and apparently the most satisfactory division is one resting upon the regions or parts affected. Hence, in the paper now presented, injuries to the fœtus in labor will be divided into those involving the head and neck, those of the trunk, and, finally, those of the extremities.

Injuries of the head and neck.—Contused wounds of the scalp and of the face, and incised, punctured, and lacerated wounds of the former are met with. So far as contused wounds of the face are concerned, it usually happens that they follow difficult delivery with the forceps, especially if the instrument be a powerful compressor; so, too, these result if the blades are applied obliquely, or antero-posteriorly to the head instead of to its sides. But in most all cases the effects are trivial and soon disappear. Punctured and incised wounds of the scalp have been made by the obstetrician mistaking a caput succedaneum for

[1] Read before the Philadelphia County Medical Society, October 26, 1887.

the fœtal skull. Turnier mentions an instance of a wound thus inflicted leading to the death of the child from erysipelas a few days after birth. More extraordinary is a lacerated wound of the scalp made in the effort to apply forceps, the operator introducing one of the blades between the scalp and the cranial bones.[1] An example of this terrible blunder is mentioned by Chaussier,[2] and I have met with a similar case.

Sloughing of a portion of the fœtal scalp has been observed following some cases of spontaneous labor.

Thus, Prestley[3] has reported a case of this kind, resulting in death eight days after delivery; the labor was protracted for forty-eight hours because of a narrowed pelvic outlet. Lizé,[4] of Mans, states that in the case of a multipara, forty years of age, the waters ruptured five days before the birth of her child, which presented by the vertex, but occupied an occipito-sacral position. Five days after delivery, a slough involving almost the entire extent of the occipital bone appeared; three days subsequently it became detached and the child recovered. Bouchut quotes from Lorain a case of gangrene of the scalp in a newborn child occurring in the service of Moreau at the Maternity. The mother was a primipara, and the labor lasted forty-eight hours, terminating spontaneously; the child died on the nineteenth day. Dr. Goodell informs me of a case in which an oblique application of the forceps was made—one blade being in relation with the right frontal bone, and the other with the left occipital—and the right anterior portion of the head was so bruised that sloughing occurred a few days subsequent to birth; after the detachment of the slough a fatal hemorrhage occurred.

Depressions and fractures of the cranial bones, separation of their union to each other, fractures of the bones of the face, as well as disjunction of their articulations and joints, have been observed more or less frequently in cases of difficult labor, manual or instrumental—some of them, indeed, in spontaneous labor.

In regard to depressions of the bones of the fœtal skull, some obstetricians have asserted that they are always accompanied by fractures. That was the opinion of Danyau, of Lachapelle, and of Schröder. But the following case,[5] given by Matthews Duncan, seems to strengthen the view held by most obstetricians, that such depressions may occur without the bone involved being broken. The case was one in which persistent digital impression was produced on the right parietal bone of a fœtus during birth, by the finger of the accoucheur, who was endeavoring to cause rotation. The result was slight, short, but frequently repeated epileptiform seizures, which lasted some time after the digital impression had disappeared, and were finally replaced by choreic movements. Now it seems hard to conceive that the pressure of the finger produced a fracture of the bone. Dugès[6] has given a history of great depression in one of the parietal bones, not followed by any serious consequences. The child was delivered by the feet through a pelvis of which the conjugate was estimated at three inches and a quarter. Powerful traction upon the shoulders and upon the lower jaw was necessary to bring the head past the obstruction, and the parietal bone, which was in relation with the sacro-vertebral angle, presented a depression half an inch in depth and two inches in breadth. The infant was resuscitated with difficulty, then had convulsions, but in a few days was quite well, and in fifteen days the depression had entirely disappeared.

Minor depressions or indentations are sometimes seen, especially after the application of the forceps, and in rare instances such marks are permanent. But we must not be in haste to conclude that these indentions found upon the head of a newborn child are proofs of instrumental delivery, for Osiander[7] has stated that, having delivered a child by podalic version through a narrow pelvis, he found upon its head a depression into which the end of a forceps-blade accurately fitted; so that he himself would have concluded, had he ever seen a similar depression, that the delivery had not been spontaneous, but by the forceps.

Fractures of the fœtal skull have been observed as the result of direct violence, as when a woman expels her child while she is standing, and it falls on the floor. Or, again, a woman,[8] near the close of the second stage of labor, the child's head being at the vulvar opening, threw herself out of the window, and several fractures of her limbs, as well as a fracture of the child's head, resulted. But apart from these cases in which the injury has resulted from direct violence, and those observed in delivery, whether spontaneous, manual, or instrumental, in narrowed pelves, which will be referred to in a moment, fracture may occur when the labor is in all respects perfectly normal, so far as duration and facility are concerned. Thus, Dr. Charles West[9] has reported the case of an infant dying from convulsions nine days after birth, the labor having been an easy one and lasting but five hours; the mother had previously given birth to two living children, and these labors too had been normal. Yet upon an autopsy of the third child, a fracture of the right parietal bone, with effusion of blood between the cranium and dura mater, the effusion being more than half an inch thick and occupying the entire fossa of the bone, was discovered. He states in his report that fractures of the skull have been known to take place during easy labors, and wholly independent of any preternatural degree of ossification of the skull. Monteith[10] mentions having attended a case of perfectly natural labor, yet the child had a fracture of the right parietal bone; there was a

marked depression in the middle of the bone, and the fracture extended to the sagittal suture on one side, and to the coronal on the other. It is quite apparent that a case such as either of these might give rise to medico-legal investigation, or to unjust censure of the obstetrician.

Coming down to fractures of the bones of the cranium or face, or rupture of joints involving the maxillary symphysis, or the cervical vertebræ, or fracture of a vertebra, for it is claimed that usually the body of one is broken rather than a separation between two vertebræ, as the consequence of great traction occurring in manual or in instrumental delivery, an important question arises as to the amount of force that may be safely used either with hand or instrument. In illustration of the great force which has been employed in forceps delivery without injury to mother or child, I quote the following from Dr. Peugnet.[1] He states:

"I was called to Mrs. K., a multipara, in labor with her third child. The first two were delivered by craniotomy. The vertex presenting, R. O. A., and impacted between the sacrum and the pubes, the conjugate diameter of the superior strait greatly contracted, I applied forceps, and had great difficulty in locking them. Dreading the laceration which might ensue in this case from side-to-side lever action, I concluded to rely upon direct and steady traction. My strength giving way, her husband held me round the waist, whilst the patient was held *in situ* on the dorsum by four women. In forty-five minutes I had the satisfaction of bringing the head down upon the perineum. The delivery was then speedily accomplished. Both mother and child, a girl, did well."

The least that can be said in regard to this case is, that the result was very remarkable, and it is doubtful whether the practice pursued could be repeated in any considerable series of similar cases without injury to both mother and child.

Delore,[2] after remarking that the fœtal head may endure, without injury, a great compressing force if applied to a large surface, and if made by a regularly concave surface, as that of the blades of the forceps, states that from his experiments he found that a compressing force of two hundred and twenty pounds did not cause a fracture. But, on the other hand, if the blades slip, if the pressure is made upon a small surface, fracture follows the exercise of much less force. Further, a blunt, angular body, such as the sacro-vertebral angle, the spherical surface of which is described by a radius of three-fourths or one inch, produces a fracture with a force of forty-four pounds. As the force which is exerted in difficult labor is more than forty-four pounds, fracture results.

Nevertheless, these results are not in complete accord with those of Goodell,[3] though, as will be seen, he is discussing the question of the amount of force of traction that may be safely used in a narrowed pelvis without injury to the neck of the child. Nevertheless, the subject of injury to the bones of the head is also involved, and in only one instance, I believe, does he mention fracture of one of the cranial bones. He states that he has on several occasions delivered living children after throwing on their necks a weight of 130 pounds. He further says that, although exerting all the manual strength at his command, he has never seen the body part from the head; he mentions one instance in which there was not the slightest apparent injury to the neck though the sacral side of the head had been broken in. Further, in another case, the force of traction upon the child's head, combined with suprapubic pressure, amounted to 200 pounds. Stone[1] has more recently reported a case of podalic version, and delivery by traction through a narrowed inlet, in which he put on the neck of the child all the force of which he was capable, using the pump-handle movements described by Goodell. The child was dead. There was no fracture of the bones of the head.

"The spine had parted in the upper dorsal region during the traction upon the trunk, which was necessary to cause the shoulders to come low enough to reach the arms. The cervical spine was not broken."

Delore's conclusion as to the amount of force followed, in pelvic narrowing, by fracture of the cranium of the fœtus is erroneous, or such injury ought to have been observed in all the cases where a force even approaching 100 pounds were used.

Champetier's[1] investigations as to the force that could be safely used in the delivery of the fœtus, led him to the following conclusions, the first of which does not correspond with the results obtained by Goodell: First, there is danger of fracturing one of the parietal bones, whatever the method of extraction, if the total force employed reaches seventy-five to eighty-eight pounds, the infant being at term, forty-four to fifty pounds if it be premature. Second, the inferior maxillary of a child at term will bear, without rupture, a traction of fifty-five pounds. Third, the vertebral column of an infant at term was ruptured in three cases by a force of one hundred and ten pounds.

So far as objected that these results have been obtained by experiments upon dead children, and, therefore, they are not applicable to the force that may be exerted upon living ones, the answer of Matthews Duncan may be repeated. He, after consulting physiological and physical authorities, could say that a child living and one recently dead were the same as to tensile strength.

In this connection it is well to refer to the amount of traction which may be safely applied to the lower jaw of the fœtus, as stated by Duncan[2] from his own experiment. It will be observed that his results are not the same as those announced by Champetier. Duncan states: "It is now ascertained that a force of half a hundred weight (fifty-six pounds) may, at least in some cases, be applied by dragging the lower jaw of the fœtus without producing any easily discovered injury of the parts." He further says that compound dislocation would be almost certainly

fatal, and in one of his experiments this injury was done by a weight of fifty-six pounds. Not only does Duncan's statement as to the force which the inferior maxillary will bear without injury differ from that of Champetier, but the difference is still greater from that given by Delore, who makes this eighty-eight pourds.

Fractures of the cranium usually involve the parietal bones, but they may also occur in the frontal, in one of the temporals, or in the occipital. Jacquemier first pointed out the separation between the squamous and the basilar portion of the occipital bone, to which some more recent writers[1] have directed attention without giving him just credit. He has also stated that he met with fracture of the occipital in that part of the bone above the protuberance.

Ruge,[2] referring to separation of the epiphyses between the squamous portion of the occiptal bone and the articular part, states that Schröder is the only one who has recently drawn attention to it, and, notwithstanding its importance in regard to the life of the child, this lesion is not referred to in classic works as one of the immediate consequences of extraction. The lesion may also occur in a narrowed pelvis, though the presentation be cranial. In these cases there may be not only effusion of blood, but further compression by the squamous portion having its anterior inferior margin forced against the medulla.

On the other hand, severe injury of the frontal bone has been observed without serious consequences. Thus, Dugès saw a child recently delivered, and the left eye was almost completely outside the orbit, so great was the depression of the frontal bone, yet the infant did not have convulsions or any other grave symptoms. I have, however, seen protrusion of the eyeball in a newborn, following fracture of the frontal bone by Hodge's forceps, used in a case of tedious labor in a primipara, the delay being from an occipito-sacral position; the child lived for a week after birth. That an infant may survive very grave injuries in labor is proved by a case reported by Lamotte,[4] in which a surgeon, in a case of shoulder presentation, had torn away the arm, and then performed craniotomy, evacuating a large amount of the cranial contents; yet the child was born alive.

Zweifel[5] regards fissures and fractures of the cranial bones as only of clinical signficance if a sinus be injured and consequent hemorrhage occurs. On the other hand, Delore[6] asserts that all these fractures are grave, on the ground that they may be accompanied by contusions of the brain. Further, there may be hemorrhages between the bone and the periosteum, in the cavity of the arachnoid, or between the pia mater and the brain. If the solution of continuity be at the position of a sinus, there is frequently rupture of the vessel. He adds that in all cases in which the head has undergone severe compression from dystocia, he believes hemorrhages occur. The significance of this last remark will be appreciated, especially when we consider the remote consequences upon the mental condition of the child, as urged more especially by some English observers.

Injuries to the bones of the face are usually of the inferior maxillary. This bone may be fractured, or separation of the mental symphysis may occur. Ruge mentions cases in which, in addition to injury of the bone, there were lesions of the soft parts—as, for example, tearing of the skin at the angle of the mouth, as well as the mucous membrane of the pharynx and rupture of the genioglossus. Yet if we fail to use traction upon the lower jaw in cases of difficult head-last labors, we miss what may prove an important means of delivery in some cases, and which may be of great value when other means fail. Some years ago, in a case of narrowing of the pelvic inlet, having failed to deliver with forceps, I performed podalic version, and sought to deliver by traction, while a consultant aided with suprapubic pressure. I am confident I did not use the force which some operators have safely employed under similar circumstances, yet the cervical vertebræ gave way, either by separation, or by fracture, and I found apparently nothing but the integument holding the head to the body. I then succeeded by traction upon the inferior maxilla, suprapubic pressure assisting in bringing the head into the pelvic cavity. That the head may be left in the uterus, the body being dragged away, is a fact proved by occasional instances in the history of obstetrics. In other cases the division has been made, not by rupture, but by cutting through the neck. An instance is reported[1] in which the obstetrician failing to deliver the head in a case of shoulder presentation, after detaching the arm and bringing down the feet, performed decollation, and the head and the placenta remained in the uterus for forty days. Freund mentions a case in which the head was left in the uterus for ten years.

Probably the most remarkable case of multiple injuries to the face has been recorded by Petit.[2] The face presented, rupture of the uterus occurred, and the woman died undelivered, though the forceps had been used. The autopsy of the child showed multiple separations of the bones of the face, and fractures.

Paralysis of one of the facial nerves has been observed most frequently, but not exclusively, after the use of the forceps. In a paper read before the American Gynecological Society in 1885, I have referred to eight cases of spontaneous facial hemiplegia, and also mention one case observed by Seeligmüller, in which the paralysis affected both sides of the face. But the disorder usually occurs from the use of the forceps, and is caused by the pressure of one of the blades at the stylomastoid foramen, or a little in front of the lobe of the ear. Landouzy, who has best described the affection, has remarked that in the infant the complete absence of the mastoid apophysis, and the slight development

[1] Thus Bednar, Die Krankheiten der Neugeborenen und Säuglinge, Wien, 1853, refers to it as a hitherto unobserved injury.

of the auditory canal, favor the possibility of this compression of the facial nerve near its point of emergence. In six weeks, according to Parrot and Troisier, recovery usually takes place in paralysis of the facial caused by forceps. Many cases, however, are well in ten days. Nevertheless, while recovery is the rule, it should be remembered that in some the injury is permanent. Duchenne[1] refers to two patients, one fifteen years old, and the other five years and a half, in each of whom the paralysis continued.

It should also be observed that there may be facial paralysis in the newborn caused by protracted labor and intracranial hemorrhage. Injuries of the sterno-cleido-mastoid muscle have been observed by several. In reference to torticollis of obstetric origin, Stromeyer and Dieffenbach explained the affection as resulting from improper application of the forceps, the muscle being bruised or torn. Nevertheless, this explanation is rejected by Saint-Germain as not plausible. A very large proportion of infants that have wry-neck, are born with pelvic presentation, and it is asserted that in the traction exerted rupture of a greater or less number of the fibres of the muscles takes place, and a hæmatoma follows; finally, the contractions of the cicatricial tissue result in drawing the head into its unnatural position. One of the first references to tumors of the sterno-cleido-mastoid was made by Melchiori[2] in 1862. He spoke of them as indurations of muscle, sometimes met with in young infants, and to which he found no reference in authors. He met with the disorder four times, and he described the affection as an indurated, plastic deposit; while he mentions temporary deformity of the neck, he does not speak of any case in which this was permanent. In referring to the etiology, he suggests that compression of the muscle or laceration of some of its fibres may take place during labor.

The next year both Dr. Wilks and Sir James Paget[3] met with cases of what they described as chronic induration of the sterno-cleido-mastoid. Another case of the affection was reported the same year by Harris, and thus the published cases in a few months were at least six, but no reference was made by any of the reporters to the previous observations of Melchiori. Bryant[4] in 1863 reported two cases of thickening of the sterno-cleido-mastoid. One patient was four, the other eight weeks old when he saw them; in each instance the birth was with pelvic presentation. Probably in all the cases, or at least in a majority of them, the disease was hæmatoma. Nevertheless, Blachez[5] regards these tumors as caused by an interstitial myostitis in consequence of traction upon the muscle. He describes the tumor, observed in one of his patients, as elastic, almost painless, and the size of a pigeon's egg; it was situated in the right sterno-cleido-mastoid, and was not discovered until two or three weeks after birth, when the attention of the parents was called to it by the infant's keeping the head inclined to the right side.

Zweifel recognizes injuries of the sterno-mastoid muscle in labor as a cause of torticollis. Professor Albert,[1] of Vienna, referring to a child with torticollis, stated that the sterno-cleido-mastoid may become contracted during intrauterine life, or be injured during birth. In breech presentations, and in difficult forceps delivery a laceration of this muscle may occur, and be followed by inflammation and contraction. While such injury is more frequent after head-last labors, yet they are also met with in vertex presentations, and if the forceps have been used.

On October 2, 1861, a paper was presented to the London Obstetrical Society by Dr. Tyler Smith for Dr. W. J. Little, the title being "Upon the influence of abnormal parturition, difficult labors, premature birth, asphyxia neonatorum, on the mental and physical condition of the child, especially in relation to deformities."[2] In this paper, which, by the way, mentions two cases of wry-neck, that he attributed to difficult labors, the author says:

"It is impossible to connect the persistent affections of the intellect, of volition, and of organic life, with the injury the several nervous centres suffered in some instances before the fœtus had reached the maternal pelvis, in others whilst in transit through it; and in a third set of cases, where the fœtus was exposed to neither of these kinds of injury, it suffered from asphyxia neonatorum, suspended animation, and its concomitant congestions, effusions, capillary apoplexies of the brain, medulla oblongata, and spinal cord."

Dr. Langdon Down, in discussing the obstetrical aspects of idiocy, stated that in a very large number of cases of idiocy the subjects were born after difficult labors, these being usually tedious, and he held that if a neurotic tendency was present the tedious labor and suspended animation might determine the catastrophe, where otherwise all might have gone fairly well.

The following note from one of Dr. Little's[3] correspondents may be of some interest; it is in reference to a young man in regard to whom inquiry had been made by Dr. Little:

"I have again ascertained he was asphyxiated for two hours when born, and that he has always been a weak creature, very slow in mental development, with difficulty in speaking, trembling and shaky, unable to fix his attention on a book, and a bit of a punster."

The final statement, "a bit of a punster," is conclusive as to the intellectual feebleness of this unfortunate man!

These views are further strengthened by the statement of Dr. Arthur Mitchell[4] that he believes there is a connection between difficult labor and idiocy.

Injuries of the trunk.—The chief lesions of the trunk are rupture of the connections between the dorsal vertebræ, or fracture of one of these, injuries to the abdominal wall by a badly directed blunt hook, effusion of blood in muscles, similar to those that have been referred to as occurring in the sterno-cleido-mastoid, retropleural hemorrhages along the spinal column in case rupture of this column occurs, hemorrhage in the abdominal or thoracic cavity, and

[4] Medical Times, 1862, 1863.

collections of blood beneath the capsule of the liver, or of the kidneys, and rupture of the sacro-iliac joint. Hagen has collected forty-four cases of injuries to the fœtus occurring in extraction after version, and twenty-nine of injuries in pelvic presentations; in the former there are three of rupture of the sacro-iliac joint. It is probable, as suggested by Zweifel, that some cases of ankylosis affecting this joint, of which the etiology is obscure, are to be attributed to injury in birth. Zillner[1] has reported a rupture of the sigmoid fissure occurring in labor.

Injuries of the arms.—In connection with these lesions those of the scapula and clavicle, which belong to the arms rather than to the trunk, will be considered. Before states that fractures of the humerus are more frequent than all others; since they are usually readily cured, and as they are generally caused by *malpraxis* they are rarely published. But he further says that this accident may occur in the hands of the most expert accoucheur if the pelvis be contracted. They most frequently occur in the disengagement of the arms after podalic version when extraction is necessary, and they may also happen in pelvic presentations, but usually, if we do not have to extract the child—that is, if the cephalic can be left solely to nature—the arms will not ascend, but remain applied to the chest. Smellie[2] states that he fractured the humerus in a case in which he turned and delivered by the feet, and this is the only one he gives, while he mentions three cases of fracture of the femur, two occurring in the practice of his assistants, and one in his own.

All obstetricians agree that in bringing down an ascended arm it is important no pressure be made until the internal angle of the elbow is reached, and that three or four fingers should be employed, and not one or two. Pajot regards it as important that the posterior arm should be liberated first. Küstner[3] describes separation of the epiphysis of the head of the humerus from the diaphysis as one of the injuries of labor which may be overlooked, or falsely regarded as a luxation, fracture of the neck of the scapula, or injury to nerves. Fractures of the clavicle, separation from its sternal attachment, transverse fracture of the scapula, separation of the epiphysis of the neck of the scapula, injury of the acromion process, and dislocation of the humerus, have been observed.

Fracture of the clavicle is most frequently caused by pressing directly with one or two fingers in the endeavor to bring the head through the pelvic inlet after podalic version, or in pelvic presentation. McClintock, in one of his annotations to the Sydenham Society's edition of "Smellie," observes, "Although Smellie gives no example of fracture of the child's clavicle during delivery by the pelvic extremities, yet, in my experience, it is a bone very apt to be broken by the manipulations of the accoucheur, more so even than the humerus; this may, perhaps, be explained by its greater degree of ossification."

Paralysis of the arm.—Sinkler recognizes hemiplegia as, in some cases, the consequence of injury at the time of birth, either from the forceps or from the pressure of a prolonged labor. Nadaud gives seven cases of paralysis of the arm attributed to the forceps; the first one of this injury reported is one of Smellie's. Jacquemier mentions an instance of paralysis of the deltoid following a long and difficult, but spontaneous, labor; the recovery was complete in fifteen or twenty days. He attributed the disorder to compression of the axillary nerve against the humerus at the point of its attachment to the deep face of the deltoid. Fasbender found a tumor, as large as a pigeon's egg, situated above the right clavicle, in an infant soon after delivery; the hæmatoma gradually disappeared, but at first there was paralysis caused by nerve compression. Delore suggests that paralysis may be caused by the rupture of a nerve trunk near its connection with the spinal cord. He states that this accident is not rare in the newborn or in young infants as a consequence of traumatism; it is followed by incurable paralysis, which is compatible with life if an upper member only is affected.

Disengagement of the extended arms in pelvic deliveries, traction upon the axilla in delayed delivery of the body in vertex presentation, the traction in some cases being with the blunt hook, in others with the finger, have resulted in paralysis of the arm. So, too, the same disability has followed a case in which the arm has protruded in the shoulder presentation, and delivery effected by podalic version.

Luxation of the humerus has, in some instances, been mistaken for obstetric paralysis. Further, it is important to distinguish between cerebral and traumatic paralysis. Duchenne[1] gives an instance in which there were both cerebral and obstetric paralysis, the latter consequent upon a fracture of the ulna near the elbow.

Fractures of the femur may be spontaneous, or consequent upon artificial delivery. Meyer has recently[2] reported two cases in which spontaneous fracture of the femur was observed; in one a single femur was broken, but in the other both femurs. In May, 1847, Dr. Vanderveer[3] reported a case of such fracture in childbirth. But probably more fractures of the femur are to be attributed to the attempt to pull down a lower limb in pelvic presentation when the presenting part is already partially in the mother's pelvis, before pressing up that pre-

[1] Centralblatt f. Gynäkol., 1885.

[2] Sydenham Society's edition of Smellie's Midwifery, vol. iii., pp. 200, 208. The great obstruction in the first volume, op. cit., occurs in "In consequence of preternatural cases, when considerable force has been used in delivering the child, the whole body ought to be examined, and if there is any ink or contusion on the head or neck (supposing it presented with point on), and gently rubbed off or dissolved with the ball or touch of a handkerchief, if any limb is dislocated or broken, it ought to be reduced immediately; luxations, though [illegible] are, of more difficult reduction, for the soft parts about the joint, the humerus being easily dislocated, and [illegible] dislocations. The bones of the arm and thigh are more subject to be fractured than any other of the extremities. The first is easily cured, because the arm can be kept from being moved, but a fracture of the thigh-bone is much more troublesome case, for notwithstanding all the difficulty of keeping the bones in proper situation, the parts often necessarily moved in curing the child."

senting part, or from the use of the blunt hook. Delore's experiments show that with the untired finger traction to the amount of thirty-three pounds may be made upon the groin, and this cannot break the femur. If a force of one hundred and twenty pounds is employed upon the femur, fracture occurs; if the instrument be perpendicular to the bone, the latter gives way with a pressure of forty-four pounds. Again, the bone has been broken, or that which is equivalent, separation of the epiphysis been caused from traction upon the leg. A. R. Simpson mentions an instance in which, podalic version having been performed, the right lower limb was brought down, and traction made; subsequent examination showed that there were three such fractures.[1]

Luxations of the femur consequent upon obstetric operations, according to Ruge, are exceedingly rare; upon 300 autopsies of newborn infants he did not find a single true dislocation of this bone. Küstner, in referring to luxations of the hip, speaks as follows:

"Göschen relates a case in which Langenbeck reduced such luxation after the subject, a girl, was thirteen years old, and mentions in this connection that Stromeyer had met with twenty cases. The only possible way in which this injury could occur would be by sudden and violent force drawing down the limb, and then dislocation upon the ilium might result. But the force must be great. I have suspended to the leg of a child, from six to ten minutes, a weight of from sixty-six to eighty-eight pounds, without any injury to the joint."

Complete paraplegia in connection with facial paralysis of the right side has been observed following a difficult labor in which the forceps was used. Examples of rupture of the spinal cord, in connection with rupture of a vertebra, have been observed, and, of course, paralysis of the lower limbs. It is remarkable that in two such cases the children lived for some hours. Paraplegia in the newborn is, as Nadaud states, usually an evidence of serious lesion of the cerebro-spinal organs, and the child dies after a short time.

I think the study of these cases of obstetric injuries, which might be greatly extended—for much more remains unsaid than has been said—ought, in the first place, to lead us to a larger charity for fellow practitioners, as many of the most serious injuries in childbirth may occur without the slightest blame necessarily attaching to the accoucheur. Another lesson is that an important distinction should be made, as urged by Ruge, between podalic version and extraction, never resorting to the latter, unless absolutely necessary, after the performance of the former, and thereby many of the obstetric lesions of the fœtus may be avoided. Very wisely, Lamotte says, referring to the injuries that may be done in labor to the child by the accoucheur, "The hand improperly used is more dangerous than any instrument."

Again, the question arises as to the safest manual means for the delivery of the head in head-last labors. In Cieslewicz's collection of cases of injuries of the fœtus in labor, there are several in which very serious consequences resulted from employing the Prague method. One of these, reported by Gusserow, showed, upon post-mortem examination, rupture of the vertebræ and most of the soft parts of the neck so complete that the head was attached to the trunk only by the skin and the vertebral arteries. Ruge, rejecting both the Prague and the Vienna method, prefers elevation of the occiput, bringing the face down, and carefully conducted expression, as least liable to injure the fœtus.

Another question of practical interest is the best method of delivery in pelvic presentations, when interference is necessary. Should we follow that employed by Goodell, in all cases bringing down a foot as soon as possible, and thus be commander of the situation, in case necessity for extraction arises? Must we use the blunt hook? Is the application of the forceps to the breech to be generally advised?

Again, while treatment of fractures of an upper limb, or of the clavicle, is said to present usually no great difficulty, can a similar statement be made as to fracture of the femur? What method of treatment is best? In depressed fractures of the skull, is it not probable that some lives might be saved by the use of the trephine? and in other cases, not followed by death, perfect mental integrity insured?

Finally, many questions as to the diagnosis of obstetric paralyses of the newborn arise, and, also, as to when and what treatment should be employed.

TWO CASES OF ABDOMINAL SECTION FOR TRAUMATISM, AND TWO CASES OF STAB-WOUND OF THE ABDOMEN WITH PROTRUSION OF OMENTUM.

BY JOSEPH M. FOX, M.D.,
OUT-PATIENT SURGEON TO THE PENNSYLVANIA, UNIVERSITY, AND CHILDREN'S HOSPITALS, PHILADELPHIA.

The following cases came under my care during the past summer and the summer of 1886 while in charge of the wards of Drs. T. G. Morton and William Hunt, at the Pennsylvania Hospital.

Case I. *Stab-wound of liver; abdominal section; death.*—George K., aged thirty-two years, was admitted into the hospital, June 28, 1887, with a stab-wound of the abdomen. He was intemperate in his habits and had been on a spree for the past four days. He was stabbed with a penknife during a fight, a short time before his admission to the hospital.

Upon admission the patient was suffering from shock and was partly intoxicated; his temperature was 98° and his pulse 100 and weak. The wound was an inch and a quarter in length, parallel with and one inch below the border of the ribs, and one to one and a half inches to the right of the median line; he had some fulness and tenderness of the abdomen. No visceral injury could be detected by the finger passed through the wound into the abdominal cavity, but as he had lost such a large quantity of blood, his shirt and pants being saturated with it, and from the position of the wound it was believed that his liver had been injured, I, therefore, thought it best to open his abdomen.

The operation was performed three and a half

hours after the injury. After the patient was etherized the wound was extended to the median line and downward, making an incision five inches in length. A considerable quantity of fluid blood and a few small clots were removed from the abdominal cavity: the right lobe of the liver was found to be wounded, the cut being three-quarters of an inch in length and one-half inch in depth, situated over the gall-bladder about an inch and a half above the lower border of the liver. The wound was touched with the Paquelin cautery to control the hemorrhage and the abdominal cavity was thoroughly washed out with warm water passed through a blunt trocar and tube attached to an irrigating apparatus and the cavity was then sponged dry. The abdominal wound was brought together with silk sutures and an iodoform and bichloride gauze dressing applied. The time occupied by the operation was about one hour and fifteen minutes.

Shortly after the operation his pulse was 120 and his temperature 97°, but the latter rose in a few hours to 100 .

Before the operation was completed his skin became moist, and some hours later he suffered from a profuse cold sweat, his pulse at the same time became weaker and more frequent, he said he was free from pain and it was observed that his abdomen became more relaxed, but he was very thirsty and inclined to be restless.

He was given stimulants by hypodermatics and by the mouth, but he gradually failed and died about twenty hours after the operation.

Autopsy.—The abdominal incision looked well and the abdomen was relaxed; the abdominal cavity contained about a half ounce of blood-stained serum, but no signs of peritonitis were found and there had not been any further hemorrhage; the wound in the liver also looked well.

REMARKS.—I was very much disappointed in the result of this case, as I thought he should have recovered; death was due, I think, to the excessive loss of blood before the operation and to his habits; peritonitis I feel sure would not have developed, as the abdominal cavity was thoroughly washed out and left in a good condition, as the post-mortem examination proved.

Some difficulty was experienced in keeping the intestine in the abdominal cavity during the operation, especially while the incision was being closed; it was also difficult to draw the liver forward sufficiently to touch the wound with the cautery, as the edge of the liver, while the patient was in the recumbent posture, had been drawn up at least two inches above the position it had occupied when he was stabbed.

From the loss of blood and sweating his blood-vessels were almost emptied, and for hours before death his pulse was scarcely perceptible at the wrist.

CASE II. *Pistol shot wound of abdomen; abdominal section; recovery*.—Peter McG., aged eighteen years, blacksmith, was admitted into the hospital July 4, 1887.

He was accidentally shot while struggling with a friend who had a loaded pistol in his hand. Upon admission about a half hour after the injury his general condition was fair, his temperature was 98⅘°, and his pulse 110, there was slight fulness of the abdomen, and he complained of a dull pain in the umbilical region; the bullet-wound was one and a half inches to the left of, and a half inch below, the umbilicus; a probe readily passed along the wound into the abdominal cavity, taking a direction backward and to the right.

The operation was performed at 1 P.M., three and a half hours after the injury, and I was assisted by the resident surgeons. After the patient was etherized, the abdomen was opened by an incision in the median line, extending from two and a half inches above to four inches below the umbilicus, and a considerable quantity of fluid blood was found in the abdominal cavity.

The bullet had passed through the omentum near its attachment to the transverse colon, through the transverse colon, and then through the jejunum near its commencement, and through the mesentery of another coil of jejunum, lodging, it was thought, in the muscles of the back, to the right of the spine, but it was not traced further.

The four intestinal wounds were sewed up with fine silk, about twenty Lembert sutures being used; the wound in the mesentery was also brought together with silk sutures.

No fecal extravasation had taken place, the intestines appearing quite empty; there was considerable discharge of gas and blood from the wound of exit in the jejunum while it was being stitched, but this stopped as soon as the stitches were tied; some extravasated blood and a bleeding vessel were also found at the wound in the omentum, the vessel being ligated; there also seemed to be slight bleeding from some deep point in the back, which it was thought best not to waste time in looking for, but to trust to its being controlled by the pressure of the abdominal walls. In looking over the small intestine, a recent invagination was found in the ileum, of about one inch in extent, which was readily reduced, no adhesions having formed.

The intestines during the operation were kept covered with towels wet with a warm solution of the bichloride. The abdomen was thoroughly washed out with warm water passed through a blunt trocar and tube attached to an irrigating apparatus, so that all parts of the cavity could be reached.

The abdominal incision was brought together with silk sutures, a rubber drainage-tube being first passed about two inches into the abdominal cavity just above the umbilicus, and an iodoform, bichloride gauze, and absorbent cotton dressing applied.

The time required for the operation, including the application of the dressing, was one hour and ten minutes.

During the operation he had been given one or two hypodermatic injections of brandy and tincture of digitalis, as his pulse was weak. Just after the operation his temperature was 101°, and his pulse 120; at 4 P.M. his temperature had risen to 102 , but at 8 P.M. it had fallen to 100°, and his pulse to 104.

In the evening he was somewhat restless, and had a slight tendency to sweating; he was ordered a hypodermatic injection of morphia and atropia,

which had the desired effect; he was also ordered enemata of beef-tea and whiskey every four hours through the night.

July 5. He had passed a comfortable night, and was doing very well; his morning temperature was 100½°, his pulse 94, and his respirations 16. The abdomen was relaxed, but felt somewhat sore, otherwise he said he was free from pain; there had been a free discharge of bloody serum through the drainage tube. He was ordered small quantities of beef-tea and peptonized milk by the mouth, and the enemata were continued. At ten o'clock in the evening the drainage-tube was removed, as all discharge had stopped; after this he continued to do very well, with the exception of two or three slight attacks of vomiting which occurred during the first three days.

7th. The patient had a natural looking passage from the bowels.

9th. His temperature had fallen to 99°, and his pulse was 72; he was allowed fuller diet, and the nutritious enemata were stopped. Part of the stitches were removed to-day on account of suppuration having commenced along their tracks from the stitches cutting; the remaining sutures were removed three days later, and the parts were supported with adhesive plaster.

22d. He was allowed to get up; the wound had healed with the exception of a small superficial ulcer at the upper part.

August 5. Patient passed from under my care; his wound was perfectly healed, and he was apparently in his usual health, but he said that at times in making exertions he would have pains in his abdomen.

Remarks.—The above, I believe, is the first successful case of abdominal section for gunshot wound that has occurred in this city, the few other cases that have been operated on have all died.

A very interesting point in connection with this case, and which was one of the first things to attract my attention after the abdomen was opened was the invagination of the ileum; it was situated somewhere near the middle of the small intestine, and had no doubt followed the injury; the wounding of the intestine most likely causing increased peristaltic action which led to the invagination.

Some difficulty was experienced in returning the intestines into the abdominal cavity, and keeping them in while the abdominal incision was being sutured, as the walls was very tense, and this tension was the cause of the stitches cutting, and the suppuration which followed.

Although no diagnostic symptoms of injury of the viscera were present in this case, abdominal section was decided upon from the fact that the ball was found to have entered the abdominal cavity.

I am very much indebted to the resident surgeon, Dr. Samuel B. Shoemaker, for the interest and care he took in the after-treatment of this case upon which, in a large degree, success in such operations depends.

Case III. *Stab wounds of chest and abdomen, with protrusion of omentum; death on the thirty-fourth day from empyema.*—Alexander H., aged twenty-eight years, was admitted into the hospital August 14, 1886, having been stabbed with a penknife about three-quarters of an hour before admission.

Upon admission the patient, a man of intemperate habits, large and very muscular, was suffering from severe shock and loss of blood. His temperature was 95°, and his pulse frequent and very weak. He had a stab-wound of the abdomen about two inches above, and one inch to the left of the umbilicus, through which the omentum was protruding, and he had also been stabbed in the chest about two inches to the left of the sternum, the knife passing between the second and third ribs, wounding the lung, as his expectoration was bloody, and most likely cutting the intercostal artery, as there was a large quantity of blood in the pleural cavity, and he had bled freely, externally; he also had another wound four inches in length on his left side, in the line of the nipple, exposing the ribs.

The abdominal wound was enlarged to about two inches, but no intestinal injury could be detected with the finger, and no cut could be found in the omentum; two and a half inches of the protruding omentum were removed, its base tied with catgut, and the stump returned into the abdominal cavity; the deep muscles and peritoneum were then brought together with three catgut sutures, and catgut was used for the superficial stitches; the other wounds were also sutured with catgut, and antiseptic dressings were applied.

The next morning the patient had reacted from the shock, but his pulse was still weak, and his respirations were frequent and shallow. Inflammation of the lung afterward set in with fever, delirium, and extreme restlessness. The abdominal wound did well until the fifth day, when the dressing became displaced, and the superficial stitches gave way; it was afterward found impossible to keep any dressing on for more than a few hours at a time, on account of his restlessness. The wound suppurated, but he did not have any peritonitis; the other wounds healed by first intention.

In a few days his lung cleared up, but the blood in the pleural cavity, instead of being absorbed, became purulent.

He passed from under my care on September 1st, at this time the abdominal wound was healing, and the others were healed, his delirium had passed off, but he still had slight fever and there was considerable effusion in the left pleural cavity; the effusion afterward increased, and he died September 17th of empyema.

At the autopsy the abdominal wound was found healed and the abdominal cavity normal, with the exception of the stump of omentum being attached to the seat of the abdominal wound.

Case IV. *Stab-wound of abdomen with protrusion of omentum; recovery.*—John O'M., aged twenty-five years, was admitted into the hospital July 24, 1887, having been stabbed with a knife a few minutes before admission.

Upon admission the patient, a strong, healthy-looking man, was suffering from shock; his temperature was 97°, and his pulse 84; he had lost very little blood. The wound, which was one and

a quarter inches in length, was situated five inches to the left of, and three-quarters of an inch above, the umbilicus. The finger readily passed through the wound into the abdominal cavity, but no visceral injury could be detected, and no wound could be found in the omentum. The base of the protruding omentum was tied with catgut, and about an inch and a half removed, and the stump was returned into the abdominal cavity. The wound was brought together with catgut sutures, and the usual antiseptic dressings applied. The highest temperature reached after the operation was 99½°; the wound healed by first intention, and the patient did not have a bad symptom: he was discharged on the twelfth day after his injury, perfectly well.

REMARKS.—In the last two cases, as no visceral injury could be detected with the finger passed into the abdomen, and as no cut could be found in the omentum, it was believed that no visceral injury was present; and, therefore, it was considered unnecessary to perform abdominal section. In the first case, if silk had been used for the abdominal stitches, as I believe it always should be, if there is likely to be much tension on the stitches, I think the wound would not have been torn open during the delirium of the patient.

The spray was not used, otherwise all the operations were done under strict antiseptic precautions, with the exception of simple warm hydrant water being used for washing out the abdomen in the first and second cases.

SULPHURETTED HYDROGEN VERSUS THE TUBERCLE BACILLUS.

BY E. L. TRUDEAU, M.D.,
OF SARANAC LAKE, N. Y.

IN an article published in THE MEDICAL NEWS for May, 1887, Dr. Hugenschmidt extols the efficacy of H_2S in rendering innocuous tubercular products, and quotes in support of his views the experiments of Niepce, who claimed that tubercular sputum exposed for ten minutes to an atmosphere containing 3 per cent. of H_2S was thereby rendered entirely innocuous to rabbits. These results have recently been frequently quoted and were so directly opposed to the evidence offered by my own recorded experiments with the gas in the proportions recommended by Bergeon, that I decided again to test the matter in the laboratory, making all the conditions as favorable as possible for the triumph of the sulphuretted vapor over the germs.

On May 10, 1887, a tube containing a pure culture of the tubercle bacillus was subjected for twenty minutes to a stream of pure *undiluted* H_2S, made from sulphide of iron and sulphuric acid. The conducting tube was pushed through the cotton and held within half an inch of the coagulated serum, and the jet of gas allowed to play freely on the bacilli upon its surface. The entire culture soon became so blackened by the action of the sulphur as to resemble dark-gray paint. The microbes thus treated were then mixed with sterilized water and injected into the pleural cavities of two full-grown rabbits. These animals were at once placed in a large box, well fed and kept under a shed in the open air all summer, a favorable environment having been found to postpone materially the fatal issue in inoculated rabbits. On October 19th, or 162 days after the operation, both rabbits died within two hours of each other. The autopsies, which were made by Dr. Richard Hall and myself, showed typical and advanced pulmonary tuberculosis in both rabbits; the right lung was literally riddled with tubercles and large caseous foci, and the left lung was also extensively involved, while the bronchial glands were enlarged and cheesy.

This simple experiment seems worthy of record, inasmuch as the evidence it presents may help to correct any false impression already existing as to the germicidal value of H_2S. It also serves to demonstrate the resisting power of the tubercle bacillus and its spores as well as the difficulties attending any attempt at its destruction in living tissues by chemical agents. If so thorough an exposure to the undiluted gas is incapable of destroying this microbe, or of materially staying its destructive power, how futile must be the attempts made to incommode it by rectal injections, or inhalations containing infinitesimal quantities of this apparently feeble agent.

MEDICAL PROGRESS.

SURGICAL ANTISEPSIS AS PRACTISED BY NUSSBAUM, OF MUNICH.—NUSSBAUM still uses the spray, employing weaker antiseptics for rooms not already infected, and stronger preparations for suspicious rooms. Operator and assistants cleanse their hands for three minutes with soap and water, then with five per cent. carbolic acid, and then with sublimate solution. Sponges are not used. Nussbaum considers the aseptic treatment of wounds to be an ideal, realized with great difficulty; the sterilization of a wound is still more difficult, and a break in the chain of precautions will destroy the whole. Nussbaum lays especial stress on rest to an injured part; if possible, elevation; protection against infection; and thorough drainage. Chromic acid catgut is used as suture material. In lacerating wounds of the parenchyma of organs, or of cavities of the body, a dressing of material saturated with an antiseptic, and still damp, is used; when necrosis and suppuration are not expected dry dressings are used. The wet dressing consists of carbolized gauze wrung out of a two and a half per cent. carbolized solution, or of twenty per cent. iodoform gauze wet in boric acid solution and used in tampons; over these are placed dry gauze and salicylated cotton, among whose folds gutta-percha tissue is placed. Instruments and utensils are cleansed with five per cent. solution of carbolic acid. Nussbaum thinks very highly of salicylic acid in powder as a local application to fresh wounds. It is antiseptic and insoluble. Iodoform he also uses to promote granulation. For dry dressings peat cushions and wood wool are used, in addition to antiseptics.

Nussbaum mentions eighty different substances which have been investigated as antiseptics in surgery.—*Centralblatt für Chirurgie*, October 22, 1887.

A Spray for the Treatment of Whooping-cough.—Kolover sprays the fauces with the following solution in treating whooping-cough:

R.—Quiniæ sulph.	gr. 50.
Acid. sulphur.	gtt. 30.
Aquæ destill.	℥ 5½.

This may be used every two hours for the first three days, and every three hours for the remainder of the first week, after which it will be unnecessary.—*L'Union Médicale*, October 18, 1887.

Morphine Phthalate.—Bombelon writes enthusiastically about this new salt of morphine, which he thinks has important advantages over all other morphine salts. It is uncrystallizable, but can be procured in shining transparent scales, which dissolve easily in five times their weight of cold water. The advantages he points out are briefly: 1. A form strikingly distinct from that of any other alkaloidal salt, rendering mistakes of identity almost impossible. 2. Extreme solubility in cold water. 3. Freedom from any irritating property, when used hypodermatically. 4. Permanence of its aqueous solutions, in contrast with those of other morphine salts.

It is prepared by dissolving pure morphine to saturation in a hot aqueous solution of phthalic acid, filtering the solution, concentrating by evaporation, and "scaling" on plates of glass.—*Pharmaceutical Era*, October, 1887.

Ocular Asepsis.—Gayet, of Lyons, has investigated the presence of bacteria in and about the eyes, and found that in 178 cases, specimens of secretions taken from the conjunctivæ produced bacterial growths in 139, while 39 of the inoculated tubes remained sterile. In 100 eyes only 28 were free from germs. Age had no influence, but statistics showed that only 10 per cent. of men were free from germs, while 38 per cent. of women were exempt. Most of the tubes gave positive results in from twenty-four to forty-eight hours. Gayet employed careful antisepsis in his operations upon the eyes, using sublimate, and boric acid 1 to 600. In his first series of 157 cases, 107 were completely successful, 39 were complicated by minor accidents, and 11 had phlegmonous inflammations. In a second series, in which boric acid was employed, secretions were tested from 35 cases, 32 of which contained germs and 3 were sterile. Of the 32 cases in which the boric acid treatment was used, 27 were entirely successful, 3 gave good results, and 2 had phlegmonous inflammation. Gayet concludes that the majority of cases conceal bacteria under their eyelids. The use of antiseptic or aseptic means appears to have very little influence on the presence of germs in the conjunctival sacs; one can never be certain of disinfecting the field of operation. The germs which are found are not all pathogenic, but suppuration occurs in 6½ per cent. of cases, while it is estimated that 75 per cent. of tissues are fertile soil for bacterial growth. The spores seem to comprise the dangerous species, for they are found in eyes destroyed by accident, in which suppuration is inevitable. These spores are not always dangerous, for we can isolate those which will not produce suppuration.—*Revue de Thérapeutique*, October 15, 1887.

The Clinical Diagnosis of Chlorosis.—Graber, of Munich, concludes from his clinical observations of chlorosis that it is purely a blood disease, which is characterized by an excessive alkalinity of the blood plasma, with alterations in the form, size, and color of the red blood-cells. The diagnosis is made by establishing the following points:

1. Increased alkalescence of the blood.

2. Normal number of corpuscles, with lessened quantity of contained hæmoglobin.

3. Normal proportion and condition of leucocytes present.—*Therapeutische Monatshefte*, October, 1887.

Typhoid Fever in the Tropics.—The peculiarities of typhoid fever in India are thus described by Surgeon Bigg, in the *British Medical Journal* of October 22, 1887:

1. The disease is sporadic.

2. It has originated when the drinking water was analytically pure, the drainage engineering perfect, and the surrounding sanitation vouched for by the sanitary and medical authorities as being good.

3. The absence of lenticular spots.

4. The existence of constipation throughout the disease. When looseness of the bowels is present, it is caused by the irritation set up by the presence of the accumulation.

5. The absence of enlargement of the spleen, unless that organ is specially affected.

6. The abdominal lesions are more diffused and scattered, involving ileum, jejunum, duodenum, and stomach. Ulceration is also sometimes found in the colon.

7. The abdominal organs may be quite free from disease.

Ephedrin, a New Mydriatic.—Nagai, of Tokio, has obtained an alkaloid from a plant bearing the name of *Ephedra-vulgaris helvetica*, which has been used by Miura, and has shown interesting mydriatic properties. The muriate is an easily soluble, white, crystalline substance, whose solution readily decomposes under the influence of light. The hydrochlorate, when given in doses of one-eighth or one-sixteenth of a grain, produced death in frogs, with progressive paralysis of respiration and cardiac action, no stage of acceleration having been observed. The heart ceased to beat in diastole. The pupils were greatly dilated. In mammals respiration and heart-beat were greatly accelerated, and both ceased suddenly, with choreic spasms and rise of temperature. Arterial tension was diminished. The pupil dilated when the drug was given subcutaneously, and when its solution was dropped into the conjunctival sac. Death occurred from respiratory and cardiac paralysis.

Fatal doses were in the proportion of five grains to every thirty-five and one-fifth ounces avoirdupois of the body weight of the animal experimented on. Experiments with six and seven per cent. solutions in men gave varying mydriatic effects. When one or two drops of a ten per cent. solution were dropped into an eye, dilatation of both pupils followed after from forty to sixty minutes. When the refraction of both eyes was the same, and no inflammation was present, the dilatation was equal. The pupil was not entirely dilated, but suffi-

ciently so as to permit an examination of the whole retina.

When a strong light was turned upon such an eye a feeble reaction of the pupil was observed. Accommodation was very little or not at all affected.

Children and old persons were more susceptible than the young and strong. In cases of irritation or inflammation of the iris dilatation of the pupil did not occur. The duration of the mydriatic effect was from five to twenty hours.

No ill effects were observed after using the drug for fourteen days. Alteration in intraocular tension were not observed. Comparison with one per cent. solution of homatropine showed that the effect of atropine solution persisted sixty-nine hours. — *Wiener medicinische Presse*, October 16, 1887.

THE DIAPHOTOSCOPE.—SCHÜTZ, of Frankfort-on-the-Main, presented to the Dermatological Section of the recent Congress of Naturalists and Physicians, at Wiesbaden, an apparatus for endoscopy which resembles the ordinary ophthalmoscope in size and form, and mode of use. It includes, however, an electric source of light, with the proper mechanism for avoiding the transmission of heat, by means of which a thorough illumination of cavities to be explored may be obtained. The battery required to equip the apparatus is compact and convenient in size, and the inventor presents the whole for the investigation of the profession as an addition to the resources of those who practise endoscopy.— *Monatshefte für Praktische Dermatologie*, No. 20, 1887.

THE TREATMENT OF WHOOPING-COUGH.—MOIZARD has used the following powder by insufflation:

Benzoin. pulv.,	
Bismuth. salicylat. . . .	āā 5 parts.
Quiniæ sulphat.	1 part.

The only apparatus needed is a simple rubber tube, and a source of air blast. The powder may be inserted in the end of the tube, and the tube placed in the nostril; air is then forced in, and the powder carried within the nares.

CARTAZ has used

Bismuth. subnit.	2 parts.
Benzoin.	4 parts.

GUERDER has used an impalpable powder of equal parts of boric acid and roasted coffee, by insufflation.

GRAFFNER has employed the following solution in spray, with excellent results:

Cocain. hydrochlor. . . .	gr. $\frac{1}{10}$ to $1\frac{1}{2}$.
Aquæ destill.	ʒ $1\frac{1}{4}$.
Potass. chlorat. . . .	gr. 8.
Aquæ amygdal. . . .	♏ 8.

Cocaine may be also mixed with chloroform, in proportion of 6 to 100. Of this 10 drops should be placed in a glass of warm water, and the vapor inhaled.— *London Medical*, October 20, 1887.

THE INFLUENCE OF THE MICROÖRGANISMS OF THE MOUTH AND INTESTINES UPON DIGESTION.—VIGNAL has studied the action of seventeen species of microörganisms found in the mouth and intestines upon digestion; and his results are summarized as follows by the *London Medical Record* of October 15, 1887.

Of these organisms, 8 dissolve cooked albumen, 5 swell it or render it transparent; 10 dissolve fibrine, 4 render it transparent or swell it; 9 dissolve gluten; 3 transform starch, but only 1 acts with some energy, another seems to live upon it, but without transforming it; 7 coagulate milk; 6 dissolve casein; 9 transform lactose into lactic acid; 7 intervert cane-sugar; 7 cause glucose to ferment and transform it partially into alcohol; all these actions are more or less energetic.

Among these microörganisms, 6 resist more than twenty-four hours the action of the gastric juice at 36° to 37° C. (98.8° to 98.6° F.), whether the culture is recent or old with spores; 5 resist its action more than two hours, when the culture is recent, and more than twenty-four hours when it contains spores; 2 others resisted one hour only, when the culture was recent, and the spores of 1 of these resisted twenty-four hours, those of the other six hours only; the last 5 do not resist its action even for half an hour, whether the culture be recent or old.

Bile and the pancreatic juice, prepared artificially and possessed of very powerful action, have no destructive action on these microörganisms.

In fecal matter M. Vignal found again 6 of the buccal microörganisms (the bacillus mesentericus fuscus; the bacillus *d*, common in the colon; the bacilli *b*, *c*, and *e*; and the coccus *k*) and 4 other microörganisms, 7 streptococci, 1 coccus, and 2 bacilli. 1 of these latter dissolves albumen, 2 render fibrine transparent, 3 dissolve gluten, 1 transforms potato starch but not common wheat starch, although in order to furnish it with nitrogenous matter veal extract was employed in place of water; 2 coagulate milk; 1 partly dissolves casein, and coagulates what it does not dissolve; 3 transform lactose into lactic acid, 3 intervert cane-sugar, and 2 partly transform glucose into alcohol. The action of these microörganisms must be considerable on aliments, for a series of numerations showed that there were more than 20,000,000 of them in a decigramme of fecal matter, and these were not all developed in the mediums employed.

In order to attempt to realize what takes place in the digestive tube where the microörganisms are not isolated, M. Vignal cultivated several series of phials, on the one hand, with dental tartar and coatings from the tongue, and, on the other hand, with a little water in which fecal matter had been dissolved.

The attack of the substances contained in the phials was at first very energetic; but from the third day, sometimes from the second, the action was permanently arrested. Is it to be concluded that the microörganisms of the mouth and of the fecal matter, when mixed together, have no action on alimentary substances? Evidently not. The transformations they undergo under the influence of these microörganisms have come to a stop in the phials, because the glass sides of these could not, like the intestine, absorb the products they give birth to as fast as they were produced.

To sum up, the result of these researches is to justify M. Pasteur's opinion that these microörganisms play a very important part in digestion, and also that the phenomena of digestion in general, and particularly the part played by microorganisms, are more complex than was at first supposed.

Local Refrigeration.—Bailly has used chloride of methyl by an apparatus, which he terms a stypophore. By this means he carries the degree of effect produced to the grade of vesication, if needed. He applies this treatment in neuroses of various kinds, and styles it stypotherapy.—*L'Union Médicale*, October 20, 1887.

Poisoning by Antifebrin.—Doll reports the case of a woman suffering from migraine, who purchased sixty grains (according to the apothecary's statement) of antifebrin, and took it in two doses at short intervals, at about 11 A.M. In three hours emesis, cold perspiration, and coma developed. At 9 P.M, Doll was summoned. He found the forehead, face, nose, ears, upper thorax, hands, and feet icy cold, and covered with cold perspiration; the other portions of the body were warm and moist: the color of the face was cadaveric; the eyes were closed, but opened when roused; pupils moderately dilated, and reacting feebly. The heart beat tumultuously, pulse 120, arterial tension varying greatly; respiration accelerated; abdominal pain and nausea present, attempts at emesis made, but unsuccessfully. The patient answered questions, stating that she had become unconscious after taking the drug. Free stimulation was given during the night, but alcoholics were avoided, as antifebrin is soluble in alcohol. The intoxication terminated with profuse perspiration and free defecation. The patient did not remember that she had talked with the physician. The effect of the drug resembled the condition of hypnotism more than anything else.

Two days afterward anorexia and headache persisted. The sensorium was free, and no other abnormal symptoms were present.—*Deutsche medicinische Zeitung*, No. 72, 1887.

A Nutrient and Sedative Enema may be prepared after the following formula:

Beef bouillon	℥ 3⅛.
Eggs	1.
Bordeaux wine	℥ 6¼.
Bicarbonate of soda	gr. 8.
Tinct. opium	gtt. 4.
Chloride of sodium	gr. 3.
Peptone	℥ 4.

—*Révue de Thèrapeutique*, Oct. 15, 1888.

Death by Heart Failure from Gastric Irritation.—If the means of masticating food be wanting, the first stage of the process of digestion cannot, of course, be performed, and this is in itself a great evil; but as a recent fatal case has shown, actual perils to life from physical causes may arise, and perhaps become disastrously effective. By post-mortem demonstration, it has been proved that an accumulation of unmasticated food taking place in the stomach may so distend the stomach as to press upon and irritate the heart in such manner that, being in a morbidly weak or exhausted condition, its natural function may be arrested and death take place by syncope. It is a familiar fact that a greatly distended stomach may cause "palpitation" and other distressful experiences, and it is not in the least degree surprising to find that the excitation set up may be so aggravated as to produce fatal effects in a special state of the organism. But it is important to notice how this untoward ending is reached, because the attainment of this issue is only a question of degree in the disturbance. The operation from cause to effect is purely one of nerve action, and the *modus operandi* is either completely reflex, in which case the process is exhaustive as regards the particular centre affected, or partially reflex, the circuit, so to say, being broken at the centre, and the force of the peripheral excitation exerting an inhibitory influence on the cardiac or occasionally on the respiratory centre. It seems probable that in certain cases there may be spasm of the muscular coat of the vessels of the heart (perhaps the coronary), or of the heart itself, producing either a condition resembling that which is supposed to obtain in some forms of "angina," or arresting the ventricular contraction in systole, or, it may be, by asystole, though this last-mentioned ending is perhaps more commonly reached by inhibition, as in another class of cases. When the excitation caused at the periphery is of a nature corresponding with, and in some respects resembling, high tension of an electric current, the stimulus propagated along the afferent nerve trunk may so act on the centre, indirectly, perhaps, as to interrupt its action. In this last event death will occur by arrest of the ventricular movement in diastole or arrest of the systole. Or the obstructive or exhaustive action may be upon the respiratory centre with seemingly "asthmatic" symptoms at the opening of the attack, in the course of which death occurs. Happily, cases of a fatal issue from peripheral irritation of the nerves are not of very common occurrence; but this renders it the more desirable that those which do occur should be very carefully investigated. The subject of death from "heart-disease" is one that greatly needs to be studied in the light of precise pathology.—*Lancet*, October 22, 1887.

Minor Points in Surgery from Nussbaum.—Nussbaum, of Munich, in using the thermo-cautery, employs a strip of wood, like a ruler, pierced by one or more holes as desired. This is dipped in ice-water and pressed firmly against the part; the cautery is then applied through the apertures. By this means bleeding and too extensive burning are prevented. Nussbaum frequently burns deeply into tumors which cannot be removed, causing a contraction and cicatrization of the growth, checking its progress.

In wounds of the cardiac ventricles Nussbaum advises the alternate opening and closing of the external wound four or five times in twenty-four hours. Coagula are thus removed, and fatal decomposition of the blood is prevented.

In parenchymatous bleeding tampons of cotton soaked in peroxide of hydrogen have given excellent results in checking hemorrhage.—*Centralblatt für Chirurgie*, October 22, 1887.

The Spread of Diphtheria.—At the late International Congress of Hygiene, at Vienna, Professor Teissier, of Lyons, gave the result of his experience as to the spread of diphtheria. In his opinion the infective agent of the disease could not be propagated either by water or by food, and only in very rare cases by direct contagion from person to person. He believed that the virus was present in the earth, and was conveyed into

the human organism by means of the dust which penetrated into the air-passages. He attributed great importance to the diphtheria of fowls as the means of communicating the disease to man, and affirmed that he could prove that the disease had actually been communicated in this way.—*British Medical Journal*, Oct. 22, 1887.

Iodol in the Treatment of Blennorrhagia.—A simple but efficient mode of using this drug in blennorrhagia is by combining it after the following formula:

Sodii	10 parts.
Gummi arab.	5 "
Aquæ destill.	200 "

An emulsion may be made.—*Revue de Thérapeutique*, October 15, 1887.

A New Ophthalmometer.—At the recent meeting of the German Ophthalmological Society, at Heidelberg, Dr. C. S. Bull, of New York, exhibited an instrument which he had devised, which is described as follows by a correspondent of the *Cincinnati Lancet* of October 29, 1887:

Consisting of a brass strip like a ruler about two feet long, with a handle beneath by which to hold it; at one end a disk-screen with a sight-hole, behind which a series of lenses is adjusted and readily changed; on the surface of the ruler (as I will call it for convenience) is engraved a series of *dominos* drawn in exaggerated perspective; on looking through the lens some one or another of these dominos is seen in perfect shape—for instance, an eye looking through a — 5 dioptric lens and seeing the domino with points sharply and perfectly defined is emmetrope—the domino lies at just the focal distance of the — 5 lens (about 8 inches); if the eye sees any domino beyond the five point, hypermetropia is shown, and its degree to within a fraction of one dioptric; myopia is proven when a nearer domino is defined. An attachment for estimating astigmatism is equally rapid and simple.

Precautions to be Enjoined upon a Patient Suffering from Chancroid.—Besnier advises the following cautions in the *Revue de Thérapeutique* of October 15, 1887:

The contact of urine with the chancroid should be avoided, as suppuration is then favored.

After micturition the chancroid should be washed with a solution of boric acid and covered with a protective ointment.

The pubes should be frequently bathed with soap and water, and a pomade of boric acid, one-tenth per cent., thoroughly applied. If a bubo occurs, the parts should be shaved, and collodion applied.

Tarnier's Basiotribe.—Tarnier's basiotribe, a somewhat complicated instrument which was described before the Paris Academy of Medicine in December, 1883, has recently been used in three cases in Professor Kovacks's clinic in Budapest, with, it is stated, very satisfactory results, the application being made with great facility, no splinters penetrating the scalp, and the mothers being all able to leave the hospital on the tenth day.—*Lancet*, October 22, 1887.

Ninety Intestinal Parasites in One Individual Case.—Dr. Roux, Surgeon of the Cantonal Hospital at Lausanne, describes in the *Correspondenzblatt für Schweizer Aerzte* of August 15, 1887, a singular case in which the patient, a girl, aged 21½ years, discharged after two 90 minim doses of extract of male fern) at least ninety bothriocephali lati. The worms passed out in a bundle, the patient assisting the delivery by tearing the package with both her hands, and at the same time uttering shrieks like a woman in labor. The agonizing delivery lasted ten minutes. The mass of parasites filled up a half of a chamber utensil. The disentangling and counting took exactly four hours and a half of the author's time. As an individual only such a worm was considered which had a head, and at its other end measured not less than 3 or 4 millimetres in breadth, or which had an absolutely thread-like (though headless) anterior end, and measured not less than 1 metre in length. Numerous very long ribbons, which did not answer those conditions, were left out of the reckoning; neither were any of the ribbons which had been discharged several times by the girl for a couple of weeks previously taken into account. There could be no doubt, therefore, that the number of worms, given as 90, in reality far surpassed that figure. The length of individual bothriocephali varied between 250 and 60 centimetres, a large number measuring only between 100 and 60. Except some slight nervous phenomena (such as occasional headaches, vivid dreams, *semi-somnambulisme*), the patient did not present any morbid symptoms. She was a robust and ruddy, and even cheerful and active, country girl, with excellent appetite and digestion, and with 95 or 97 per cent. of hæmoglobin in her blood (as Gowers-Sahli's hæmoglobinometer showed). The case seems to give a support to Dr. Zschokke's theory, according to which the prevalence of bothriocephalus latus amongst the population residing around Lake Leman should be attributed to the eating of infected fish, mainly that of perch (*perchette*). At least, the girl, who had come to the locality from Argovia about the Easter of 1884, during a period of several months' duration, in 1886, was dining on perch (and bothriocephali) once a week, or even still more often, the patient residing at the time at Bonvard, near the lake mentioned.

Indications for Intrauterine Medication for Puerperal Sepsis.—Bokelmann considers intrauterine douches indicated:

1. When, forty-eight hours after birth, the temperature rises to 101.3 F. or 102.2 F., with frequent pulse, without a recognizable cause for it.

2. When fragments of placenta or membranes remain in the uterus as a cause for disturbance.

3. When symptoms of infection of the endometrium are pre ent.—*Berliner klinische Wochenschrift*, No. 37, 1887.

Iodol in Otitis Media Purulenta.—Purjesz, of Budapest, has treated eighteen cases of suppuration in the middle ear with iodol. The remedy was applied by insufflation once daily. Lessened secretion and painless improvement followed. Two cases only resisted treatment. No unpleasant effects referable to iodol were observed.—*Therapeutische Monatshefte*, October, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE.

PER ANNUM, IN ADVANCE. . . . . $5 00.

SINGLE COPIES. . . . . 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, NOVEMBER 12, 1887.

OUR QUARANTINE DEFENCES.

ANOTHER Mediterranean steamer has arrived at the New York Quarantine, bringing another batch of immigrants from the cholera-infected localities of Italy. Notwithstanding the assurance of the Health Officer who performed the official inspection, that the ship, crew, and passengers are in an excellent sanitary condition, and that the ship's log shows no evidence of disease during the passage, this new arrival occasions renewed anxiety that, in the absence of a thoroughly equipped and efficient quarantine, the continual influx of people and baggage from cholera-infected districts, sooner or later, will plant this terrible scourge somewhere in our midst. If the utmost care and vigilance be not constantly exercised by the quarantine officers at the port of arrival, especially with regard to baggage and concealed cases of cholera which find no mention in the sanitary record of the voyage, the experience of the last epidemic of 1873, no less than our present knowledge of the means by which this disease spreads, points to what may ultimately occur this year or the next. It is now known that outbreaks of cholera at Carthage, Ohio; Crow River, Minnesota; and Yankton, Dakota, in 1873, were caused by infected household goods of emigrants from Holland, Sweden, and Russia. "These immigrants *sailed from healthy ports, in healthy vessels,* and were subjected to the usual sanitary requirements of the period. They passed through New York and all the intermediate territory without injury to the public health. But when their infected goods were unpacked in the interior of the continent, they liberated the poison which gave rise to the local outbreaks."

As bearing upon the frequent perfunctory manner of disinfection practised at the "model quarantine stations" in this country, and as supplementary of the criticisms which have previously been made in THE MEDICAL NEWS, concerning the inefficiency of our quarantine safeguards, it may not be inappropriate to refer, at this point, to the remarks of the President of the American Public Health Association in his Annual Address, (see page 561), in which he describes the method of so-called disinfection which he actually witnessed at the port of New York, in the month of September last, on his arrival from Brazil.

It is to be hoped that the authorities at New York begin to understand that whatever alarm has been excited by the presence at that port of two cholera ships and the frequent arrival of immigrants with personal effects from districts where cholera has been recently raging, has been caused rather by the knowledge of the deplorable state of the defences exposed by the report to the College of Physicians of Philadelphia, than by a blind, unreasoning fear of a dread disease. And it may be remarked, just here, that it is neither through the inconsiderate passage of resolutions by quarantine commissioners hindering in the future any access to quarantine stations for the purpose of investigations in the interests of science and the public health, nor through the vituperation, by presidents of quarantine commissions, of the motives, or the acts, or the statements of scientific men who fearlessly make a plain, disinterested, and temperate report to a scientific body of personal observations respecting matters which affect the welfare of sixty millions of people, nor through unscrupulous attempts to prevent prompt and searching reforms by invoking against them the bitterness and prejudice of partisan politics, that this reasonable alarm is to be allayed. The New York quarantine establishment should be at once so thoroughly improved, both in plant and administration, that the country may not only feel secure, but really be safe from the introduction of cholera through that port, and it should be at all times open to the inspection of properly accredited examiners.

We learn with satisfaction that the Mayor of the city of New York has recently not only addressed the President of the United States with regard to the temporary prohibition of immigration from the cholera-infected districts as a measure of public health, but has also sent an official communication to the Health Officer of the Port of New York, calling his attention to the faults pointed out in the Philadelphia report, and offering to raise by voluntary subscription any reasonable sum necessary to make the quarantine at that port what it should be.

Through the evils of our present quarantine system the greatest city in our country, and with it the whole country itself, must rely for protection against

epidemic disease upon voluntary subscriptions from private citizens, alarmed by their recent knowledge of dangers which have threatened them for years. But the report of Drs. Wilson, Shakespeare, and Cleemann, pointed out the fact that the ports of Philadelphia and Baltimore are even much more defenceless against a foreign invasion of cholera than is that of New York, and we should be glad to learn that active measures are being taken to remedy the condition of affairs at these points.

Too implicit trust in the approach of winter, a season in which cholera epidemics do not usually prevail in cold latitudes, as a safe guarantee against the introduction and ultimate spread of this disease, is dangerous, for it should be remembered that Moscow has witnessed a severe winter epidemic, and it should not be forgotten that a late visitation of cholera in the United States came in the dead of winter, and through the port of New Orleans.

It is to be hoped, then, that our present and future danger from cholera, and the justly disquieting facts revealed by the above mentioned report concerning the intrinsic weakness of our maritime defences, together with the public anxiety at present existing, will forcibly aid the efforts of the conservators of the public health in their endeavor to procure national legislation this winter which will provide efficient ways and means for the constant defence of the general public from epidemic diseases brought into our ports from foreign shores.

MERCURIAL HYSTERIA.

The various effects produced by different metallic substances finding a constant but slow entrance into the body are so constantly mistaken by the practitioner for symptoms of some organic disease of idiopathic origin that the paper of Letulle in the *Gazette Hebdomadaire* of Sept. 23 and 30, 1887, is of interest, in that it calls attention once more to the possibility of the production of markedly aberrant symptoms by a metallic poison other than lead.

Hysterical hemianæsthesia or monoplegia due to the presence of lead or arsenic in the system has been recognized for years, and carefully studied by Vulpian, Charcot, and others, notably Debove, who applied the term *hystéries toxiques* to all conditions of this character. In 1877, Dr. Jean published the records of two remarkable cases of hemianæsthesia due to the chronic absorption of mercury, and his report has been followed in France, by Hallopeau, Aigre, and several others.

Subject to these attacks are artisans engaged in the manufacture of barometers, thermometers, mirrors, and all the handicrafts in which mercury is employed. Abnormal conditions arising from this cause are, therefore, even more frequent in men than in women, and the diagnosis of a case of hysteria occurring in an otherwise healthy male should lead the clinician on the path toward questions calculated to discover any mode of contamination by this metal. The mere fact that the hysterical condition, or other nervous disturbance, has lasted for months, or even years, seems to be no ground on which to base an opinion against the presence of some toxic material, for Letulle reports a case of this character who had passed through the hands of no less than six physicians during six and one-half years. It should be remembered, also, that mercury is as capable of producing strange and varying symptoms as is any other poison of like nature, and all the writers on the subject have met with cases in which limited or general choreas, hemiplegia or monoplegias have existed along with marked sensorial disturbances. Aphasia is by no means a rare occurrence, and tremulousness, closely resembling that of Parkinson's disease, often tends to make a correct diagnosis the more difficult.

The methods of treatment are naturally much the same as those applied in chronic poisoning by lead, and consist in the elimination of the cause, both primary and secondary. The patient should be removed from the mercurial exposure, and those drugs should be administered which we know tend to aid in the elimination of such poisons and the building up of the system.

COLD WATER INJECTIONS IN CATARRHAL JAUNDICE.

Recommended several years ago by Krull, lavage of the intestine in jaundice has already gained in favor, and the reports by Lowenthal, Eichorst, and Krauss show that in many cases a more rapid recovery follows than when alkalies and diluents are administered by the mouth. In the *Revue de Médecine* for September, Chauffard reports seven cases, in six of which the obstruction to the bile flow was overcome in from four to six days; in one case on the eighth day. From one to two quarts of cold water are injected. The temperature of the water may be a little raised on succeeding days. The injection usually induces a lively peristaltic action, which may be irregular and cause painful colic. To the extension of the movements to the duodenum Krull attributes the beneficial effects of the treatment, as the active contraction of this part of the bowel is likely to cause expulsion of the obstructing mucus. Chauffard regards the action as entirely reflex, the cold water inducing a strong contraction of the gall-bladder and larger bile-ducts. Normally it is in this reflex manner that the chyme in the duodenum induces expulsion of the contents of the gall-bladder, and it seems probable that the sudden shock of a large injection of cold water would induce active contraction of the walls of the ducts.

In this country the method has been used with

success by Musser and others at the Philadelphia Hospital, and it is worthy of a more extended trial than it has yet received.

QUARANTINE DOES NOT DEAL WITH THE MOST DANGEROUS DISEASES.

In relation to the importation of scarlet fever to Sutton's Bay, Mich., by emigrants on the steamship "Ohio," reaching New York September 30, 1887, noticed in our issue of October 29th, Dr. William M. Smith, Health Officer of the Port of New York, says: "Developed cases of diphtheria and scarlatina arriving on vessels at this port are removed to Ward's Island. It is impossible, under the law for the Health Officer or the authorities at Castle Garden, to quarantine persons who have been exposed to the contagion of these diseases; consequently, the sick on board vessels during the voyage, doubtless, often infect the relatives, or those with whom they come in contact . . . and who carry the latent contagion to interior communities. I would be glad if the law allowed those exposed to the contagion of these diseases to be held for observation, as is the case when persons are exposed to the contagion of smallpox."

The instance mentioned above is an illustration of what Dr. Smith says, the child having been exposed during the voyage, was taken sick with scarlet fever the day after arrival at New York; so the infected child went on its way, to spread scarlet fever. In Michigan at least, ten times as many deaths occur from either scarlet fever or diphtheria as from smallpox, and the question may be well asked, Is it not time that the whole subject of quarantine was investigated by the States, and by the United States Government, with a view to protecting the people of this country from the introduction of the really dangerous diseases?

DEATH OF MOSES GUNN, M.D., LL.D.

This well-known surgeon and teacher ended a long and active professional life at Chicago, on November 4, 1887, aged sixty-five years. Of Scotch descent, he was born in the State of New York, where his youth was spent, and where he received his medical education at the Geneva Medical College, graduating in 1846. He settled at Ann Arbor, Michigan, where he commenced at once to teach anatomy. On the organization of the University, he was appointed to the Chair of Anatomy and Surgery, and the latter branch he taught for fifteen years. In 1853 he removed to Detroit, where he practised, contributing frequently to the current periodical literature. In 1861 he accompanied McClellan's army, seeing much active and arduous service. In 1867 he succeeded Daniel Brainard in the Chair of Surgery in Rush Medical College, where his business energy, skill, and popularity as an operator and teacher contributed largely to the prosperity of the college.

In 1851–52 he made a series of dissections and experiments to determine the pathology of dislocations of the hip and shoulder, and he was one of the first to formulate clearly and demonstrate the method of treatment by manipulation. As an operator in plastic surgery, he was especially expert; and as a teacher of surgery he was unsurpassed. He was a member of numerous societies, among them the American Surgical Association, and presided over its annual meeting in April, 1886, on which occasion he contributed a paper on "The Union of Nerves of Different Functions," which was published in The Medical News of May 8, 1886.

Mayor Hewitt, of New York, has written to Dr. W. M. Smith, Health Officer of that port, calling his attention to the criticisms made by the Committee of the College of Physicians of Philadelphia on the management and arrangements of the Quarantine Station there, and suggesting that the defects be remedied. The Mayor says that if a lack of money stands in the way of making needed changes, he will undertake, by an appeal to his fellow-citizens, to raise any reasonable sum. The Mayor has also written to President Cleveland, suggesting that a friendly representation made to the Italian Government might secure greater precautions in the clearance of vessels from the cholera regions, until the disease has disappeared therefrom.

The first award under the William F. Jenks Prize Fund, of the College of Physicians of Philadelphia, will be made by the Committee, for the best essay upon "The Diagnosis and Treatment of Extra-uterine Pregnancy," as soon after January 1, 1889, as may be practicable. Papers for competition must be written in English, and be presented by the said date. The prize essay is to become the property of the College. The prize amounts to $250, and is open to all the world.

We understand that Dr. J. Solis Cohen has resigned his professorship in diseases of the throat and chest at the Philadelphia Polyclinic, and that he contemplates withdrawing from the attending staff of the German Hospital, at the close of his present term of service, the main object in these withdrawals being to gain time for literary work.

REVIEWS.

Anæmia. By Frederick P. Henry, M.D., Professor of Clinical Medicine in the Philadelphia Polyclinic, etc. Pp. 136. Philadelphia: P. Blakiston, Son & Co., 1887.

Our knowledge of the various forms of anæmia has been so greatly extended within the past few years that

a special monograph will be heartily welcomed. Among American writers no one is better qualified than Dr. Henry to write on this subject, to which for a long time he has devoted earnest study. In the first part of the work the methods of examination are described and the symptoms, diagnosis, and treatment of anæmia fully discussed. Dr. Henry offers an excellent classification of the varieties of anæmia. Under the first division, primary anæmias, are included affections of the cytogenic organs, chlorosis, Hodgkin's disease, leukæmia, and pernicious anæmia. The secondary anæmias are those of fever, hemorrhage, cancer, etc. The toxæmia resulting from the poisons of lead, arsenic, etc., form a third group; and a fourth, the parasitic anæmias, caused by the anchylostomum, the filaria, the organisms of malaria, and the Bilharzia hæmatobia.

We take special pleasure in calling the attention of practitioners to this work as one from the study of which they will rise with clearer ideas on the diagnosis and treatment of forms of disease met with every day in practice, and the true nature of which is too often overlooked or misunderstood.

SOCIETY PROCEEDINGS.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, October 26, 1887.

THE PRESIDENT, J. SOLIS COHEN, M.D., IN THE CHAIR.

DR. THEOPHILUS PARVIN read a paper on

INJURIES OF THE FŒTUS DURING LABOR.

(See page 561.)

DR. W. T. LUSK, of New York, said: Dr. Parvin, in his exhaustive *résumé* of the subject, has said that we should exercise charity toward those under whose care these accidents may happen. At the same time I think we should, as scientific men, look upon this record as most humiliating, and should ask ourselves if we should exercise this charity toward ourselves as individuals, should these accidents fall to our lot.

In going over the subject there may, however, be found one or two matters which have been overlooked, or which it might be well to make more emphatic. In speaking of fractures of the skull occurring in spontaneous deliveries, cases which occurred many years ago have been given. In modern times reports of fractures in head-presentations terminating without the intervention of art are very rare. My attention has been called to one such case reported by Veit. The patient had received large doses of ergot. When the child was expelled it was found that the right parietal bone was separated from its fellow, from the occipital, and, to a great extent, from the frontal bone, and two fractures were found in the bone itself. It is a question, whether the cases of spontaneous fracture reported many years ago were due to the abuse of this certainly most unreliable drug.

I saw last summer a very interesting case of depression of the skull following a rather easy forceps delivery. I was sent for because the question had arisen between two practitioners as to the advisability of trephining the skull—introducing an instrument and elevating the depressed bone. I am not sure that this might not be good practice in some instances, but so far we have had no experience as regards results. We know that if the child shows no immediate symptoms from the depression, it is likely to thrive, and that in time the depression nearly or entirely disappears. In the case above referred to we decided to wait, the child has been thriving since, there is still a quadrilateral depression in the frontal region which has not entirely disappeared. I was quite certain that the mother of this child had a contracted pelvis with projection of the promontory; but, in making an examination some three or four weeks after the birth of the child, to my surprise, found that the woman had a fairly roomy pelvis. The anteroposterior diameter measured at least three and three-fourths inches. The only conceivable cause of the depression was the blade of the forceps. This was to me certainly a novelty.

With reference to the amount of force which may be exerted on the neck of the child, I think that if we rely upon the experiments to which reference has been made, we are likely to be led into error. There is no doubt that the resistance of the neck under pressure varies greatly in different subjects. While the neck of one child will bear a weight of 160 pounds, the vertebræ of another will separate under a much less amount of tension. I do not believe that there are even circumstances in which such an enormous pressure as 160 pounds should be exerted. If the after-coming head is retained by tonic retraction of the womb, such traction force must tear through the cervical tissues. If the head is retained by the brim of the pelvis, it is nearly certain that the child will be stillborn when the necessity for such an amount of force exists. It is a question whether we ever should use much force in pulling on the child; whether, indeed, the head cannot better be shoved through the pelvis by suprapubic pressure, in the manner described by Dr. Goodell and Dr. Taylor.

There is one injury to the child which I do not think was particularly referred to by the author. He spoke of the dislocation of the occipital bone which sometimes occurs. In the case of a flattened pelvis, where the head enters in the transverse diameter, it will sometimes happen, where forceps are used, that the pressure of the blades bears directly upon the forehead and upon the occiput. This will be tolerated for a certain length of time, but, when continued, the pressure ultimately affects the medulla oblongata. It is then difficult to get the child to breathe, the respiratory sense being destroyed, and often the child is born dead, as the result of such pressure. It is always well to be careful that, when the blades of the forceps cannot be applied to the sides of the head, they are applied in the oblique diameter.

With reference to the fracture of the clavicle, it sometimes happens that this injury is due to direct pressure; more frequently, according to Ruge, it is due to the introduction of the hand into the vagina to bring down an extended arm. If the pelvis is small, the vagina rigid, and there is insufficient room for the hand, as the result of pressure upon the shoulder, the clavicle is apt to bend like a bow, and break in the middle.

In a well-conducted labor, the arms should not become extended above the head. In cases where this

does take place, we know the directions that are given to draw on the elbow and push the arm over the face, but where the space is small you cannot always press the arm around the front of the face in the limited time required to extract the child alive. In these cases I think that we are justified in breaking the arm to accomplish delivery. Cases of true dislocation are probably exceedingly rare, at least we have no evidence of cases where the lesion has been demonstrated by dissection, but separation of the epiphyses closely resembles dislocation backward or forward, and until dissections were made, dislocation was considered a common accident. There are one or two points in regard to separation of the epiphyses that are of interest. As a consequence of this fracture, Küstner has shown that the cartilaginous portion of the bone is rotated outward by the action of the infra- and supra-spinatus and the teres minor muscles, while the shaft of the bone is rotated inward by the pectoral muscle, the latissimus dorsi, and the teres major. If the position of the arm is not rectified and union is allowed to take place, the movements of the arm will be more or less affected. Both external and internal rotation can then be accomplished only to a slight extent. Separation of the epiphyseal end of the humerus closely simulates paralysis, and some recent writers have gone so far as to assert that all cases of supposed paralysis of the arm are really cases of this injury. This is, however, not always the case. Last summer I attended an excitable primipara, who, early in labor, passed into a maniacal condition which necessitated keeping her under an anæsthetic. After the chloroform had been kept up for two or three hours, the cervix was partly dilated, and not wishing to continue the chloroform, for the immunity which attends its use in labor does not apply to its prolonged administration, I put on the forceps before dilatation was complete, and with considerable difficulty extracted the head through the cervix, the vagina, and through the vulva. The perineum did not tear, but the moment the head escaped, the vaginal orifice closed down tightly on the neck of the child, and I was compelled to introduce two fingers into each axilla to complete the delivery. After the birth one arm was found to be paralyzed. As I knew these have been recently asserted to be cases of epiphyseal separation, I examined the arm with great care, but failed to find the slightest evidence of fracture. There was no pain. There were no evidences of brain disturbance, although the pressure of the forceps had been continued for a long time. The galvanic current was applied to the arm, frictions were employed and it was kept warm, and in about ten weeks the child began to move its arm, though recovery is still far from complete.

To pass over the other points referred to, I should like to say a few words in regard to extraction in breech cases. It is nearly impossible where the arm has been bent behind the neck of the child to extract the arm without fracture. Then why not fracture the arm? Is the physician responsible if this accident occurs as the result of efforts to release the member? I should say, no, but he is responsible for the displacement of the arm behind the head. If he leaves the body alone and does not twist the trunk, the arm will not remain extended. The child does not spontaneously flex its arm and place the forearm underneath the occiput.

There is a case recently reported by Englebach which I would add to the list of accidents. In this case the child was born with an enormous swelling of the scrotum, due to an effusion of blood into the tunica vaginalis of each side.

I have taken some interest in the questions connected with the extraction of the breech when both extremities were reflected upward, and I wish to reiterate what I said two or three years ago with reference to the use of forceps to the breech. In a recent brochure Küstner condemns this method, but confesses to have never tried it. We all know that in the exercise of the usual method, a person with strong fingers is capable of exerting a great deal of force which bears to a great extent on the sacro-iliac synchondroses, and under these circumstances rupture of the sacro-iliac joint is likely to take place—a rupture which may be followed in after life by the development of the Nægelé deformity. I think that the application of the forceps to the breech is easier than a person who has not tried it would suppose. I speak of cases where the breech has reached the floor of the pelvis. Here it is not necessary to use a great deal of force. If the breech is brought down to the perineum and then allowed to recede, and this is continued until physiological softening of the pelvic floor and perineum takes place, a very moderate degree of force is required. I think that the use of the forceps under these circumstances is attended with less risk to the child than the employment of the fingers or the blunt hook. I have succeeded with the forceps in three cases where the fingers had been used in vain.

I do not feel like occupying any more of the time of the Society. I would say, in conclusion, that this is a subject to which too much attention cannot be given, for woman after passing through the discomforts of the period of gestation, and the perils of labor, is entitled to the only reward that it is possible to give her, that of having a living child, sound in body and limb; and anything that will contribute toward the prevention of such a record as we have heard to-night is certainly worthy of the attention of any body of scientific men. At the present time the public hold us responsible if we allow a patient to die of puerperal fever. It would probably intensify our interest in the subject if the public were to take a similar position with reference to dead and injured children.

Dr. Wharton Sinkler said: A very large proportion of the cases of paralysis that I have met with in infants, have followed instrumental or prolonged and difficult labors. The most frequent form that we meet with is facial paralysis, either unilateral or bilateral. This generally results from the pressure of the forceps upon the facial nerve or upon the mastoid process. Facial paralysis may, however, result simply from the impaction of the child's head in the pelvis without the use of the forceps.

Hemiplegias are often met with in the newly born as a result of the use of the forceps. A few days ago I saw a child with right hemiplegia, and the mother stated that the child had been delivered by forceps, and that immediately after birth there was a deep depression behind the left ear. I found upon examination of this child, who was now sixteen months old, that a depression still existed in the left mastoid process. There was right hemiplegia present. The right leg was spastic and the

movements of the arm limited and incoördinate. Spastic paralysis of what is sometimes called double spastic hemiplegia very frequently occur in children who have been born by the breech. These conditions generally persist during life and are associated with a feeble condition of the intellect.

Professor Parvin has referred to injuries to the sterno-cleido-mastoid muscle. I have seen cases where the child has lost power in all the muscles of the neck so that it was unable to support the head. Some of the cases have been delivered by the breech and considerable traction made. Some have followed delivery by forceps perhaps from pressure on the spinal accessory nerve, or perhaps from extravasation of blood. In the case of paralysis following difficult or instrumental labors, the lesion is often an extravasation of blood over the motor convolutions, a meningeal hemorrhage. If the amount of the extravasation is great, the prognosis is, of course, bad, but in some of the cases, especially where there is monoplegia, where there is paralysis of one arm alone, the child entirely recovers the use of the limb; and in facial paralysis recovery, as a rule, occurs in a few days, but the condition may persist during life.

DR. W. GOODELL said: I present for inspection, this evening, a specimen of firmly united fracture of an infant's humerus, of which I am not ashamed, but rather proud; for by the fracture I saved the child's life. It was a case of breech presentation, where the heart's action was failing, and the ominous convulsive movements of the child were giving out, which indicates the near approach of death. The arm was up alongside the child's head, and, if I had had more time, I could have brought it down without injury; but every second was precious. So I snapped the arm, and quickly delivered a living child. It died a few months afterward, of cholera infantum, and the mother, knowing my interest in the case, allowed me to obtain the specimen. I have reported elsewhere a unique case, where fracture was produced by the maternal forces. The vertex presented, the pains were strong, the passages ample; but the head did not descend. Suddenly, during a severe pain, a hand shot out of the anus, without tearing the perineum. While I was gazing on in amazement, another pain suddenly took place. There was an audible snap, the hand as quickly disappeared from the anus, and the child was born with a fracture of the clavicle. The rent in the vagina was sewed up, and the fracture dressed with adhesive strips. The vaginal wound healed up perfectly, and the child recovered without deformity. This remarkable accident I attribute to the arm being thrown across the nucha. The protruding hand perforated the vagina, and was button-holed there. Then the advancing body forcibly dragged the arm down the back of the child, and the clavicle was fractured by the twist or strain it got.

In a case seen with my friend, Dr. James F. Wilson, fracture of the clavicle, and of the skull also, occurred. It was an exceedingly difficult case. She was delivered in her first labor by craniotomy, by Dr. Wilson, in conjunction with the late Dr. Parry. In this, her second labor, after using the forceps ineffectually, we turned, and delivered in a very few minutes, by vigorous traction, and by very great pressure from above. The fractures were caused by the projection of the sacro-iliac promontory. The child recovered perfectly.

I have repeatedly seen facial paralysis; but in instrumental labors it has occurred only when the blades of the forceps were not applied exactly to the sides of the child's head. Dr. Parvin speaks of the child living a few hours after the performance of craniotomy. It was to such an occurrence that we owe the travels of Mungo Park, who was a physician, but who, early in his professional career, was so disgusted by this accident that he gave up practice. In his case the infant lived to manhood. With regard to head-last labors, I have tried to deliver the breech by the use of the forceps on the buttocks, and have succeeded with them, but they are liable to slip off. I therefore always bring down a leg in breech cases, and then I have command of the situation. The force of traction which the neck will bear is uncertain, and doubtless varies greatly; but I believe that the man who, in trying to save the child, breaks the most necks, saves the most children, and I respect him accordingly. Such labors are always very dangerous to the child; the percentage of deaths is a very large one. I look on a child in breech presentation as a child drowning, to whom help must be sped—help at all hazards. It is emphatically a case of "neck or nothing," and we must not sacrifice the life of the child to any sentimental considerations about breaking its neck.

One point that, perhaps, does not come strictly under injuries to the fœtus, but may be considered here, since it causes the death of the fœtus, is pressure on the cord, prolapsed or wound round the neck, by one of the blades of the forceps, and especially by the occipital one, when the blades are not applied exactly to the sides of the head. I am sure this has occurred at my hands. An annoyance in cases of face presentation is the subsequent unnatural position of the child, which for days will lie with its head greatly extended, though it ultimately takes the natural position.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, November 3, 1887.

THE PRESIDENT, A. JACOBI, M.D., IN THE CHAIR.

DR. JOSEPH D. BRYANT read a paper on

HOW CAN THE PROFESSION AID THE BOARD OF HEALTH?

As to the relations which should exist between the medical profession and the Health Department, he said that there ought to be complete harmony in all matters pertaining to the public health. In the past this had by no means always been the case, and the two bodies had for the most part been much greater strangers to each other than should have been the case. He believed, however, that each should labor with common purposes, the prolongation of human life and the alleviation of physical suffering. It was the province of the Board of Health to deal more particularly with the prevention of disease, and of the medical profession with its treatment; but the preventive measures of the Board ought, of course, to receive the active and cordial cooperation of the profession.

All the medical sanitary inspectors are now detailed to the department of contagious diseases, and it is their duty to visit at once the locality of any case of contagious disease reported to the Board, and see that

proper measures for isolation, disinfection, etc., are promptly and thoroughly carried out. When, in any instance, it is found that suitable medical treatment cannot be pursued, or that isolation of the patient cannot be secured, they advise that the case be removed to the hospital.

In the department of contagious diseases are included the bureaus of vaccination and contagious diseases in animals, and employed in the latter are expert diagnosticians in this special field. Convenient and comfortable means are provided for the transfer of patients to the hospitals of the Board, and the admirably constructed Willard Parker Hospital at the foot of East Sixteenth Street, is fitted up with all the modern appliances for the successful treatment of disease. It has accommodations for seventy-five or one hundred cases of diphtheria and scarlet fever, and efficient house-physicians and an excellent medical board. The reception hospital is also under the supervision of the same medical board. On North Brother's Island are the fine new smallpox hospital and five pavilions, each with accommodations for twenty-five or thirty patients, for contagious diseases other than smallpox. On this island there is also considerable unoccupied space on which temporary structures can be erected in case of emergency. Every provision is thus made for the comfort and welfare of patients suffering from every variety of contagious disease.

The Board is at this time paying special attention to the matter of contagious disease, and the urgent need of this is sufficiently attested by the fact that from the 1st of January to the 30th of September there were no less than 1575 deaths from diphtheria reported in the city. There is entirely too much indifference on the part of the public to such affections as diphtheria; while a single case of a disease like cholera, the prevalence of which would seriously interfere with the business interests of the community, would at once cause profound excitement and receive the greatest possible attention. The Board has great odds to contend against, as it is estimated that from 15 to 25 per cent. of the cases of contagious diseases occurring in the city are never reported by the medical attendants in charge of them. It is estimated, also, that from 25 to 30 per cent. of the births are unreported.

He then proceeded to answer the question, How can the Profession aid the Board of Health? This can be done signally, he thought, in the following ways:

(1) By reporting at once all varieties of nuisances dangerous to life and health.

(2) By promptly reporting all forms of contagious disease. In this way many valuable lives could be saved and epidemics could be averted.

(3) By enforcing strict isolation and employing proper disinfectant and antiseptic measures in cases of contagious diseases.

(4) By reporting all cases in which isolation cannot be secured or proper medical treatment carried out.

(5) By visiting the Willard Parker Hospital, and thus being able to speak from personal observation of the advantages which it affords.

(6) By being careful not to send patients with contagious diseases to the dispensaries.

(7) By heartily coöperating with the medical inspectors of the Board of Health in any case in which the latter are met with.

(8) By reporting all food or drink adulterations coming under notice.

(9) By reporting any instance observed of decaying fruit or other kind of unwholesome food offered for sale.

(10) By reporting all defects in plumbing, light, and ventilation observed in houses visited.

(11) By paying special attention to the sanitary condition of the homes of patients.

(12) By promptly reporting all births. This is of special service in securing the more general vaccination of infants.

Dr. E. G. Janeway said that the suggestions made by Dr. Bryant covered most of the matters in which the profession could be of service to the Board of Health. The importance of reporting all cases of contagious diseases is evident to all, and the statistics of disease can never be made accurate until every physician is willing to report every case he meets with. He has known the recurrence of smallpox in New York to be more than once due to unreported cases of the affection. The benefit of reporting all cases of typhoid fever, for instance, has been repeatedly shown in England in enabling the authorities to trace the origin of the trouble to contaminated milk. The relation of contagious diseases to the public schools is a matter of vital importance, and it is absolutely essential that the school officers should be promptly informed of the existence of a contagious disease in any family a member of which is a scholar.

It is also highly desirable that physicians should report any cases of *suspected* contagious disease coming under their observation. Public opinion on sanitary matters is moulded by the medical profession, and it should be the aim of the latter to inspire the public with confidence in the Board of Health. Otherwise the influence and efficiency of the Board will be seriously impaired. The good work done by the bureau of vaccination has undoubtedly been the means of successfully controlling smallpox in the city during the last few years, and it is essential that this should be continued in the future, and that even more vaccinations should be made than in the past. When, as is occasionally the case, unfavorable circumstances attend vaccination, it is not unfrequent to have physicians intimate (and usually without adequate reason), either that the virus used is bad, or that it is the vehicle for the transmission of syphilis. Such slighting remarks do a great deal of harm, and he has known them to be the means of preventing a large number of vaccinations, as reports of this kind are apt to spread through tenement-houses.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, October 28, 1887.

The President, James Perrigo, M.D., in the Chair.

SARCOMA OF THE FEMUR.

Dr. Bell exhibited a patient whose right thigh he had amputated three weeks before for sarcoma of the lower third of the femur. The wound united by first intention throughout, and the patient was now well.

The wound healed under two dressings; bone drains were used. The following is the history of the case:

J. W., æt. eighteen, was admitted into the Montreal General Hospital, September 30, 1887, suffering from a large tumor involving and completely surrounding the lower third of the right femur. The tumor began as a small, movable, painless nodule on the anterior surface of the bone immediately above the knee-joint. It grew rapidly and soon completely encircled the bone. He walked about as usual until the end of June, when he began to suffer acute pain in the swelling. In August he was admitted into hospital, when the tumor was diagnosed as a periosteal sarcoma, and amputation was advised. His friends would not consent to any operative measures, and he left the hospital. He returned again on the 30th of September in a very grave condition. The tumor had increased very much in size and the patient was greatly emaciated; his pulse was constantly as high as 120–140, and his temperature ranged from 101°–103° F. The surface of the tumor was red and inflamed, and the leg below very œdematous. On October 3d, amputation was performed by the circular method through the upper third of the thigh. The recovery of the patient was rapid and particularly satisfactory. The stump was dressed for the first time on the eighth day. The temperature never rose above 98.8°; and on the 27th of October (twenty-four days after the operation) he was discharged with a perfectly sound stump. An examination of the tumor showed that it was a round-celled sarcoma occupying the lower third of the femur, but not extending into the interior of the bone. The synovial pouch beneath the quadriceps extensor muscle was filled with pus. The epiphysis separated easily from the shaft, and an inflammatory condition was found in the space between. Dr. Bell regarded this case as a fair sample of the results obtained by dry dressing and bone drainage.

Dr. Roddick congratulated Dr. Bell on the good result of the case. In such cases he preferred removing the whole bone, as then there is less chance of recurrence. With regard to the use of bone drains, he had some years ago used them extensively, but had given them up. Recently he had tried them again, but he found that they absorbed too rapidly, and that, although the drain was absorbed and the wound closed up, still there was often a collection of fluid left behind, which had to be let out.

Dr. Shepherd had also, several years ago, used bone drains, but had abandoned them because of their uncertainty, some absorbing too rapidly and others not at all. He preferred rubber drains. His plan was to change the dressing twenty-four hours after operation, remove and shorten tubes to less than half an inch, and then not make the second dressing for a week or ten days, according as the case progressed. The reason he examines the wound and removes the tube at the end of twenty-four hours, is because the oozing from the wound is greatest during the first day, and also because the tube is not infrequently becomes plugged with blood-clots and then, of course, renders it useless. He had had remarkably good results in his amputations by this method, and mentioned a case of amputation of the thigh performed in a very old man for senile gangrene, which healed by two dressings in three weeks. Neuber, who introduced bone drains, now never employs any drain at all, but stuffs the wound with iodoform gauze for two or three days, and then makes use of secondary suture. His results, according to his published cases, were excellent.

Dr. Armstrong inquired whether any of the surgeons had used Levis's solid rubber drains. They consist of a number of pieces of solid rubber rods placed like catgut in the wound and are better than hollow tubes as they never get plugged with blood-clot.

OSTEOTOMY OF THE TIBIÆ.

Dr. Bell also exhibited a patient, æt. three years, on whom he had performed osteotomy of the tibiæ for incurving due to rickets. He had performed MacEwen's operation with most satisfactory results. There was only one dressing applied.

Dr. Roddick said that three years was too young to perform this operation and that he himself never operated in such cases under nine years, but used apparatus to correct the deformity. Apparatus is of little use for the cure of knock-knee, but answers well for bow-legs. He thought that subcutaneous fracture is preferable to MacEwen's operation in bow-legs and he had had excellent results from this method of treatment.

Dr. Gurd said that in cases of bow-legs of very young children the deformity was frequently corrected by improved hygienic conditions and good food.

STRONGYLUS FILARIA.

Dr. Johnston exhibited a microscopic section through the lung of a sheep in a case of broncho-pneumonia where great numbers of the strongylus filaria were found in the alveoli, which were filled with exudate. There were also severe bronchitis and peribronchitis of the smaller tubes. The adult worms were not found within the bronchi, having probably been coughed up. The embryos were not able to develop in the lung.

RINGWORM OF THE NAIL.

Dr. Johnston also exhibited a microscopic section of a nail showing parasitic onychia. The specimen was sent him by Dr. Bell. The chains of trichophyton were seen in moderate numbers on the deeper layers of the nail and between the nail and its bed. A mass of dry porous tissue over the bed of the nail was free from the parasite.

Dr. Bell said the specimen was taken from the thumb nail of a girl æt. twenty years. She had accidentally cut the nail about the middle a year ago, a small brown spot immediately commenced to grow at this point and when he saw her first the nail was raised from its bed to the extent of half an inch by a hard, dry cancellated structure resembling cancellated bone. There was no ringworm in any part of her body nor had she been exposed to contagion from any known source.

Dr. McConnell read a paper on

ACETANILID.

After describing the history and actions of this drug, which is best known by the name of antifebrin, he detailed his experience of the remedy derived from its administration in twenty cases. In every case it had been given with benefit; he had given it in typhoid fever, pneumonia, puerperal septicæmia, and erysipelas.

In typhoid fever it is most useful in relieving the intense headache of the early stage of that disease. The temperature was reduced in two to four hours 5° or 6°. In all his cases it began to fall within fifteen minutes after the administration of the drug. He gave it in doses of from six to fifteen grains. Three doses in twelve hours were sufficient. He found that it stimulated the vasomotor system, relieved pain of a neuralgic character, promoted sleep, and diminished the rate of the pulse.

Dr. Proudfoot said antifebrin is very useful in reducing the inflammation and relieving pain in cases of iritis.

Dr. Stewart had only used antifebrin in two cases of locomotor ataxy for the relief of the lightning pain with excellent effect. He thought that it is not yet decided whether it is useful in fever; it certainly has the effect of destroying the oxyhæmoglobin and thus reduces the patient's resisting power.

Dr. Reed had tried the drug for the relief of neuralgic pain and had found not the slightest result; he thought that the drug had had its day.

Dr. McConnell, in reply, said that the destruction of oxyhæmoglobin only takes place when the drug is given in poisonous doses.

Several members stated that they had found the drug of no use at all in erysipelas.

NEWS ITEMS.

An Authoritative Society.—In an editorial in the *Maryland Medical Journal* of November 5, 1887, a reference made by Dr. W. C. Van Bibber, in a recent address before the Baltimore Academy of Medicine, to the College of Physicians of Philadelphia, is commented upon as follows:

Dr. Van Bibber has referred to the value of an authoritative society to the profession and to the State. Dr. Van Bibber has happily selected as his model the College of Physicians of Philadelphia, which combines in its purposes and in its work all that is useful in a scientific medical organization. Were there in all our large cities medical organizations working so harmoniously and efficiently in the promotion of the higher aims of medicine and in guarding the interests of society as the College of Physicians, it would be a cause for professional congratulation among a large class of physicians who never fail to endorse methods or purposes which advance the cause of human good. We have before us at this time another illustration of the high aim of the College of Physicians in the shape of a report of a Committee appointed by the College on October 5, 1887, to investigate the efficiency of our quarantine arrangements for the exclusion of cholera and other epidemic diseases. The work performed by the Committee of the College of Physicians in the preparation of this report has been both laborious and painstaking, and the conclusions reached, if properly considered and carefully enforced, cannot fail to work a far-reaching public benefaction.

The thorough investigation of this important subject at this time by the College of Physicians assumes a commanding position and enforces upon professional attention the importance of a cöoperation among the medical societies of the United States, looking to the early adoption of a uniform and efficient quarantine of all exposed ports. In fact, in a resolution offered by the Committee of the College, the authority to issue an address to the medical societies of the country, and seek their cöoperation in this respect, was adopted. The initiative taken by the College of Physicians in this matter was not only timely, but in the extreme humane. It has been shown that our Atlantic ports are totally unprovided for the safe and humane treatment of cholera-infected emigrants, and that unless something be done to improve our quarantine regulations, great suffering and injustice may be imposed upon emigrants arriving from cholera-infected countries.

The great authority of the College of Physicians leading in this matter cannot result in other than good to the people of our country, and to those who seek an asylum on our shores.

Corrosive Sublimate and Quinine.—Powell calls attention to the fact, not generally known, that when moderately concentrated solutions of corrosive sublimate and a quinine salt are mixed, a precipitate is thrown down, immediately or after some time, consisting of a double chloride of mercury with the alkaloid. Prescribers and dispensers should make a note of the fact.—*Pharmaceutical Journal.*

Typhoid Fever Cases in Lapeer City, with Sources of Contagion.—Dr. H. McCall has forwarded the following account of a small typhoid outbreak to the Michigan State Board of Health:

About September 1, 1887, Myron Gardner, railroad employé, came from the South, sick with fever, to his father's home. His case was supposed to be malarial. No care was exercised with stools in the way of disinfection, but they were thrown into a privy vault in the rear of the house, and in close proximity to the well. Wash-water was thrown on the surface of the ground, which was very dry at the time. About the 7th or 8th of September, a copious rain fell and soaked the sandy soil; and on the 14th, William Gardner and wife, father and mother of Myron, and E. D. Gardner, a brother, were attacked with fever. On this day I got home from Washington, and found four of them down with a severe type of typhoid fever; and in two weeks Myron's wife and child were attacked; also a child, across the street at Terry's, who had used water from the Gardner well. About the same time, three cases occurred among those in the adjacent Clifford house, south of Gardner's, who also used water from the Gardner well. None of the people from either of these houses were in the Gardner house. In the Walker house, still further south, one case has occurred; and I was at a loss to account for this case, till a few days ago, when the young man said that at the mill where he was working they had used water from the Gardner well for a few days, owing to disarrangement of the pump at the mill. Two others of the mill hands, Anderson and Lester, who used the same water, were attacked about the ame time. Lester is now convalescent; Anderson is dead, as also a child at Terry's. When I took charge of the cases I ordered the discontinuance of water from the Gardner well, and the disinfection of the stools; and no new cases are now reported. People who assisted in taking care of the Gardner and other families, and who used

water from other sources have not been attacked. Clearly Mynne Gardner brought the fever home, the well becoming infected after the first rain from slops and privy drainings and the other cases got their seed from the water.

THE CHOLERA IMPORTATION.—The indignation felt by the whole world at the laxity of the New York quarantine finds favorable expression in the *Sanitary News* of October 29, 1887, as follows:

The fact is that the general government should establish and maintain a quarantine system at New York. It should begin at once by prohibiting intercourse with Italian infected ports. It should assume the care of this national question. The Western health boards should call extra sessions, pass resolutions asking the President to put in motion the emergency fund, and begin to take active steps against an active enemy. We, in Chicago, do not fear the swarthy Italians from Palermo, but the health commissioner was busy Thursday morning in hunting them up and endeavoring to get their infected baggage. The period of incubation was twice passed on these immigrants before the notice was received. Their baggage can not be gathered and disinfected, but as this danger is liable to be kept up as long as the Italian line can get vessel into the port of New York, Dr. Koch should get his railway inspection into action again, and endeavor to prevent the importation of the disease and not sale.

CHOLERA IN INDIA.—Cholera has prevailed very extensively throughout India during the present hot season. It has spread northward, westward, and southward. The Northwestern Provinces and Punjab have been severely visited. The disease has broken out in Peshawur, and caused great loss of life. Several outbreaks have been reported from Central India, and seventeen districts of Bombay Presidency have been visited. The town of Bombay has suffered to a slight extent. The disease has prevailed severely in Burma and broken out in Singapore. It has also been reported from Kabul. Beyond India, the disease lingers in some parts of Italy, and a few cases appear to have occurred in Malta. This is, therefore, emphatically a year of active epidemic movement so far as cholera is concerned.—*Indian Medical Gazette*, September, 1887.

PROFESSOR BILLROTH.—The numerous friends of Professor Billroth all over the world will be pleased to learn that his health is thoroughly restored, and that he has resumed his cliniques at the General Hospital, Vienna. On the occasion of his first lecture he received a great ovation. The theatre was crowded with professors and students for a long time before the lecture hour had arrived, and the entrance of Professor Billroth was welcomed with loud and long-continued applause. On their advancing and tendered in the name of his colleagues and the pupils a hearty welcome to the professor's auditorium. Upon this receiving from the latter loud acclamations of applause. In reply, Professor Billroth made some touching remarks, recalling the time when, nearly years ago, he first taught in that place, with colleagues such as Hebra, Rokitansky, Oppolzer, Skoda, Dumreicher, Dittel, Heller, and others, who had all since passed away. He warmly thanked those present for their kindness during his illness, and their reception of him that day. He had not expected to be there again, but he had been snatched from death by the self-sacrifice and devotion of his colleagues. He spoke of the kindness and love which had been bestowed upon him on all sides, and said that he would devote all his strength to the welfare of mankind, the glory of the old Vienna University, and the prosperity of Austria. He then proceeded to speak of the life work of von Langenbeck, and suggested that, in respect to his memory, the meeting should be closed. After this, Professor Billroth took them over his wards, and operated on a case of double harelip.—*Lancet*, October 22, 1887.

AN INTERNATIONAL DICTIONARY OF LIVING WRITERS.—The contemplated publication during the coming year of a work under the above title is announced by M. De Gubernatis, of Florence. It will contain an account not only of the authors of books, but of contributions to journals of various kinds, the aim being to describe the *personnel* of the literary men of to-day.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, FOR THE WEEK ENDING NOVEMBER 5, 1887.

FESSENDEN, C. S. D., *Surgeon*.—Detailed as Chairman of the Board for the Physical Examination of Officers of the Revenue Marine Service, November 1, 1887.

MUHL, F. W., *Passed Assistant Surgeon*.—Detailed as the Recorder of the Board for the Physical Examination of Officers of the Revenue Marine Service, November 1, 1887.

BEVAN, A. D., *Passed Assistant Surgeon*.—Relieved from duty at Portland, Oregon, ordered to the Marine Hospital, New York, November 2, 1887.

CARRINGTON, P. M., *Assistant Surgeon*.—Relieved from duty on the Revenue Steamer "Rush," ordered to the Marine Hospital, San Francisco, California, November 2, 1887.

PERRY, T. B., *Assistant Surgeon*.—Relieved from duty at the Marine Hospital, San Francisco, California; ordered to assume charge of service at Portland, Oregon, November 2, 1887.

GOODWIN, H. T., *Assistant Surgeon*.—Relieved from duty at Norfolk, Virginia, ordered to the Marine Hospital, New Orleans, Louisiana, November 5, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 5, 1887.

FITZSIMMONS, P., *Surgeon*.—Ordered to the U. S. Steamer "Marion."

ATLEE, L. W., *Assistant Surgeon*.—Ordered to the U. S. Steamer "Marion."

BATES, N. L., *Medical Inspector*.—Ordered to the U. S. Steamer "Trenton."

BEALE, HENRY G., *Passed Assistant Surgeon*.—Ordered to the U. S. Steamer "Trenton."

WHITE, STEPHEN S., *Assistant Surgeon*.—Ordered to the U. S. Steamer "Trenton."

RILEY, P. M., *Passed Assistant Surgeon*.—Detached from the U. S. Steamer "Trenton," and wait orders.

ACHESON, RICHARD, *Passed Assistant Surgeon*.—Ordered to the U. S. Receiving Ship "St. Louis."

THE MEDICAL NEWS *will be pleased to receive early information of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or notices should be marked.

Letters, whether worthy for publication or private information, must be authenticated by the names and addresses of their writers—not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

A WEEKLY JOURNAL OF MEDICAL SCIENCE.

VOL. LI. SATURDAY, NOVEMBER 19, 1887. No. 21.

AMERICAN PUBLIC HEALTH ASSOCIATION.

FIFTEENTH ANNUAL MEETING.

THE ANNUAL ADDRESS.

Delivered Tuesday, November 8, 1887.

BY GEORGE M. STERNBERG, M.D.,

PRESIDENT.

(Concluded from page 561.)

As I have already intimated, the exotic pestilential diseases to which I have referred are the levers which move corporations to make necessary sanitary improvements. But for sanitarians, aside from their effect in this way, they are of secondary importance. The number of victims which they claim is a small matter compared with the number who succumb to certain indigenous or naturalized infectious diseases which are equally subject to control by well-known sanitary measures. The chief aim of the American Public Health Association should be to ascertain what measures are most effectual for the restriction of their endemic maladies, such as typhoid fever and the malarial fevers, and for the banishment of all diseases in which the contagion is given off from the persons of the sick, such as scarlet fever and smallpox. So far as diseases of the class last mentioned are concerned, we may safely say that we know how they may be banished from a community, viz., by isolation of the sick and disinfection of all infectious material; and in the case of smallpox, by vaccination. Our main mission, therefore, is to insist upon the thorough execution of these measures.

But our mission does not cease here. We have not only to teach the American public how to guard against infectious diseases by quarantine restrictions, isolation of the sick, disinfection, and municipal sanitation, but also to teach them the principles of personal hygiene. Not only will their individual susceptibility in the presence of an epidemic depend largely upon their personal habits and mode of life, but we must show them how often organic and functional diseases of the various organs essential to life are induced by excesses in diet, improper food, the habitual use of spirituous liquors, etc. I conceive that a most important part of our work in the future should consist in popularizing information of this kind. The noble example set by our generous colleague, Mr. Lomb, of Rochester, should be followed by our Association, if its finances permit, or at least we should present the subject to philanthropists who, like Mr. Lomb, may desire to be guided by our counsel in their efforts to do good to their fellowmen. As a matter of fact, our limited means will not justify us in offering prizes for essays on sanitary subjects, and the most that we can afford is to print and distribute at cost such essays as may seem suitable for popular distribution.

In another direction, however, we may accomplish much good with comparatively small amounts of money, whenever our treasury will admit of it. I refer to special investigations in sanitary science, committed to expert investigators who are willing to devote their time to the work, and who would ask only for such sums as might be necessary to cover the actual expenditures for apparatus, material, etc.

The exact knowledge which has been obtained during the last decade with reference to the etiology of the infectious diseases, has been promptly applied in a practical way by sanitarians; and every addition to our knowledge in this direction is of the greatest importance to sanitary science, which, so far as we can see, will reap far more benefit from an exact knowledge with reference to the essential characters of each specific disease germ than can be hoped for by the clinician.

It is not creditable to us as a nation that so small a share of the progress in this direction is due to American investigators. In the absence of any department of the National Government having the power and disposition to support investigations in this field of science, the few who have pursued bacteriological studies in this country have worked under disadvantages which were not only discouraging, but absolutely incompatible with the most efficient work and fruitful results. But the future is more hopeful. Individual munificence, in several of our large cities, has supplied the means which should have been provided long since by the National Government, for pursuing investigations in bacteriology and in experimental pathology.

In Baltimore we have a well-equipped bacteriological laboratory under the direction of the able professor of pathology of the Johns Hopkins University. In New York, Boston, Philadelphia, and, I believe, in several other cities, bacteriological laboratories have been established in connection with well-known medical schools.

In Brooklyn, the Hoagland Laboratory, now in process of construction, under the immediate supervision of the gentleman who provides the funds required for the building and its equipment, will supply all of the facilities, both for students and for advanced investigators, which can be found in the best equipped laboratories of Europe. I am informed, also, that our colleagues from the State of Michigan who are always in the front rank in urging upon their legislature measures which will advance the sanitary interests of the State, are making an effort, which is likely to be successful, to establish a bacteriological laboratory in that State. We have to thank one of our colleagues from the State mentioned for a most important discovery in the field of sanitary science. I refer to the discovery of tyrotoxicon by Professor Vaughan. With a well-equipped laboratory under his direction there is good reason to

believe that this discovery, so creditable to American science, would not stand alone to the credit of the good State of Michigan.

Our Association has already taken the initiative in encouraging, and assisting, from its slender treasury, investigations in sanitary science. The Committee on disinfectants, appointed at the St. Louis meeting, in 1884, has made an extended experimental research with reference to the value of various agents for the destruction of disease germs. The final report of this Committee will be submitted at the present meeting. I say final, because in my judgment all the necessary data are now at hand for determining the agents most useful for disinfecting purposes under various circumstances, and I think the conclusions of the Committee may be accepted as a safe guide for future practice. It is true that more work can be done to advantage in this direction, and it will be desirable to test from time to time new agents which may be suggested for disinfecting purposes; but the main object of the Association has been accomplished, and we now know what agents can be relied upon for the destruction of disease germs of various kinds, and in what proportion these agents must be used to be efficient.

In consideration of the limited means at our disposal for encouraging the scientific investigation of sanitary problems I would suggest that the Association raise a special fund for this purpose, by calling for contributions from its members, and from others who may be willing to aid us in our efforts in this direction. If you approve of this suggestion, I trust that some member will introduce the necessary resolutions.

One of the subjects which might be taken up by a Committee appointed for the purpose and aided from the special fund would be a biological investigation of the water supply of towns and cities in the United States. Evidently such an investigation would be a protracted one, and it would be advisable to begin with those towns which have a notoriously bad water supply. Perhaps it could be arranged that a portion of the expense, at least, would be paid by the town or city whose water supply was examined, as the inhabitants of such town or city would be especially interested in the results of the investigation. Another question of the greatest interest to us is that which relates to the possibility of protecting individuals from fatal infectious diseases by inoculations with an attenuated virus.

Protection from smallpox is no longer a solitary instance of prophylaxis by inoculation. In anthrax, in swine-plague, roguet, and in pleuro-pneumonia, protective inoculations have been practised upon a large scale, and the value of the method is fully described. The evidence in favor of Pasteur's inoculations for the prevention of hydrophobia is such that we can scarcely doubt that it has a relative value, notwithstanding the considerable number of deaths which have occurred among those who have been inoculated. The recent report of the English Commission, made after a thorough investigation, is favorable to the method, which may, perhaps, hereafter, be modified so as to give still better results.

In the various infectious diseases of the lower animals which have been studied during recent years, including those forms of septicæmia which are only known to us by laboratory experiments, we have much evidence that protective inoculations with an attenuated virus may be successfully practised. And there is good reason to hope that in all diseases in which a single attack protects from future attacks, protective inoculations may be practised when once we have succeeded in isolating and cultivating outside of the body the specific infectious agent. We know already four methods by which the virulent potency of disease germs may be attenuated, viz., by exposure to oxygen, by exposure to heat, by exposure to the action of certain chemical agents, and by passing through the body of certain animals.

The last mentioned method is that practised by Pasteur in attenuating the virus of rouget. He finds that the virulence of the microbe is diminished by passing it through a series of rabbits and that by this means an attenuated virus suitable for protective inoculations in swine may be obtained.

The possibility of attenuating a virus by exposure to the action of certain chemical agents was discovered by myself, in 1881, in the course of a series of experiments upon disinfectants in which the virus used was the blood of a rabbit just dead and containing the micrococcus found in the buccal secretions of man, which I have named *M. Pasteuri*.

Among the diseases in which there is good reason to hope that a method of prophylaxis by inoculations with an attenuated virus might be successfully practised, if we could once succeed in isolating and cultivating the specific germ of the disease, is yellow fever, a disease in which, as a rule, a single attack protects.

As you know, it has been claimed by both Dr. Domingos Freire, of Brazil, and by Dr. Carmona y Valle, of Mexico, that the yellow fever germ is discovered, and that a method of prophylaxis by inoculation has been experimentally demonstrated. As I have just returned from a special mission, the object of which was to investigate the claims of these gentlemen, you will naturally expect to hear from me at this time, with reference to the results of my investigations. I regret to say that I am unable to gratify you in this natural expectation. My orders explicitly direct "me not to make publication of my investigations and of the conclusions reached by me," until I have submitted my final report to the President of the United States.

I have already occupied so much time in speaking of matters which I consider of prime importance that I cannot attempt to make any general review of recent bacteriological researches which have a bearing upon public hygiene. As a matter of fact, all additions to our knowledge of pathogenic microörganisms are of special importance to us as sanitarians, and it is now generally recognized that the only safe basis for practical sanitation is that which is afforded by an exact knowledge of the etiology of infectious diseases, and of the biological characters of the specific infectious agents in these diseases. Since the importance of these studies has been generally recognized, and the methods of research have been perfected, the number of trained workers has rapidly increased, and at present the greatest activity prevails in the laboratories of Europe. This is shown by the number of memoirs relating to experimental investigations made in this department of science which are constantly appearing in the journals devoted to medicine and hygiene in all parts of the

world, but especially in Germany, in France, and in Italy. The *Jahresbericht* of Baumgarten, for the year 1886, contains abstracts of 533 papers relating to micro-organisms. With reference to *cholera*, I may say to you that recent researches give support to the conclusions of Koch as to the pathogenic *rôle* in this disease of the spirillum discovered by him in the intestines of cholera patients. Its constant presence in this disease seems to be demonstrated, and it is now generally admitted by bacteriologists that there are definite characters by which it may be distinguished from similar organisms obtained from other sources, such as the Finkler-Prior spirillum, and the cheese spirillum of Deneke, which closely resemble it.

Lustig, Director of the Cholera Hospitals at Trieste, examined the dejecta in 170 cases of cholera, and found the spirillum of Koch in every case: on the other hand, the bacillus of Emmerich was found in only 40 out of the whole number of cases examined. Tizzoni and Cattani also found Koch's spirillum in the contents of the intestine in 24 cases examined by them during the epidemic at Bologna in 1886. At Padua, also, researches made by Canestrini and Morpurgo gave the same result, the spirillum was constantly found in the dejecta in recent cases. These observers state that the cholera spirillum retains its motility and reproductive power for a considerable time in sterilized distilled water. They were able to obtain cultures after two months from such water. This important fact has been verified by Pfeiffer, who found, however, that in the presence of common saprophytic bacteria the cholera microbe soon died out. Hueppe has shown that the cholera spirillum forms reproductive elements, which he calls arthrospores. These are not so readily destroyed by desiccation as are the fresh bacilli, but they have nothing like the resisting power to heat and chemical agents which characterizes the endogenous spores of the bacilli. The exact proportion in which various disinfecting agents are destructive of the vitality of the cholera spirilla, has now been determined with great precision, and will be stated in detail in the report of the Committee on Disinfectants for the present year. This Committee has also made extended experiments of the same kind in which the typhoid bacillus, and various other pathogenic organisms have served as the test of germicide power. The chemical products developed in cultures as a result of the vital activity of the cholera spirillum have been studied by Bitter, Buchner, and Cantani. The last-named author claims to have demonstrated the presence of a poisonous ptomaine in cholera cultures, which, when injected into the peritoneal cavity of dogs gives rise to symptoms resembling those of cholera. A recent observation of value is that of Bujwid, who finds that *bouillon* cultures of the cholera spirillum have a peculiar chemical reaction, by which they may be distinguished. According to this author, the addition of a five to ten per cent. solution of hydrochloric acid to such a culture gives rise, within a few minutes, to a rose-violet color, which subsequently, when exposed to light, changes to a brownish shade. The reaction does not occur in impure cultures. The Finkler-Prior spirillum is said to give a similar reaction after a longer time, but the color first developed is of a more brownish hue.

The question of the etiological *rôle* and biological characters of the typhoid bacillus discovered by Eberth in 1880, has occupied numerous bacteriologists during the past year, and very important additions have been made to our knowledge with reference to this organism. The researches of Beumer and Pieper, of Seitz, and of Fränkel and Simonds, are especially worthy of notice, but time will not permit me to give an abstract of the results reached by these and other investigators. I can only say, in a general way, that the earlier researches of Eberth, Koch, and Gaffky, are confirmed as regards the presence of this bacillus in the intestinal glands, the spleen, and other organs in typhoid cases, and that very little doubt exists among bacteriologists as to the etiological relation of this organism to the disease in question, although no satisfactory proof by inoculation in lower animals has yet been found. This, however, is not surprising, inasmuch as we have no evidence that any of the animals experimented upon are liable to contract the disease, as man does, by drinking contaminated water.

According to Wolffhügel and Riedel, the typhoid bacillus and various other pathogenic organisms tested, retain their vitality for a long time when preserved in ordinary well or hydrant water, and even undergo a considerable development in such water. Frankland, also, has found that certain pathogenic bacteria tested by him increased rapidly in numbers in the water of the Thames, and even in distilled water. Meade Bolton, on the other hand, found that micrococcus tetragonus, staphylococcus aureus, the typhoid bacillus, and the anthrax bacillus, not only did not increase in number in sterilized water, but soon perished, while certain non-pathogenic species commonly found in water, increased rapidly in numbers, in sterilized distilled water. A more recent research is that of Kraus, who employed well water and hydrant water from the city water works of Munich, which, without being sterilized, was infected with pure cultures of various pathogenic organisms diluted with distilled water. The infected water was kept during the experiment at a temperature of 10½° C. (51° F.). Plate cultures were made from day to day. The results were as follows: the typhoid bacillus had disappeared by the seventh day, the cholera spirillum could not be found in plate cultures after the second day, the anthrax bacillus had disappeared at the end of four days; in the meantime, the ordinary water organisms had increased enormously in number. From these experiments, considered in connection with those of Bolton and of Wolffhügel, Kraus concludes that the rapid destruction of pathogenic bacteria in non-sterilized water is a direct result of the action of ordinary water-organisms. If this be true, it is evident that these water-bacteria are conservative from a sanitary point of view, and that the biological test of drinking water, which gives the number of colonies which are obtained from a given quantity, has no special value in the absence of an exact statement of the kind of bacteria and their pathogenic potency. The time has come when we must demand that those who undertake the biological examination of water with reference to its potability shall give some more definite information than that a certain number of colonies were found, some of which liquified gelatine, and some did not. Up to the present time we have but few instances of the finding of known pathogenic bacteria

in water used for drinking purposes. Koch found his spirillum in a water-tank in India, and several observers have reported the finding of the typhoid bacillus in drinking water. Recently Beumer examined the water of four wells in a vicinity where cases of typhoid fever had repeatedly occurred. From one of those wells colonies were obtained by the plate method which proved to have all of the characters of the typhoid bacillus. The distinguished German chemist Brieger has succeeded in obtaining a toxic ptomaine from cultures of the typhoid bacillus, which has the composition $C_7H_{17}NO_2$.

The question of the etiology of croupous pneumonia has received much attention during the past year, and it is now evident that the bacillus of Friedländer, which has been cultivated for some years in the laboratories of Europe under the name of "pneumococcus," is not entitled to this distinctive appellation. On the other hand, evidence is accumulating that a micrococcus which I have described under the name of *M. Pasteuri*, and which is found in normal human saliva, is far more frequently found in the exudate into the alveoli during the acute stage of croupous pneumonia than that of Friedländer. I first experimented with this micrococcus in 1880, and isolated it in pure culture in 1881, but it was not until January, 1885, that I discovered its presence in pneumonic sputum, and made inoculations rabbits with the material.

The record of my first successful experiment, published in the *Transactions of the Medical Society* of New York for October, 1885, was as follows: "January 2, 1885, I inoculated two rabbits subcutaneously with pneumonic sputum, collected with great care by my friend Dr. Zeibig, and brought to me at once from a private patient, a boy, sixteen years of age, in the second day of a bilious remittent fever. Both rabbits were found dead on the morning of January 4th. In both the subcutaneous appearances were identical with those constantly observed by me in rabbits killed by the subcutaneous injection of my own saliva, every vessel of the abdominal cavity and extending from point of injection, enlarged edema, and presence of pus and micrococci as found and described in the saliva (subcutaneous putrid fever)." In the same paper I said:

"It seems extremely probable that this micrococcus is concerned in the etiology of croupous pneumonia, and that the infectious nature of this disease is due to its presence in the fibrinous exudate into the pulmonary alveoli.

"That the blood be considered as distinctly septic [also] by the experiments which I have recorded [with some lower animals]. The constant presence of this micrococcus in the mucoid secretions of healthy persons [and] critical cases [are] favorable to the [supposition] of an attack of pneumonia [and] a secure prophylaxis. The exercise of [a] tendency to [lessen] resisting power of the pulmonary tissue, and thus weakening these structures so that the [action] of the micrococcus is [exerted]. The [occasional] occurrence of the disease in the [same] person [at] different [times] is [explained] by the [fact] that [the] resisting power [is] also, that a reflex vasomotor paralysis, affecting a single lobe of the lung, for example, when induced by exposure to cold, may so reduce the resisting power of the pulmonary tissues as to permit this micrococcus to produce its characteristic effects.

"Again, we may suppose that a person, whose vital resisting power is reduced by any of the causes mentioned, may be attacked by pneumonia from external infection with material containing a pathogenic variety of this micrococcus having a potency, permanent or acquired, greater than that possessed by the same organism in normal buccal secretions."

The extended researches of Fränkel and of Weichselbaum show that this micrococcus is very commonly, if not constantly present in the exudate of croupous pneumonia, and both of these investigators are inclined to attribute to it a specific pathogenic rôle in connection with the malady in question. Fränkel's first paper was published in 1887. In this paper he says:

"Finally, as regards the relative frequency of the two hitherto investigated microbes, in cases of pneumonia no positive statement can yet be made. Nevertheless, I am inclined to regard the lancet-shaped pneumococcus, which is identical with the microbe of sputum-septicæmia, as the more frequent and the actual infectious agent of pneumonia, on the ground that this organism is so much more frequently found in the sputum of pneumonia-patients than in that of healthy individuals. This conclusion is further supported by the consideration that it has not hitherto been possible to isolate directly from the rusty sputum, Friedländer's microbes."

Weichselbaum remarks that he has found this organism in twenty-four cases of pneumonia, eighty of which were of primary and sixteen secondary. On the contrary, he found Friedländer's bacillus in only nine cases; in three of these cases it was associated with the diplococcus above referred to, and in only three instances was it obtained alone in pure cultures.

Weichselbaum arrives at the conclusion that pneumonia may be caused by several different organisms, but that the diplococcus which I have called *M. Pasteuri*, is, in the way which none of the German authors have found willing to accept, is by far the most frequent cause of primary croupous pneumonia.

Whatever may be the final conclusion with reference to the specific etiological rôle of this or other microorganisms in pneumonia, we must recognize the importance of secondary causes which control the endemic and epidemic prevalence of the disease, and these have been well and satisfactorily set forth in a very satisfactory manner by our distinguished member of our Association, Dr. Brieger, of Moabit.

Among the most important investigations of the past year are those of Councilman, of Baltimore, and Osler, of Philadelphia, in reference to the presence of microorganisms in the blood of malarial fever patients. Both of these observers confirm the discovery of Laveran, who, for the first time, as the result of extended researches made in Algeria, that blood drawn from the fingers of such patients, during a febrile paroxysm, contains a parasitic hæmatozoon, which presents itself in different phases of development, and which in a certain proportion of the cases was observed as an actively motile flagellate organism. Osler and Councilman

have found all of the forms described by Laveran, and the last-named observer reports that in recent researches in which blood was obtained directly from the spleen, the flagellate form was almost constantly found. Whether the amœboid "plasmodium" found by Marchiafava and Celli, of Rome, represents an early stage in the development of this organism, or whether it simply represents a change in the red blood-corpuscles, which occurs also in other diseases, as is claimed by Mosso, has not yet been definitely determined. It is somewhat curious that just when we are receiving satisfactory evidence of the presence of the parasite of Laveran in the blood of malarial fever patients, the bacillus of Klebs and Tomassi-Crudelli, which appeared to be dead and buried, has again been introduced to our notice by the distinguished German botanist, Ferdinand Cohn. In his paper published in June last, he gives an account of the researches of a young physician, named Schiavuzzi, who has made researches in the vicinity of Pola, a malarial region in Istria. The method followed was that of Klebs and Tomassi-Crudelli, viz., examination of the air and water in malarial localities, and inoculation experiments in rabbits.

The bacillus was constantly found in the air, and the rabbits inoculated presented symptoms and pathological lesions believed to be identical with those of malarial fever in man. I cannot at the present time go into a critical discussion of the evidence presented, but would refer you to an experimental research made by myself in New Orleans in the summer of 1880, in which I repeated the experiments of Klebs and Tomassi-Crudelli, and arrived at the following general conclusions:

"Among the organisms found upon the surface of swamp-mud, near New Orleans, and in the gutters within the city limits, are some which closely resemble, and perhaps are identical with, the bacillus malariæ of Klebs and Tomassi-Crudelli; but there is no satisfactory evidence that these, or any of the other bacterial organisms found in such situations, when injected beneath the skin of a rabbit, give rise to a malarial fever corresponding with the ordinary paludal fevers to which man is subject."

I see no reason to modify the opinion here expressed, notwithstanding the endorsement given by Cohn to the results announced by Schiavuzzi. These researches relating to organisms in the air and water, and experiments upon rabbits, especially in the hands of an inexperienced investigator, cannot have any great scientific value in the elucidation of an etiological problem. The sources of possible error are too numerous, and the method is in any case inadequate for the complete solution of the problem. It is essential that the infectious agent, especially one so easily demonstrated as this bacillus, be proved to be present in the blood or tissues of malarial fever patients, and in the absence of such proof, experiments upon rabbits and researches in the air of malarial regions can have but little weight. It may well be that in the swampy districts of warm climates, where malarial fevers prevail, one or more species of bacillus will be found in the air or in the water, which are absent from the drier air and running waters of non-malarious uplands, but this is simply an interesting fact in natural history relating to the distribution of organisms of this class, and by itself cannot be accorded any value in a consideration of the important question of the etiology. The method of research pursued by Laveran, by Marchiafava and Celli, by Councilman, and by Osler, is the true one, and none of these gentlemen have encountered the bacillus of Klebs and Tomassi-Crudelli in their extended researches. On the other hand, they are in accord as to the presence in the blood of a peculiar flagellate organism, and of certain spherical and crescentic bodies which are believed to represent different stages in the life-history of this infusorium.

If the time permitted, I would be glad to continue this review of the recent progress made in the interesting field in which I have been for some time an enthusiastic worker, but your patience would be exhausted long before I could reach the end of the story.

The importance attached by the profession to studies of the nature of those referred to is well stated in a recent editorial in the London *Lancet*, relating to the International Hygienic Congress recently assembled at Vienna. The editor says: "The Vienna meeting will serve the double purpose of indicating the necessity of skilled investigation of the causes of disease, and of encouraging statesmen to rely upon work of this character, rather than upon collective opinion.

"The excellent work which is carried on in the continental laboratories has undoubtedly had its effect in teaching the value of exact knowledge, but there was none the less too great a desire at Vienna to record by resolution the opinion of numbers, regardless of their fitness to exercise any proper judgment upon the points at issue."

Before concluding my address, it becomes my sad duty to remind you of the losses which our brotherhood of sanitarians has sustained during the past year, to speak of those whose voice will no more be heard among us, who have joined the great army of the dead. Happily for us they have left a record behind them, of honest endeavor and earnest words spoken in behalf of their fellow men. Their names are not simply recorded in the list of our members, but also in our hearts; and a permanent record of their contributions to sanitary science will be found in the papers to which their names are attached, which are contained in the volumes of our transactions.

And now, Gentlemen of the American Public Health Association, having already exceeded the limits which I had intended to place upon the length of my address, nothing remains but to thank you for the kind patience with which you have listened to me, and for the high honor which you conferred upon me at Toronto, in electing me your President for the present meeting.

ORIGINAL ARTICLES.

A DEATH DURING, AND A DEATH BEFORE, THE ADMINISTRATION OF ETHER.

By D. HAYES AGNEW, M.D.,
PROFESSOR OF SURGERY IN THE UNIVERSITY OF PENNSYLVANIA.

On the 3d of August, 1887, I was called to visit by appointment, Mr. R. D., æt. forty-five, at his hotel in Philadelphia, for the purpose of removing two ulcerating hemorrhoids, which had resisted the

ordinary means of treatment for several months, and were causing the patient great discomfort. Dr. White was asked to accompany me and administer the ether. There were no ascertainable reasons why an anæsthetic should not be given, as neither the heart nor kidneys were diseased, and the patient appeared to be in good health. Only one year previous I had divided and stretched the sphincter ani of Mr. D. for fissure, administering the ether myself, and after anæsthesia, entrusting the agent to a friend of the patient, who was present, for the brief time required for the operation. About six ounces were taken at this time.

At the time of the last operation nothing occurred during the early stage of the inhalation, other than what is witnessed every day when ether is exhibited. In the course of fifteen minutes the patient, though somewhat rigid, was placed across the bed. One of the tumors was dragged down, transfixed, and ligated with a double ligature. When about to seize the second, the breathing, which had been strong and free, suddenly ceased. The operation was immediately suspended, and the usual methods for resuscitation instituted. These consisted in examining the throat for the probable presence of some obstructing cause, dragging the tongue forward, the use of artificial respiration, flagellating the surface with the end of a wet towel, ammonia to the nose, partial inversion of the patient, and, finally, the passage of the electro galvanic current through the phrenic nerves. Notwithstanding these measures were persisted in for at least three-quarters of an hour, during twenty-five minutes of which time the pulsations of the heart could be recognized, not a single effort of natural respiration occurred. The man was dead.

The post-mortem made by Dr. Formad, revealed complete collapse of the lungs, marked traces of an old meningitis, attributed to a former sunstroke, and what satisfactorily explained the sudden termination of life, the rupture of a calcified vessel in the floor of the fourth ventricle, the recognized physiological centre of respiration: all the vessels comprising the circle of Willis were in a similar state of atheromatous degeneration. It was evident, therefore, that the increased vascular tension of these cerebral vessels, caused by the ether, determined the lesion, a result which might have followed any unusual excitement, mental or physical. The heart and kidneys were healthy.

The question naturally occurs, Could this sad disaster have been prevented? Certainly, in view of all the circumstances, it could not. *First.* The ether was that known as Squibb's. The can contained eight ounces; two ounces remained in the vessel; two ounces, it is fair to suppose, had been retained in the folds of the towel, leaving four ounces, or, at most, less than five ounces which had been inhaled. *Second.* There was a sufficient admixture of atmospheric air with the respired vapor, as the anæsthetic was administered from an ordinary towel folded into a cone and with an opening at the apex. *Third.* The position of the administrator, Dr. White, that of reclining alongside of the patient, with the face of the latter in full view, would have enabled him to detect at once any signs of approaching danger, which, from his long experience in giving anæsthetics, would have been quickly recognized; and, *last*, the impossibility of being able to ascertain during life, the state of the bloodvessels of the brain disclosed by the autopsy, and rendered very improbable in a man of forty-five years of age.

After forty years of surgical work, often, too, of the gravest character, and sometimes requiring prolonged anæsthesia, without an accident in a single instance, I had come to believe that the exhibition of ether, unless recklessly administered, was entirely free from danger. Several deaths, I am aware, have been reported, from time to time from its use, even in the hands of the most careful operators, but I never could divest my mind of the idea that in these cases there was some undetected element involved more influential in the issue than the ether, as in the present instance.

The following case, which came directly under my own observation only a few weeks before the death of Mr. D., is in point.

I was called to one of our suburban towns to see a case of strangulated hernia. The patient was a female about seventy years of age. The intestine had been incarcerated for three days. Her pulse was quite good, and there were no signs of collapse. I noticed the pupils were much contracted, no doubt from the opium which had been administered. I directed her medical attendant to place the patient properly in bed, and prepare a cone for giving the anæsthetic, while I made my preparation for the operation. This was done. In a few minutes I was ready to proceed, and then told the doctor to give the ether. While reaching for the bottle, and before removing the cork, the patient gave a sudden convulsive movement, at the same time ejecting a large amount of stercoraceous matter from the stomach, and expired in a moment. Had the etherization been commenced, or the operation begun, before the death of the woman, the fatal result would have been charged to either the anæsthetic or to the knife.

THE ORIGIN OF SOME DISEASES.[1]

BY EZRA M. HUNT, M.D.
SECRETARY NEW JERSEY STATE BOARD OF HEALTH.

THE class of diseases variously known as contagious, transmissible, or communicable has ever attracted the most earnest consideration of medical men and of all sanitarians. By the quickness and often obscurity of their invasion, by the malignant type they too often exhibit, and by the large areas over which they extend, they not only make large demands upon the skill of the profession, but arrest the attention of all mankind.

The study of epidemiology has enlarged their numbers and now shows us that many diseases once regarded as constitutional or septic are in reality specific and pathogenic or mostly parasitic.

[1] Read before the American Public Health Association, at Memphis, November 8, 1887.

The prevention and limitation of this class of maladies must ever therefore largely occupy the attention of all of those who study the causes, the courses, and the results of disease.

The study of their etiology is always a *fundamental* inquiry. While to a degree it is possible to treat a disease skilfully without knowing its causes, it is always more satisfactory and generally more skilful to know something of the causes.

But what do we mean by etiology or causes, surely not always, not generally, the beginning or efficient or final cause? Prof. Semmola, of Naples, at the recent meeting of the Medical Congress at Washington may have startled some by these words, "Medicine, like all other sciences, never demands why, well knowing that the *first* causes of things are inaccessible, and that to every scientist it should *suffice* to know in which physical and chemical conditions this or that phenomenon manifests itself, so that he can modify and govern it at his will." This is true. The best that we can generally hope is to find the *conditions*, physical, chemical, or biological, in which phenomena manifest themselves. The word *cause* is often in the same sentence used in two or three different senses. In our etiology we must remember that by cause we mean mostly the "conditions under which phenomena manifest themselves." Also that these conditions (thus called causes) mean the modifying influences present in the host or person, and the modifying influences of surroundings much oftener than they mean anything in the specific entity which we are so often calling the germ, and then calling it the cause.

While reaching back toward the beginning, even though we seldom reach the starting-point, we do come to see how it is true of every disease as of every living thing, that it must have had a beginning. It is not a mere platitude to say that there was a day when the first case of smallpox occurred.

Nor does it necessarily belong to the sphere either of creation or spontaneous generation. A case of some new disease may put in an appearance, as did cholera on the Ganges, or a case of a known and existing disease may happen that is not derivĕd from another precisely like it, but occurs because analogous conditions to those which gave rise to the first case of the kind have again occurred, and produced a pronounced deviation.

So it is possible that at the same time, as to some one disease, we may have cases of a communicable disease which have arisen from previous cases, and other cases that have resulted from a combination of influences or conditions such as gave rise to the first case. There are at least two reasons why the old dictum of *omne vivum ab ovo* cannot now be applied with the precision or with the finality with which it used to be quoted.

I. There is such a thing as *evolution*, which, while recognizing an original type, also recognizes departures from the normal which may have come to be so representative and paramount, as to constitute *newness* in all essential particulars. Since we have come to recognize that many diseases are but developments and cultures of microphytic or microbic life, we very appropriately turn to the facts of botany, not only for illustration, but for verification of our theories. And what a change has taken place in *its facts* since the days of Linnæus? We no longer cling to the divisions of orders, genera, and species so closely laid down by him. We recognize two forces—nature or heredity, and environment. A plant inherits a likeness which it *tends* to retain, but it is often so modified by environment, as greatly to change, and so sometimes as even to *lose* its identity. Environment comes to predominate over heredity. The horticulturist often takes a plant which he has found to be subject to variations, and fixes and perfects it in some one of them by cultivation.

Prof. Huxley has recently contributed to the Linnæan Society a paper on the classification of gentians, in which he claims that gentians are all specialized—that is, become gentians from some other form. *Permanency* of type has so many exceptions, that *variations* of type and the power to give fixity to some of these variations by means of cultivation or environment, must be accepted as a doctrine and a fact. Species and genera have variations, sports, modifications not dreamed of by the earlier botanists. Some of these departures are so marked and so predominant as to obscure the relationship and so far *ignore* it as to have individuality of their own. If, as we know, cultivation or surroundings can change a poisonous plant into a mild one, or can wholly modify it, it is not remarkable that a microphytic disease should lose its apparent identity, and at length in a new culture-medium or under special conditions become specialized. It is a law abundantly illustrated in the vegetable world, that environment causes variations, and that some of these variations tend to fixity of type, while others do not. All the wonderful facts of evolution show full well that we may in this way have what in respect of *symptoms and treatment* is a new disease.

Yet it is not a *de novo* origin in an absolute sense, or, if practically *de novo*, it is not *de nihilo*.

It is, that a series of changes has been evolved by environment, by conditions in persons or in surroundings, until the result of some of these changes becomes self-assertive and prevails over its heredity so as to secure for a longer or shorter period a fixity of its own.

This fixity may be a new disease.

II. The history of hybrids, the so-called accidents of their occurrence; and the fertility of hybrids is such that we are forced to look upon them as new forms of life—as becoming established into an autonomy or individuality of their own.

The horticulturist in some of the wonderful productions of new plants in the last score of years has come to be familiar with hybridisms that wholly obscure origin and that come to have a fixity of their own as much as some new diseases with which we have to deal, or as much as cases of disease which we cannot trace to a contagious source.

All this has been greatly emphasized by what we have come to know as the fertility of hybrids.

Not over thirty years ago the general view of botanists was that hybrids were sterile.

But so numerous are the exceptions and so abundant have been the results of new cultivations that this view is fully disproven. Says a recent botanical authority, "Among plants there are many instances of hybrids between species being perfectly fertile, and continuing so for an indefinite period. Experiments during the last twenty-five years have increased the number of such fertile crosses manifold. . . . Fertility of hybrid plants is the rule and sterility the exception. So far as plants are concerned, there is not the slightest ground for considering sterility as a distinctive bar, separating species. These hybrids come to have a specificity of their own so different from the parentage as to be unrecognizable, and so specialized as to be permanent. As another expresses it, "The hybrid becomes an individual not responsible to its species."

Nor is this confined to plants with spores. Some of our most skilful horticulturists are now producing varieties of *ferns* by hybridism, and every now and then some so-called change growth or sport shows wide departures.

The bearing of all this on the parasitic forms of disease is not far to seek. It, as now seems so nearly proven, so much of disease has to do with elementary and minute forms of vegetative life, it is easy to see how the facts of evolution and hybridism have a bearing upon the appearance and propagation of disease. The light of the botanical world and its marvellous revelations as to the actualities and possibilities of the origination of new forms distinct from the parentage, penetrates the hidden sphere of disease-origin, and shows how some diseases cease, how others arise, how some lapse back to their heredity, while others are made permanent or specialized by their environment and how others still are hybridized into specific forms and acquire a fertility and fixity of their own. This range of deviation is so wide as to account for very many of the anomalies of disease and for the organization, cessation, or modification of form.

In reply to my inquiry on this particular point Mr. Mehan, the distinguished botanist of Germantown, Penna., writes me: "All hybrids, that we know by actual experiment *are* hybrids, are fertile as far as I know, and reproduce their originals just the same as if they were 'original' species. I think almost every botanist of note believes in abundant, fertile hybrids in nature. Coming down nearer to your own line of thought, I believe it is conceded that all lichens are hybrids between fungi and algæ. It is tenable that new forms of disease are continually coming into existence, which can only arise from new forms of disease-producing plants (microscopic fungi) being evolved from older species; but I do not know whether there is an opinion that these new forms are the result of hybridization or of that natural law of change which seems to be a constituent part of existence—in vegetation at least."

In a paper read by Dr. M. W. Taylor, before the Epidemiological Society of London, April 13, 1887, he notes the fact that many of the fungoid varieties were but "conversions of elementary states of penicillium and oidium. It is also maintained by Zopf (the botanist), that there may be a *pleomorphism* amid pathogenic microörganisms, and that there are stages of intermediate forms resulting from the nature of the nutrient media." (See *Lancet*, May 7, 1887, pp. 933, 934.)

The view is, we believe, gaining ground, that harmless microphytes may become pathogenic, and that the different forms of microörganisms present have relation to each other, and that the culture-medium in disease, viz., the person and his surroundings, determines the character of the microörganisms full as much as the microörganisms determine the character of the disease.

If the views as to the microphytic origin of most of the communicable diseases are correct, the study of the laws of this evolution and hybridism is vital. We believe it is in this direction that we are to account for the origin of new diseases, or for such variations in type as obscure or destroy identity. If we can, through this study, arrive at the evidence that in this sense many diseases begin, we have a new department of study, in that we are called upon to define with accuracy how and why this origin takes place, in order that we may thwart or circumvent the conditions.

If it is the result of *evolution* through a long series of changes, it behooves us to study the normal, and to watch and record all the gradations by which the unfriendly result is attained, so that, at some stage, we may intercept the progressive and threatening changes that are occurring, or ascertain what condition of the person, or what condition of surroundings constitutes the influence which brings about the change or provides the fertilizing medium for the disease and causes it to break forth. If it is the result of a *hybridism* which occurs spontaneously or rapidly, we need to study precisely what forms of vegetative life thus incline to coalesce, under what condition the union occurs, and how their conjunction, development, and fertility are to be interrupted.

If special conditions of some parts—as the throat, for instance—or certain conditions of the secretions, furnish a special soil or culture-fluid for the propagation of low forms of vegetative life, this is to be studied with exactness.

In each of these lines the same methods of technical study and close record and analysis of facts by competent observers, which has prevailed in the study of minute plant life by botanists, and which has obtained in many other sciences, will, in this comparatively new field of biological and botanical research, accomplish equally valuable results. In it we are attempting to find out how much, and under what circumstances microörganisms imperil human life.

The practical value of such an inquiry is apparent, for sooner than is the case with most of the studies of nature, the results will be applicable in the prevention and treatment of disease. It will be a great gain if we can come to know that, either under the laws of evolution, or as the result of admixture or hybridism, symptoms and pathological effects become specialized so as to constitute a new disease which maintains its type.

As examples of how proximity of different diseases

may modify symptoms, we have many suggestive facts in the history of disease. Yellow fever is believed by many to be a mongrel, born on the high seas by admixture of the jungle fever of Africa with the typhus of the pent-up hold of the filthy vessel. It is not certain that typhoid fever was not once nearer to typhus, until it came to be called abdominal typhus, and then to have modifications because surroundings and the acquired power of self-propagation gave it an autonomy of its own.

It is not even now certain that there are not grades of cesspool and other adynamic fevers that will some day declare another well marked departure from what we now call typhoid, and come to have an individuality of their own.

It is not certain that when Sydenham treated scarlet fever and measles as one disease that their lines of difference were as well marked as now.

Diphtheria so often seems to have a localized origin, and common forms of sore throat are so often seen to pass away from their general into a special type, that it will not be strange if we can come to the law of departure. (See views expressed in the *Sanitary Record* of August 15, 1887, p. 88, and the contribution of Dr. Wordin, in the *Connecticut State Health Report for 1887*, that diphtheria results from the special virulence of a micrococcus which is not specific, but present in forms of foul or septic sore throat).

While typho-malarial fever has no pathognomonic lesion to distinguish it from the ordinary typhoid, yet we do know it has symptoms to distinguish it.

The advances of biological investigation have put us in regions of new possibilities, that do not involve spontaneous generation, but yet do render probable what is equivalent to the *de novo* origin of cases of disease which afterward are chiefly communicated by the first and succeeding cases.

Having settled that such origins do take place, we shall then pry into the secret of the laws of combinations and the conditions which favor the evil evolution or the facts of hybridism, and seek to combat these by starting similar processes in opposite directions, or by sterilization, neutralization, disinfection, and all the details of radical sanitation.

Such a view of the occurrence of old or new diseases and of the reasons for fixity in some and changing forms and types in others leads to several practical results.

1. The study of parasites, or germs, as they are called, is only one of the methods of informing ourselves as to the phenomena of disease, and in itself is not likely to be the key to rational and successful treatment.

2. Our attention should be directed far more than now, to the study of conditions and circumstances under which new forms appear; to the influence of persons and surroundings, instead of to the mere finding of a specific form. The latter would, of course, be most valuable as one of the facts in the chain of evidence, but we should not, as now, seek so much to look to it as the cause of disease as to inquire what conditions have *caused* this or that particular microphyte to be present.

3. We should be able to account for the occasional occurrence of a disease independent of any previous case, and for changing types of disease and new diseases, and would come to treat diseases less by their names and more in view of their type and the effect of surroundings upon them.

4. The tendency of all this is to magnify the importance of close observation and to lead us to feel that success in warding off disease and in treating it when it appears, depends mostly upon close observation and that experience which is derived from actual practice.

If we are looking to the biological laboratory for the natural history of disease, or to the chemical laboratory for the application of remedies, we shall surely fail. It is not so much that we need to find the specific germ, or the specific methods. The world is always looking after specifics. But the science and art of sanitation has far more to expect from a study of the conditions of persons and surroundings under which diseases, or types, and modifications of disease manifest themselves, as also from a study of the prevention or obliteration of such conditions, than it has to expect from the finding of microphytes as the source of disease, and seeking to cure disease by expelling microörganisms or attenuating them.

Our only design in this paper is to awaken inquiry as to modes of accounting for the localized origin of disease, without any antecedent case, on the proposition that the laws of evolution, environment, hybridism, or modification by culture, give rise to diseases so different from their prototypes as to have individuality and permanency of their own.

Because such inquiry is relevant to prevention, there is good reason to believe that by ascertaining the laws of these transformations and modifications of type and of the origination of special varieties, we shall ere long find new means for the prevention or limitation of many diseases.

THE PHYSIOLOGICAL ACTION OF THE OIL OF TURPENTINE.

By H. A. HARE, M.D. (Univ. of Pa.),
demonstrator of experimental therapeutics and instructor in physical diagnosis in the university of pennsylvania.

Notwithstanding the fact that the oil of turpentine has been used empirically for many years with great success in certain morbid conditions, but little effort has been made to study its relations with the animal organism other than by the bedside. Kobert[1] and Hoppe[2] have made studies of its action to a limited extent, as has also Azary, an Hungarian investigator; otherwise nothing has been done worthy of remark.

When from one to two drops of the oil of turpentine, having first been thoroughly stirred up with about fifteen cubic centimetres (four drachms) of water, is injected into the jugular vein of a dog weighing thirty-four pounds, there is produced immediately an increase in the number of the cardiac movements which lasts for an indefinite period. There is, how-

[1] Centralblatt f. med. Wissenschaften, 1887, p. 129.
[2] Journal für Pharmacodynamik, Bd. I, p. 105.

ever, no rise whatever in the arterial pressure, the vasomotor system being absolutely unaffected.

In a larger dose, amounting to five or ten drops, he found, the same increase in the cardiac pulsations occurs, but is followed in the course of from two to three minutes by a very marked slowing of the pulse, which is decreased in number considerably below the normal. Along with this primary increase in rate, there is a slight rise of arterial pressure which does not exceed ten millimetres of mercury, and which returns to the normal on the appearance of the slowing of rate mentioned. When a still larger dose (30 m) is administered in the same manner, the primary increase in rate lasts but for a moment, and is immediately supplanted by a very marked decrease in rate resembling that already mentioned. The arterial pressure still remains virtually unaffected. Doses of as much as two drachms of the pure oil produced a very marked fall of arterial pressure with great cardiac depression, and in one case death, in which respiration continued twenty seconds after the heart had ceased to beat. From the character of the pulse waves it was evident that the fall of pressure was due to cardiac failure rather than to any vasomotor action, and this was still further proved by the fact that asphyxia produced a momentary rise of pressure, a considerable rise being impossible in the depressed condition of the heart.

DOG, WEIGHT 31 LBS.

Table of experiments showing slight effect of two drops of turpentine on arterial pressure

In order to determine whether the cause of the primary quickening of the heart beats was due to palsy or depression of the vagi, these nerves were galvanized, and were found capable of reducing cardiac movements as completely as in the normal animal, and this proof of their integrity is still further supported by the fact that later on the drug was shown to be stimulant to these nerves. In short, there is evidence that this increase in pulse rate must be due to a direct action on the heart or to a reflex stimulation of the accelerator nerves. That the action is on the heart itself, is pointed to by the fact that the drug applied directly to the heart of the frog produced an increase in rate, and this was proved by cutting the spinal cord in the dog, thereby making sure of the accelerator nerves. Under these circumstances, the increase in rate after small doses still continued.

That the slowing which comes after the use of from five to thirty drops is due to inhibitory stimulation of centric origin is proved by the fact that section of the pneumogastric nerves immediately causes the typical rapid pulse, produced ordinarily by such a section. That the slowing is not due to cardiac depression is proved by the strength of the individual pulse waves and the constancy of the arterial pressure, and by the typical curves, after large doses, of vagal stimulation. These experiments were repeated so often and with such varying doses, but with an equally great constancy of the same result, that there can be no doubt of their truth.

The results are very much opposed to those obtained by Kobert and Hoppe, who found that the drug very powerfully affected the vasomotor system, at first causing a rise of pressure and later a fall. They found, however, as did the writer, that the heart is stopped in diastole, or, in other words, paralyzed. In their experiments, however, the vagi seemed to be unaffected.

I do not know in what lies this difference in results, unless it be due to some difference in the character of the oil used. The oil used in my own experiments was obtained from one of the most reliable druggists in Philadelphia, who was informed that the best was be used, and also of the purpose for which it was to be used. That the absence of effect on the vasomotor system was constant, was proved not only by the use of doses of various size to various dogs, but by the administration of ascending doses of from two to thirty drops of the oil to individual dogs. In all cases the results were identical. These same results were reached in curarized and uncurarized animals, so respiration could have had no influence.

On the nervous system of the frog, the drug exerts a very decided influence when used in large amount. If as much as five drops be injected into the posterior lymph-sac of a medium sized frog, reflex movements are rapidly decreased, so that they occur only on decided stimulation. When they do occur, they are, however, very strong. Mechanical stimuli first fail to produce contractions, after this even burning fails to produce any movements, or, if any occur, they are very weak. That this failure of reflex is due to sensory involvement and not to any influence on the motor portion of the nervous system, is proved by the fact that powerful contractions take place in the limbs if the batrachian so desires, although the foot may be destroyed without calling forth any movement. Later, the frog lies on its back when so placed, but is still capable of originating powerful muscular contractions.

Finally respiration becomes less and less, motion fails as well as sensation, and the animal dies.

The question as to whether the failure of sensation is due to the action on the nerve trunk or spinal cord was decided by tying a ligature around an entire limb, except the nerve trunk, and injecting the poison into the limb below the ligature, the spinal cord being therefore protected. Under these circumstances there was a decided lessening of reflexes even to severe stimuli, such as burning. At the same time it was proved that the sensory part of the spinal cord does not escape, for, if the artery in

a limb be tied and the poison given into the body, reflexes are lost even more completely. When much smaller doses are used ($\frac{1}{10} = \frac{1}{4}$ drop) reflexes are at first increased, then slightly diminished, the increase being due to a stimulant action on the spinal centres.

Summary.—1. The oil of turpentine in small doses, resembling those ordinarily given in practical medicine, produces an increase in the number of the cardiac beats due to a direct stimulant action on the heart.

2. In larger doses it produces distinct slowing of the pulse, due to a stimulation of the pneumogastric or inhibitory centre.

3. That its influence on the vasomotor system, if at all, is very slight, either with large or small doses.

4. That poisonous doses (5 c.c. to 10 c.c.) (ℳ. 80 to 160) produce death by cardiac failure when injected directly into the jugular vein.

5. That the drug in small doses increases reflex action somewhat, but in large doses decreases it, the increase being due to a stimulation of the spinal cord, and the decrease due to depression of the sensory side of the cord and afferent nerves.

MEDICAL PROGRESS.

Conduct of the Third Stage of Labor at the Rotunda Hospital, Dublin.—Macan, in his address before the Section for Obstetrics of the British Medical Association, at its last meeting, described the method employed at the Rotunda as follows:

As soon as the child's head is born the left hand is placed on the fundus, the ulnar edge being directed toward the vertebral column with the palm of the hand looking directly in the axis of the uterus. The child's eyes are then carefully wiped, and a finger is passed into the vagina to see if the cord be round the child's neck. If uterine action does not soon expel the child, or if it should make any effort at inspiration, showing a want of aëration of its blood, then pressure is made on the fundus, which is generally sufficient to cause the body of the child to be expelled. If it does not do so, then gentle pressure is exerted on the child's head so as to push it backward against the perineum till the anterior shoulder descends with a well-marked jerk past the pubes, and then the delivery is readily terminated by pressure over the fundus. As the child leaves the uterus the left hand follows down the fundus, and causes any liquor amnii that is still in the uterus to be expelled. The position of the hand must now be the same as before the child was born, that is to say, the ulnar edge must be directed backward against the woman's spine, and the fundus should be pressed, if anything, forward against the pubes. The whole hand is now gently rotated, so that the tips of the fingers irritate the posterior surface and sides of the uterus, and more especially the points of insertion of the round ligaments. We can then follow and watch over the alternate contractions and relaxations of the uterus, and judge whether it is becoming unduly distended with blood or not. In the meantime the nurse steadily ties the cord as soon as all pulsations in it have ceased, and then the uterus is never for a moment out of the direct observation of the medical man in charge of the case. Should the child be bodily asphyxiated—that is, in a state of white asphyxia—the nurse should tie and cut the cord at once, and then take charge of the fundus of the uterus, while the medical man takes charge of the infant. When there is any considerable tendency to *post-partum* hemorrhage it becomes a very nice question whether the medical man should direct his efforts to resuscitating the infant or to stopping the *post-partum* hemorrhage. In any case of doubt the mother's care demands our first attention. If the discharge of blood remains moderate, and there is no accumulation taking place into the uterus, we use gentle friction at intervals for fifteen minutes, and then make firm pressure on the fundus in the axis of the brim during the acme of a contraction. This is nearly always sufficient to expel the placenta both from the uterus and from the vagina. The hand still, however, commands the fundus, and friction is again applied when we feel the uterine contraction beginning to relax. Should this interval of relaxation pass without any hemorrhage, then we wait for the next contraction, and apply the binder during its continuance. After the binder is applied the woman again turns on her back, and the hand is rubbed backward and forward over the fundus till it is found to be in such a state of permanent retraction as to exclude all danger of *post-partum* hemorrhage.—*British Medical Journal*, No. 1390, 1887.

Imaginary Tumors of the Tongue.—At a recent meeting of the Academy of Medicine of Paris, Hardy corroborated the observations of Verneuil, Fournier, Labbé, Laborde, and others, who had reported cases of imaginary tumor of the tongue in neurotic patients. Hardy had also recognized the disorder in those suffering from the late stages of syphilis, who had taken mercury for some time. In such patients there is generally a redness and slight swelling persisting for a long time after the acute stage has passed. The sensory nerves of these parts become altered in structure, and after all gross lesions have disappeared, sensations of pain and burning cause the patients to apprehend cancer. Inspection generally reveals no alteration beyond possibly a few mucous patches. The most useful treatment has been the long-continued administration of alkalies, with the local application of glycerine and carbolic acid. In syphilitic patients, whose sensory lesions generally diminish in acuteness as the disease progresses, these sensations of cancer grow less acute as time goes on, generally disappearing.—*L'Abeille Médicale*, October 10, 1887.

Continuous Irrigation, with Hot Water, in Sepsis after Laparotomy.—Dr. Haggard, of Nashville, reports a case in which, after partial removal of a fibroid tumor of the uterus, necrosis of the remainder and sepsis occurred, treated by continuous irrigation for a week with water at a temperature of 105°, and the free use of tonics. Recovery and cessation of all previous symptoms ensued. He adds the report of a case of laparotomy for cyst of the broad ligament, in which sepsis occurred, owing to the presence of necrotic tissue, whose removal was impossible in the exhausted condition of the patient.

Constant irrigation with hot water for twelve days

resulted in maintaining the elimination of noxious material, and the patient recovered. In both cases the usual methods of drainage failed.—*Southern Practitioner*, November, 1887.

A CASE OF CHARCOT'S DISEASE.—DR. PARK reports in *The Medical Record* for November, 1887, the case of a boy, aged forty-seven, who has been bedridden for many years, presenting the peculiar deformities of Charcot's disease in a most extraordinary degree. Careful examination discriminates the case from *myositis ossificans*, and the peculiarly well-marked bony lesions are such as to render the case extremely interesting.

ANTIPYRIN IN THE TREATMENT OF DISEASES OF WOMEN.—MUNDÉ has found antipyrin useful in dysmenorrhœa, especially when attended by neuralgia, for which he gave the drug in a prescription containing caffeine in a course of menstrum, of which, when the pain was moderately severe, he gave from 3 teaspoonfuls to 3 tablespoonfuls daily. In cases of ante- or post-menstrual crisis the dosage should be largely increased; and if needed the following may be given by rectal injection:

Infusion of kousso	ʒ ½.
Decoction of poppies	ʒ ½.
Thick yolk of egg.	
Antipyrin	grs. 15 to 45.

To be made into an emulsion, and given warm.

Prompt and positive benefit has followed the use of this combination.

In dysmenorrhœa from obstruction to the flow, the following has proved efficient:

Aquæ chloroformi	ʒ 25.
Syr. digitalis	ʒ ss.
Liq. ether	ʒ 3ss.
Antipyrin	gr. 75.

Of which a teaspoonful or dessertspoonful may be given hourly.

In some cases ergotine or hamamelis may be combined with antipyrin, as follows:

Aquæ tiliæ	ʒ 25.
Ergotin.	gr. 15.
Syrupi digitalis	ʒ 5.
Antipyrin	gr. 75.

Also

Aquæ tiliæ	ʒ 25.
Fl. ext. hamamelis virg.	♏ 30.
Syrupi digitalis	ʒ 5.
Antipyrin	gr. 75.

Linden-flower water and syrup of digitalis are not officinal in America, and are convenient menstrua, and the usual preparations of this should be employed. The dosage is that usually employed with the ingredients.

Antipyrin may be given by hypodermatic injection in

Recently boiled water	ʒ 2.
Antipyrin	gr. 30.

of which 5 drops represent 3 grains of antipyrin; from 3 to 4 or 5 injections are needed to secure the effect of the drug.

To render these injections as painless as possible cocaine may be added:

Recently boiled water	ʒ 2.
Cocaine hydrochlorate	gr. 1½.
Antipyrin	gr. 28½.

which may be injected deeply in doses of 20 drops.—*Gazette de Gynécologie*, October 15, 1887.

THE ANTISEPTIC TREATMENT OF PURULENT OTORRHŒA.—Quite remarkable results have lately been obtained by the strictly antiseptic treatment of purulent otorrhœa suggested by Dr. W. Chrystie. Specula have all been kept in a 1 to 20 solution of carbolic acid, after having been carefully washed in hot water, and cotton-carriers are in each instance heated to a red heat before being used. The external canal and fundus of the affected ear are first carefully dried out with ordinary absorbent or borated cotton sterilized holders, and the fundus is then mopped absolutely clean with 1 to 40 carbolized solution cotton tufts. This in turn gently dried out, and a powder consisting of iodoform 1 part, boric acid 6 parts, is then insufflated. By this method the duration of treatment has been shortened to two or three applications in many cases, and an average of about eight treatments is sufficient to cure most cases, even when of some years' duration. Thorough treatment of the always diseased naso-pharynx is carried out with great care in all cases of purulent otitis. —*Polyclinic*.

ICTERUS NEONATORUM.—SILBERMANN is quoted by the *Centralblatt für Kinderheilkunde*, No. 17, 1887, in an extended article, in which he concludes that:

1. Icterus of the newborn is a hepatogenic, absorption icterus.

2. The engorgement with bile occurs in the biliary capillaries and interlobular bile-ducts, which are compressed by the congestion in the portal vein and blood capillaries.

3. This engorgement with blood is occasioned by an alteration in the hepatic circulation, occurring shortly after birth, which is a part of a general change in the blood plasma.

4. This blood change is a *fermentæmia* (development of blood ferment).

5. Icterus is more pronounced the weaker the child.

6. The decomposition of a large number of red blood-corpuscles furnishes abundant material for the formation of biliary coloring matters, which, under the working of the ferment mentioned, continue to decompose for a long time in the hepatic vessels.

POISONING BY SULPHUR POMADE.—EICHBAUM, of Leipzig, reports in the *Berliner klinische Wochenschrift* of October 17, 1887, the case of a man, aged thirty-seven, well developed, and previously healthy, who complained of headaches, giddiness, and attacks of partial syncope. Examination revealed the face pale, the forehead covered with cold perspiration, the pupils dilated and not reacting, the movements of the eyes free, the tongue protruded straight, tremulous, and coated. The heart sounds were a little dull, but no murmurs were present. The other viscera gave no signs of disease. Pulse 124, very small; respiration 16; temperature subnormal. There was some rigidity of

the muscles on the right side of the neck. The patient complained especially of occipital headache. There were no history or signs of syphilis or other well-marked symptoms.

By careful investigation and exclusion, a diagnosis of chronic sulphur poisoning from the use of pomade was made. This pomade consisted of—

Vaseline	100 parts.
Wax	5 "
Sulphur	10 "
Oil of roses	a few drops.

which the patient had used for some time to cure dandruff of the scalp, applying it every second day. The preparation of sulphur used was raw powdered sulphur, the oxidation of which, and its mingling with the perspiration, had formed sulphurous acid, whose absorption caused the poisoning. The cessation of the use of the pomade, the employment of hot baths, and exercise in the open air, speedily restored the patient to health. Eichbaum estimated that three and a half ounces of sulphur had been used by the patient.

Excavating Myelitis.—Hydro-myelia, syringo-myelia, and peri-ependymal myelitis are synonyms of the excavating myelitis on which MM. Jeffroy and Orchard recently read a paper before the Academy of Sciences, Paris (*La France Médicale*, Oct. 11th, No. 119). In two cases which they examined they found evidence of a slow inflammation, and they consequently reject the view that the cavities result from enlargement of the central canal from cystic degeneration of a hemorrhagic or gliomatous focus. These authors believe that the distribution of the vessels to the centre of the cord explains the anatomical disposition of the cavities. According to them, the course of events is first a myelitis affecting a special site in the neighborhood of the ependyma, and this inflammation causes an obstruction of the vessels supplying the gray matter around the ependyma, and consequently there results a softening which proceeds to excavation. The formation of the limiting wall to the cavity follows, or is posterior to these alterations, and its pathogeny is therefore the same as that of the wall of ancient foci of cerebral hemorrhage or softening. This interpretation differs from that of Grimm, who finds in the constitution of this vascular false budding membrane the characters of a tumor and the origin of the whole process.—*Lancet*, October 29, 1887.

The Engagement, in the Pelvis, of the Uterus during the Last Months of Pregnancy.—Stapfer concludes, from his clinical study of this subject, that this phenomenon is the result of a translation or transference of the entire uterus, and an elongation of the lower segment. It may proceed rapidly or slowly, definitely or temporarily. The degree of engagement may vary daily, particularly in the last weeks of pregnancy. The variations in this condition may be considerable, the fœtal head may remain as low as the perineum, or ascend to the superior strait. This uterine engagement is caused by the contractions and force exercised by the ligaments supporting the uterus, and by pressure; it is maintained by the tonicity of the ligaments and of the abdominal walls. It is favored by the empty condition of the adjacent viscera, by the absolute or relative volume of the fœtus, by the presentation, and by the elasticity of the inferior uterine segment, and of the membranes. The ascent of the fœtus to the superior strait renders changes in presentation possible, but rare. Any presentation, no matter how deeply situated, may be changed, if the forces producing it vary.—*Archives de Tocologie*, August 15, 1887.

The Treatment of the Third Stage of Labor.—Freund, of Strassburg, in the *Deutsche medicinische Wochenschrift* of October 27, 1887, gives his conclusions regarding this subject as follows: In normal cases a judicious combination of the expectant and active method in treating the placenta and membranes is best. In removing the placenta the accoucheur should wait until the first signs of spontaneous expulsion appear. In cases where the placenta must be removed at once Credé's method of expulsion is the best. Freund has observed, in normal cases, that the uterus rises toward the umbilicus when it expels the child. He imitates, with one or both hands, this action in securing the expulsion of the placenta by gently pushing the uterus upward, and at the same time compressing it.

Formulæ for the Hippurates of Calcium and Iron.—Poulet, in the *Revue Générale de Clinique et de Therapeutique* of October 20, 1887, gives the following formula:

R.—Acid. hippuric.	℥ 25.
Calcii hydrat., q. s. for an alkaline reaction.	
Aquæ bullient.	2 quarts.
Sacchar.	5¼ pounds.
Tinct. citron.	℥ 3¾.

The acid should be dissolved with the calcium hydrate in water heated to 176° F. until neutralization occurs; the other ingredients should then be added.

Syrup of hippurate of lithium should be prepared after the following:

R.—Lithii carbonat.	℥ 2.
Acid. hippuric.	℥ 8¾.
Aquæ	1 quart.
Sacchar.	℥ 37½.

This may be prepared as directed for the hippurate of lime. These syrups should be given pure, or mixed with water, before meals. The doses are two or three teaspoonsful or tablespoonsful daily for adults, and for children proportionate quantities.

Hippurate of iron may be made into pills by combining

R.—Ferri sulphat.	℥ 5.
Potass. carbonat.	℥ 7½.
Acid. hippuric.	℥ 10½.

The sulphate of iron should be first dissolved in boiling water and the solution filtered. The hippuric acid should be neutralized by the potassium carbonate and the warm solution filtered. The two solutions should be mixed, allowed to settle, and the fluid decanted. To the hippurate of iron formed ℥ 3¾ of powdered gum arabic and as much honey should be added and the whole evaporated to a suitable consistency. Pills con-

taining 5 grains each should be made, of which one should be taken before each meal. This preparation is well borne by delicate stomachs. The suppurates may be given when a mild alterative is desired, to be used for a considerable time.

POISONING BY FISH.—A Spanish naval surgeon, Señor Don Antonio Jurado Calero writing in a recent number of the *Boletin de Medicina Naval*, describes the serious effects observed on board his ship, the gunboat *Magallanes*, from eating fish caught in the Bay of Buena Esperanza on the south coast of Cuba. No less than twenty-seven of the officers and crew were affected, most of them with gastro-intestinal disturbance of a more or less severe nature, the others with nervous symptoms. Those of the first group presented nausea, persistent vomiting, and diarrhœa, followed by coldness of the extremities, small and contracted pulse, and in some cases rigors; afterward a febrile condition supervened. The men were nearly all able to return to duty within two days. They complained, however, for some time afterward of irritation of the skin. In the more severe cases there were dilatation of the pupils, marked diminution of sensibility, complete anuria from spasmodic closure of the sphincter of the bladder, and in some cases convulsive movements of the muscles. Those whose symptoms were purely nervous were not attacked till some time later than those forming the first group, and they suffered much less severely, complaining chiefly of cutaneous irritation and headache, also of sleeplessness, which last continued more or less for three or four weeks. In both forms of the affection the termination was accompanied by a cutaneous eruption like urticaria, or in some cases by the appearance of a number of pustules on the skin. This, the author thinks, indicates that the proper treatment for poisoning by fish is to act on the skin. Besides, therefore, combating the gastro-intestinal and nervous symptoms with opiates, bromide, etc., he endeavored to produce diaphoresis by giving lumps of sugar containing twelve or fourteen drops of sulphuric ether, and exhibited an antispasmodic mixture consisting of syrup of orange, lime-flower and orange-flower water, and sulphuric ether. He allowed the patients to drink hot tea freely. —*Lancet*, October 29, 1887.

ENDOMETRITIS DURING PREGNANCY. — VEIT, of Berlin, in the *Berliner klinisch. Wochenschrift*, No. 35, 1887, does not accept the nomenclature *endometritis decidualis*, but proposes *endometritis gravidarum* as a proper name for this condition. He believes that in these cases endometritis exists prior to pregnancy, but first declares itself as the condition of pregnancy advances. The only treatment possible during pregnancy is that by rest and opium; but, as soon as the pregnancy is passed, the local and general treatment of the disease should be vigorously pushed.

THE TREATMENT OF THE ADVANCED STAGES OF UTERINE CANCER.—BETRIN, of Geneva, in the *Nouvelles Archives d'Obstétrique et de Gynécologie* of October 25, 1887, reports excellent results from the use of tampons dipped in equal parts of terebene (hydrated turpentine and any convenient oil—almond, olive, etc. An abundant preliminary douche of a deodorizing solution of permanganate of potassium should be given, the parts dried with cotton, and from three to five tampons dipped in the mixture of terebene and oil should be placed in contact with the diseased tissues, and retained by a cotton tampon. The results in deodorizing and disinfecting the diseased tissues have been excellent, and no interference with the excretory functions has been observed.

NITRITE OF AMYL IN CHOLERA.—DR. PALM writes as follows of his use of nitrite of amyl in cholera, in the *British Medical Journal* of November 5, 1887:

During an epidemic of cholera in Japan, in 1879, it occurred to me to make a trial of the inhalation of nitrite of amyl in the treatment of the collapse of cholera. I did so upon the consideration that this drug appears to have an antagonistic action to the cholera poison in its effect upon the vasomotor nerves. The latter causes a dilatation and congestion of the vessels of the viscera, and a corresponding contraction of the more superficial vessels; while we have in nitrite of amyl an agent which, whatever its effects may be upon the visceral circulation, produces a marked dilatation of the superficial vessels, and must, therefore, to a corresponding degree, relieve the congestion of the visceral circulation. I found that cholera patients in a state of collapse could inhale it very freely before an effect was produced. My plan was to hold a bottle of it under the nostrils, directing the patient to sniff it up freely, and to repeat this frequently. Under its influence a small, thready pulse increased in volume, and where the pulse at the wrist was imperceptible it became perceptible. I have reason to think that in some cases it was the means of saving life. I regret that owing to the accidental destruction of my notes taken at the time, I can give no exact account of the number or details of cases in which it was made use of, but this hint may be of use to others who will have more opportunity than myself of further testing its value.

FACTORY LEGISLATION AND HYGIENE.—At the recent meeting of the Vienna Congress for Hygiene resolutions were adopted to the effect that children from fourteen to eighteen years should be allowed to work in factories for only a few hours daily, and not at all at night, and those under the age of fourteen should not be employed at all. A resolution was also passed that women should be allowed to work for only a limited number of hours during the day, and that they should never be employed at night. It was desirable that women should not be allowed to work in factories for several weeks after confinement, and that the State should take care that they did not lack the means of subsistence during this period of enforced idleness. The Section agreed in fixing from ten to eleven hours as a full working day, and a further resolution was passed that the observance of Sunday as a day of rest was one of the most urgent hygienic necessities for the working classes. The full advantages of this could only be secured if women were given the opportunity of doing their domestic work on the Saturday. A copy of these resolutions was sent to the Parliaments of all the States which took part in the Congress.—*British Medical Journal*, November 5, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM IN ADVANCE. . . . . $5.00.

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

Address, LEA BROTHERS & CO.,
NOS. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, NOVEMBER 19, 1887.

THE CROWN PRINCE'S DISEASE.

SIR MORELL MACKENZIE cables THE MEDICAL NEWS, from London, that "although there is no microscopic proof as to the nature of the present growth in the Crown Prince's larynx, it is in my opinion, no doubt, malignant. It is half an inch below and in front of the growth removed by me last summer, of which there is no return. There is, without doubt, limited perichondritis. The œdema which recently appeared was of an acute character, and had entirely passed off when I left San Remo. I think it, however, not unlikely to return in a chronic form."

The inference drawn by many from the nature of the present growth that the initial growth must have been carcinomatous, and that the correctness of the opinion to this effect entertained by some of the Prince's medical attendants at the period of Sir Morell Mackenzie's first summons is thus verified. The contrary opinion of Prof. Virchow, the eminent pathologist who examined the fragments removed by intralaryngeal procedure, seems justified by the fact mentioned in the above dispatch that there has been no recurrence at the point from which the first growth was removed.

Two points of great interest arise in connection with the present phase of the case. One is whether a benign growth has undergone malignant change; and the other, whether exsection of the diseased half of the larynx, for which preparations had been made at the period of Dr. Mackenzie's first visit, would have been better treatment than that adopted by the distinguished specialist. The best pathologists and clinicians, as a rule, assert that histologically benign growths have no tendency to become malignant. A few only think otherwise. It is a matter of clinical history in the practice of some physicians, that benign growths are sometimes followed by malignant ones "as the apparent result of long-continued irritation from the functional activity of the larynx." This may have been the cause of the unfavorable sequence in the case of the Crown Prince. Great disposition to inflammation has been observed from time to time, and functional activity has been noted as injurious.

As far as can be gleaned from the reports at present at hand, there seems as much to hope for from a laryngectomy now as there was six months ago. During these six months, however, the patient has lived in comparative physical comfort, without the sacrifice of his larynx, and without subjection to the immediate perils inseparable from submission to such a serious procedure. This gain is due to the stand taken by Sir Morell Mackenzie; and, whatever may be the ultimate outcome, his conservative treatment has certainly contributed to the welfare of his patient, and probably to the prolongation of his life. Even now it is said that laryngectomy may be safely postponed for weeks, and perhaps for months.

The prospects of a patient with carcinoma of the larynx are extremely unfavorable. Submitted to palliative and symptomatic management, including tracheotomy when called for by dyspnœa, his expectation of life may vary between the limits of eighteen months and four years, according to the character, location, and extent of the local disease and the constitutional vigor of the patient. Subjected to radical treatment by exsection of the larynx, he runs the risk of succumbing in a very short time to the immediate results of the operative procedure; but should that risk be successfully run, his expectation of life is lengthened by several years, possibly by many, provided there be no recurrence. Should recurrence take place within a few months, the operation will not have prolonged the patient's life. If the radical procedure is to hold out any fair prospect of success, it must be undertaken while the disease remains circumscribed in the structures of the larynx. Extension beyond the larynx increases greatly the immediate risks from the operation, and diminishes greatly the probability of ultimate recovery.

The question of laryngectomy becoming urgent at any period of the clinical history of a carcinomatous larynx, the decision must be made promptly. If the operation be declined, the patient must resign himself to the inevitable with what content he may. He cannot expect a rescue by changing his mind after the disease has extended beyond the larynx.

As to the procedure itself, it may be said that aseptic measures have removed from laryngectomy much of the immediate risks that formerly accompanied it. The records of operations performed during the past five years compare so favorably with those of earlier date that in a vigorous individual

with carcinoma confined to the larynx, and free from evidence of glandular involvement or carcinomatous cachexia. The operation may be regarded as advisable when performed with all the precautionary safeguards of modern improved surgical methods.

NEW METHODS OF TREATING PERTUSSIS.

Whatever methods are used in the treatment of this exceedingly troublesome disorder must depend, if used without empiricism, on some particular belief on the part of the physician as to the true cause of the disease. If he thinks that the condition is due to a neurosis, as did most of the older clinicians, and do many of the present day, he must put remedies directed toward the alleviation of the nervous disorder. If, on the other hand, he has confidence in the theory, of much later origin, that the trouble is produced by the presence of some peculiar living entity, his manner of attack must be directed to its primary object. While many other theories have been advanced as to the cause of this disease, we believe that these are the two which have been most generally accepted, and that at present the microbic theory of its causation finds the most general acceptance.

Arguing from this basis, Prof. Binz, as long ago as 1870, claimed that quinine had a specific action in whooping-cough, provided it was given in very large doses in solution, so as to come in contact with the mucous membrane in its passage through the pharynx, and, in 1871, Letzerich announced that the theory of Binz was correct, and that a peculiar microbe did exist.

Still later, Henke, in the *Deutsches Archiv für Klin. Medicin*, Bd. xii. p. 630, reported valuable results obtained by inhalations of quinine, and his reports have been followed by many others, among which may be named those of Parker, Perrera, and Sauerhering. In the hands of all these observers such practices were followed by good results, and their methods of administration only differed in the minor details, such as the proper strength of the solution to be employed, or of the variety of the salt, the hydrochlorate, sulphate, and tannate having been most generally found efficient. In some cases, however, the drug was given by the stomach in solution, in order to act on the mucous membrane of the mouth and pharynx, while in the hands of Henke, for example, the solution was used by inhalation from an atomizer. This latter method would certainly seem the more rational. The strength of the solutions may vary from one to sixty grains to the ounce of water.

Among the other drugs used with a similar object have been salicylic acid, carbolic acid, resorcin, and oil of turpentine; none of them, however, has been as thoroughly tested as the cinchona alkaloid.

Those who support the theory that the disease is due to other causes than a microbe have employed, as every one knows, nearly every drug in the pharmacopœia, without deciding on any one as being much better than the rest.

Thus, Michael has used a very large number of powders made from various substances, notably quinine, which was used more for its action on the nasal mucous membrane than for any antiparasitic effect. Benzoin and bismuth were also employed with a moderate degree of success.

Still others have used local anæsthetics, the most important of which has been cocaine, and even here the reports are quite favorable.

The treatment of individual violent paroxysms is entirely different from that directed to the ultimate relief of the sufferer, and varies greatly with the circumstances of the case. Within the last year or two, inhalations of amyl nitrite have been used several times with marked success, in certain cases where the interference with respiration was severe enough to threaten death.

THE OSTEOGENIC FACTORS IN THE DEVELOPMENT AND REPAIR OF BONE.

In our issue of October 22d we called attention to a paper by Dr. William Macewen, of Glasgow, in regard to the factors in the development and repair of bone. This paper is completed in the November number of the *Annals of Surgery*, and the discussion of the subject is continued in an additional series of propositions, which, to a considerable degree, tend to overturn the accepted views in regard to the *rôle* that the periosteum plays in the production of bone.

Proposition F states that the periosteum does not initiate the reproduction of bone. The proof of this is seen in the fact that if a subperiosteal excision of a healthy adult bone is performed, there will be little or no ossific reproduction. The periosteal tube collapses, and its position is afterward marked by a layer of fibrous connective tissue, which ultimately becomes absorbed. The osseous tissue which is developed under such circumstances is due to the entanglement of osteoblastic cells in the connective tissue, which is pulled out of the Haversian canals during the removal of the periosteum. When matured bone is irritated for a long time good bone is developed, and this is because formative osseous elements have been poured out on the surface of the bone from the Haversian canals during irritation of the bone, and have become entangled in the meshes of the periosteum. A layer of bone is thus formed, which serves as a starting-point for the formation of new bone by the proliferation of the osseous elements. The periosteum, moreover, not only does not enter into the production of callus after frac-

tures, but limits it, and in some cases actually prevents bony union, by its interposition between the fragments.

Proposition G holds that bone may be regenerated independently of the medulla, which may itself be reproduced. This is proved by the well-known fact that in certain instances of osteomyelitis, where the whole of the medulla and interior of a growing bone has been the seat of inflammation, producing a softened purulent pulp, enclosed in a shell of thin, though true bone, representing the cortical layer, the whole of the interior has been washed out, and after a prolonged period complete restoration of the calibre of the bone has resulted, though in some instances the growth in length has been interfered with, probably from involvement of the epiphyses.

Proposition H. The histogenetic phenomena support the foregoing observations, showing that the periosteum does not generate bone.

In conclusion, the author states "that a study of the whole subject, from histogenesis to experimental inquiry and pathological observation, shows that bone is produced and regenerated by proliferation of osteoblasts, and its development and reproduction can take place independently of the medulla and periosteum.

The practical import of these observations of Dr. Macewen is obvious. If the periosteum does not produce or regenerate bone, it is unnecessary to be so particular about its preservation in resections, and osteoplastic operations; whilst portions of loose bone in cases of compound fractures, trephining, and other operations where there is a loss of substance, should be carefully replaced, in the hope that they may serve as grafts, and result in reproduction of the lost parts.

THE VARIATIONS OF THE NORMAL KNEE-JERK.

Since Westphal announced its importance as a symptom in disease, this curious phenomenon has been the subject of many careful investigations. The recent papers of Mitchell and Lewis, in The News, on "The Reinforcement of the Knee-jerk," and of Warren P. Lombard, in *The American Journal of the Medical Sciences* for January last, on the nature of the process, will be fresh in the memory of our readers. The latter gentleman has continued his researches, and in the first number of the new *Journal of Psychology*, issued from the Johns Hopkins University, has published a most thorough and exhaustive study of the variations of the normal knee-jerk, and their relations to the activity of the central nervous system.

The average knee-jerk varies throughout the day, being, as a rule, greatest in the morning, soon after breakfast, and being very much less at night. The extent of the jerk varies very much on different days. The cause of the variability is, to a large extent, the result of changes in the central nervous system. Fatigue, hunger, enervating weather, and sleep, all conditions, in fact, which lower the activity of the cerebro-spinal axis, diminish the knee-jerk, while rest, nourishment, invigorating weather, wakefulness, influences which stimulate the activity of the central nervous system, increase the jerk. For the details of the ingenious apparatus for estimating the vigor of the blow and degree of excursion of the foot we must refer to the original work, the great value of which consists in the fact that we have here, for the first time, a thorough study of the variations of the normal knee-jerk, from which, as a basis, we shall be in a better position to appreciate the differences met with in morbid states.

THE OIL OF TURPENTINE AS AN ANTISEPTIC.

The present era in the history of medicine will, as some one has aptly expressed it, be known as the antiseptic or germicide epoch, and experimental therapeutists everywhere are employed in starting "cultures" and testing the anti-microbic power of the articles of our materia medica. As is usually the case, the call for an increased number of drugs to act in this manner, has been answered by the chemist and pharmacist with their accustomed promptitude, and at present we have laid before us a list of chemical combinations, purporting to be antiseptic or germicidal in their action, which has been evolved *pari passu* with the discovery of the microörganisms. Not satisfied with these, however, investigators go still further, and attempt to discover not only the drugs which are active but those whose effects are virtually negative. An example of this is well represented by the article of Holmfeld in the *Fortschritte der Medicin* of October 1, 1887, in which he calls attention to the effect of the oil of turpentine on germs of various kinds. His method consisted in taking fresh colonies of the micrococcus prodigiosus and staphylococcus aureus. The vessels used were carefully sterilized, and agar-agar and gelatine were used as culture-beds. After some hours, oil of turpentine was applied, and its effects on the life and growth of the germs noted. Under these circumstances it was soon evident that the turpentine, unless applied in large amounts and for a considerable time, produced no effect of sufficient force to enable one to use the drug in ordinary everyday life for the purposes of antisepsis. Its irritant properties when concentrated, and its loss of the little retarding power which it possesses on microörganisms, as regards their growth, on dilution, exclude it from use on the tissues of the patient, and confine its sphere of value to the instruments employed. Certainly, from our present knowledge of the drug, we may rest assured that it is only proper to use it as an antiseptic when nothing better can be obtained.

SOCIETY PROCEEDINGS.

PHILADELPHIA NEUROLOGICAL SOCIETY.

Stated Meeting, October 22, 1887.

MORRIS J. LEWIS, M.D., IN THE CHAIR.

DR. F. X. DERCUM reported

A CASE OF UNILATERAL CONVULSIONS AND ANOTHER OF HEMIPLEGIA OCCURRING IN UREMIA.

The following cases are of interest in connection with the observations of Raymond,[1] and of Chantemesse and Tennesson,[2] in the same field, and also in connection with two cases of hemichorea, associated with Bright's disease, recently reported by the writer.[3] They are as follows:

Case I.—H. S., colored, aged sixty-nine years, an inmate of the Philadelphia Almshouse, had, while in the out wards, occasionally suffered from convulsions. On several occasions he had been admitted into the epileptic ward of the hospital. Here it was noticed that he usually had several convulsions in close succession, each lasting about five minutes, and that after the attack was over he would fall asleep. His convulsions were always general, and attended with frothing at the mouth.

Mentally he was much impaired. He had delusions of persecution and sometimes imagined himself unable to walk. He was also at times violent and maniacal during the night, requiring to be strapped in bed.

On August 15, 1887, being much improved, he was, at his own request, again transferred to the out wards.

On August 27th, after having had occasional fits for several days, he was again admitted to the epileptic ward. On this day his convulsions seemed much worse than usual. They were almost continuous, and he was brought into the ward in a semi-conscious condition. In striking contrast with the seizures previously observed, the spasms now existed only on the left side, beginning apparently on the left side of the face, extending quickly to the left arm and thence to the left leg, being less severe in the last-mentioned member. During the quiescent periods it was observed that the left arm was paralyzed, as was also to some extent the left leg. The left side of the face was also paralyzed, the mouth was drawn toward the right, and the left cheek was flaccid. The conjunctiva of the right side was sensitive, but that of the left was not. The urine was drawn and examined for albumen, but none detected. The temperature was 97.2°; pulse 140. The sphincters were relaxed.

After the convulsions had ceased altogether the patient slept. Consciousness had evidently been absent during the attack, but on the following morning, August 28th, it had fully returned. The condition of left hemiplegia, however, persisted. His urine was now examined a second time, and revealed both albumen and casts, the latter in large numbers.

On the evening of the 28th the convulsions recurred, the patient having nineteen in rapid succession. On the morning of the 29th he was again conscious, and talked, but during the day he gradually became weaker and died at one o'clock.

An autopsy was held within the following twenty-four hours, and revealed the following: Calvarium of moderate thickness. Dura very adherent, the brain being removed in the calvarium. Pia not thickened, but its meshes very œdematous. Veins of vertex full. Pia presented milky opacities here and there, and was easily separated from the convolutions, a sub-pial space having been formed, which was distended with lymph; vessels of base extremely atheromatous. Brain as a whole soft, flattening by its own weight. Ventricles large and excessively pale. Choroid plexuses very pale and cystic. Velum interpositum presented whitish granulations. On section, the cortex was found pale and the white matter excessively œdematous. Serial sections of both hemispheres *failed absolutely* to reveal a *focal lesion*.

In the general post-mortem nothing of special importance was found except that the *kidneys were markedly granular* and fatty. The lungs were emphysematous, the heart fatty, and the aorta somewhat atheromatous.

Case II.—J. H., aged eighty-two years, white, in the out wards of the Philadelphia Hospital complained of weakness in the left arm and leg. This continued for four weeks, when he was admitted to the nervous ward of Dr. Mills, temporarily under my care. Here it was noticed that he dragged the left leg a little in walking and that he moved his left arm with difficulty. Sensation on the affected side was also dulled. The hemiparesis grew gradually more and more pronounced and was as sharply defined as a hemiplegia of organic origin, which, indeed, it was at first supposed to be. At last, though sluggish mentally, he was able to reply to questions and to make his wants known in his native language, namely German. Gradually, however, he failed in mind and body, incontinence of urine, delirium, and coma set in, and after having been in the ward two weeks he died. During life the urine had been examined and revealed a small amount of albumen.

On the day following death the autopsy was held and the following conditions noted. Calvarium and dura normal. Pia arachnoid loose and very œdematous, its meshes milky. Vessels of base very atheromatous. Ventricles excessively pale. Choroid plexuses presented numerous large cysts. Velum interpositum infiltrated. Brain very soft. On section, found to be œdematous throughout. Careful serial sections *revealed no focal lesion*.

The kidneys were found to be *much contracted and cystic*, markedly cirrhosed.

The other organs revealed nothing of consequence. The lungs presented some adhesions in the right pleura, the heart valves were thickened, the aorta was atheromatous.

Both of the above cases are doubtless to be relegated to affections of the nervous system occurring during and as a consequence of Bright's disease. Chantemesse and

[3] F. X. Dercum: "Two Cases of Hemichorea Associated with Bright's Disease," Journal of Nervous and Mental Diseases, N. S., August, 1887.

Tenneson,[1] have already recorded two instances of unilateral epilepsy occurring in the course of this affection and have verified one of them by post-mortem examination. Their cases are in every way a counterpart of the case here reported. The convulsions were strictly limited to one side, and the autopsy revealed merely general œdema of the brain and chronic interstitial nephritis.

The objection may be made that these phenomena of hemiplegia, hemichorea,[2] and hemi-eclampsia, are due simply to atheroma of the arteries of the brain, by means of which a portion of the cortex or a tract of the internal capsule may receive an imperfect blood-supply, be shut off, as it were, from its necessary amount, an oligæmia and œdema being the result. The weight of evidence, however, is against this interpretation. There are absolutely no areas of local softening or local necrosis to be detected, and the œdema is not confined to a spot but is general, is evenly diffused, and apparently as much in one hemisphere as in the other. Besides, the ingenious experiments of Raymond[3] leave no doubt as to the possible one-sided action of the nervous system in uræmia. It will be remembered that he first mutilated the sympathetic system of an animal by removing the superior cervical ganglion of one side. In this way he threw the entire nervous apparatus, so to speak, out of balance. He then ligated the hili of both kidneys, and the convulsions that ensued were limited to one side. He repeated the experiment a second time with the same result. It seems as though the two halves of the nervous system bear unequal powers of resistance and that the weakest yields.

Dr. Osler asked if, at the autopsy, special attention was paid to comparing the two sides of the brain. It was some time since he read the articles to which reference had been made, but his impression was that more œdema had been found on the side of the brain opposite to the side on which the paralysis was present. An interesting point in these cases is that it appears to be absolutely impossible in certain cases to make a satisfactory diagnosis between cases of hemiplegia from apoplexy and cases of hemiplegia from uræmia. He recently went over this question with his class in the case of a man brought into the hospital with hemiplegia, unconscious, and with albumen and tube-casts in the urine. He said that it was in all probability a case of hemorrhage, but that it was impossible to exclude positively hemiplegia due to uræmia. He said that it might be a case of œdema of the brain from uræmia, in which the œdema, being more marked on one side of the brain, or from some other cause, the paralysis was unilateral. He had seen one case of unilateral convulsions occurring in a man who was brought into the General Hospital at Montreal some eight or nine years ago. He had convulsions for three or four days. At the autopsy in that case nothing was found in the brain that would account for the convulsions. At that time we were not so familiar with œdema of the brain, or with the relation af œdema of the brain in Bright's disease as we are now.

Dr. James Hendrie Lloyd said that Dr. Dercum may recall the fact that, at the meeting of the American Neurological Society two years ago, he referred to a case similar to those reported. The patient was a boy, aged seventeen years. When he saw him he was in a comatose condition with convulsions, which were confined to the right side of the body. The boy had been a chronic sot, and died a few hours after he saw him. At the autopsy there was nothing found in the brain to account for the condition. The only lesion was the "pig-back" kidney. This case was undoubtedly one in which the symptoms resulted from uræmia. He thought that in the intervals between the convulsions it was possible to demonstrate the fact that the side on which the convulsions occurred was paralyzed.

Dr. Morris J. Lewis said that a man, aged twenty years, a heavy drinker, under his care, had albumen with granular and oily casts in his urine. He suffered with frequent convulsions, which usually followed the periods of heaviest drinking; and on two occasions the convulsions were most marked on the right side, and were followed by paresis, which lasted two or three days. The young man was placed in a position where he could not obtain alcohol, and has apparently made a complete recovery. There is at present no albumen, no casts, and no paresis.

Dr. Dercum said that, to the best of his recollection, the authors to whom he had referred, have noted no local œdema. He had made three post-mortems in cases of well-marked hemi-disease occurring during uræmia, and he had found no more œdema on one side than on the other. The cases reported by Drs. Lloyd and Lewis are of special interest as occurring in young persons. Most of the cases reported have occurred in old people. With reference to local cerebral manifestations from a general cause like uræmia, he recalled the case of a gentleman under his care for several years who suffers from chronic contracted kidney. He now and then has general uræmic convulsions. Some years ago he had the following remarkable seizure. He went down town to attend to some business, and while in a bank he suddenly became aphasic. He was perfectly conscious. The aphasia continued for several hours. This looks like another instance of a local manifestation from a general cause.

MENTAL AFFECTIONS ASSOCIATED WITH CHRONIC BRIGHT'S DISEASE.

Dr. William Osler said that as it was in close connection with the paper of Dr. Dercum, he should like to make some reference to the occurrence of certain mental affections which come on in connection with chronic Bright's disease. It is well known that certain mental phenomena occur in connection with chronic renal diseases besides simple uræmic coma. He had reported one case of violent mania in a man aged forty-two years, the subject of Bright's disease. When brought to the hospital, he had been maniacal for three or four days. He subsequently became comatose and died. A very interesting case was recently under his care in the University Hospital. A man was brought to the hospital Thursday evening. He saw him on Saturday. He was then quiet, in a semi-dosing condition, but could be aroused and gave a very intelligent account of himself. The whole clinical picture was that of chronic interstitial nephritis. He thought it not improbable that the man might pass into a condition of

[1] Loc. cit. [2] Dercum, loc. cit. [3] Loc. cit.

coma. There was nothing to attract special attention to his mental condition, and he did not regard his condition as critical. That night he got out of bed in the absence of the attendant, wandered about the ward and finally jumped out of the window. It was subsequently learned that, before admission to the hospital, he had been violent, requiring two or three men to hold him. We were not told this when he was brought to the hospital. He had no doubt that this was an instance of mental disturbance due to chronic nephritis. He was told by one of the physicians who had attended him that the man was full of delusions. He thought that his wife and others were persecuting him.

He saw another interesting case a year ago last Christmas. This occurred in the practice of Dr. Mullin, of Hamilton, Canada. Here there was also a medico-legal question. It was whether or not the man was in a condition to make a will. There was no doubt as to the existence of chronic Bright's disease. The mental condition was peculiar. He believed that his wife and others had designs upon his life, and it was with difficulty that he could be persuaded to take food. He thought that people were persecuting him. Although he gave a very intelligent account of himself, it was not considered advisable that he should make his will at that time. He was placed upon a somewhat more active treatment than he had previously received. This man subsequently did well, his mind had cleared, and he recovered sufficiently to get about and to make his will.

Dr. Dercum said that the negro who was the subject of uræmic convulsions, had also presented, at various times, periods of maniacal excitement and had also had delusions of persecution.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Special Meeting, September 17, 1887.

The President, Thomas M. Drysdale, M.D., in the Chair.

REMARKS ON THE REMOVAL OF UTERINE FIBROIDS BY ABDOMINAL SECTION.

Dr. George Granville Bantock, of London, began by saying that the tumor which formed the text for his remarks had been removed the day before, from a single woman aged thirty-six, a patient of Dr. Joseph Price, and weighed between five and six pounds. At first sight he had doubted the propriety of operating, because there seemed to be no indication for interference beyond the rate of growth of the tumor, and because the patient, as he had been assured by Dr. Price, very much minimized the extent of her sufferings. The matter was thoroughly explained to her, the danger of the operation was made clear, and it was pointed out, that if operation were necessary at some time, she would never be in a more favorable condition for it. She decided in the affirmative, which was fortunate, for it would be seen that the tumor had in its upper part already undergone cystiform degeneration, an incision into the cyst, giving exit to over half a pint of a thin sero-sanguinolent fluid. He was happy to say that the condition of the patient was most satisfactory.

Dr. Bantock then proceeded to the general subject of the removal of uterine fibroids by abdominal section, which, he said, was a very important one. He pointed out that operators were to be divided into two schools: the one preferring to treat the pedicle by the intra-peritoneal method, the other preferring the extra-peritoneal. The advocates of the former based their arguments on the success which has resulted in the operation of ovariotomy, from the introduction of the intra-peritoneal ligature of the pedicle. But it was scarcely necessary for him to show how fallacious such reasoning was, for the conditions were so dissimilar. It was true that there were many different forms of ovarian pedicle: it might be large or small, long or short, broad or narrow, thick or thin, but they were all essentially of the same character and capable of being more or less easily secured by ligature which might be confidently relied on if properly applied. On the other hand, the uterine stump is very different. It is composed of muscular fibre, white and yellow elastic tissue, forming a structure so peculiar that under the pressure of a ligature tied with as great a strain as it will bear, it yields before the compressing force to such an extent that in a few hours the ligature may be quite loose. This occurs even when the pressure is exerted with the aid of a screw, and he pointed out to those who were present at the operation that at the first tightening of the screw there was complete arrest of the bleeding for the time, but that at intervals of ten or fifteen minutes the screw would take a turn or more with facility. In this way an amount of constriction was attainable which, if attempted at once, would probably lead to the breaking of the wire or the cutting of the tissues. He had just come from the meeting of the American Gynecological Society, where he had read a paper on the subject of the treatment of the pedicle, and where the opposite school was so well represented in the person of Dr. Martin of Berlin, and he had the satisfaction of feeling that, for the time at least, he had established his position.

Now the pedicle in this operation varies very much, not in the nature of the tissues forming it, but in the extent and manner in which the parts are involved. Thus the tumor may spring by a distinct pedicle, from the fundus, or some part of the free surface of the uterus. In such a case the application of the extra-peritoneal method is very simple, and his results have been uniformly good; for in thirteen of these cases, all the patients recovered. On the other hand, of all the cases of this kind treated by the ligature and intra-peritoneal method, five in number, only one was successful. Moreover, he had attempted the method in several cases and had been obliged to resort to the extra-peritoneal method after failure of the ligature, though preceded by compression with very powerful forceps. When the body of the uterus is extensively involved in the growth then matters may be very much complicated. The broad and ovarian ligaments may be so lax that it is a simple matter to include ovaries and uterus in one encircling loop. Such a case is little more difficult than an ovariotomy done with the clamp. But the ovarian ligament may be so short on one side that it has to be ligatured separately. That had to be done in the case that furnished the occasion for these remarks. As a rule, it is advisable in such a case to secure the uterus and other ovary first, to transfix the stump with the supporting pins placed across the abdominal wound, to cut away the tumor, trim the stump, and then remove the ovary, lest in tightening the

instrument any part of the ovarian pedicle should be pulled through the loop of the ligature. In the case under consideration it was not necessary to observe this order as the broad ligament on the left side was very lax while the ovarian ligament was very short. On the right side the ovary could be raised quite out of the pelvis. Sometimes both ovaries are thus tied down and have to be secured separately. The same precautions must be observed.

But the disease may involve the whole of the body of the uterus, properly so called. Then one must make a pedicle, and this is the most difficult state of things to overcome. It was for such a state of things he had devised his method of partially enucleating the body of the uterus and the lower portion of the tumor. The large vessels of the ovarian plexus are secured on each side by two pairs of forceps or stout ligatures, the lower of each pair being placed an inch higher than the level of the proposed constriction. Then the peritoneal investment is divided all round on a level between the upper and lower forceps, and reflected downward toward the cervix and nearly to the level at which the loop of the serre-nœud is to be applied. In doing this it is necessary to seize the peritoneal edges with forceps placed at intervals of about an inch. When the reflection is completed these instruments are collected and raised up and the wire loop is applied outside of the peritoneum. Sometimes, and especially when it is desirable that the patient should not lose much blood, it is well to throw an elastic ligature around the uterus and broad ligaments as soon as the division of the peritoneum is effected. Applied in this way, it serves to draw in the broad ligaments toward the uterus and to enucleate the tumor. It is to be removed as soon as the serre-nœud is applied above or outside it, of course. In this way an inch or more in the length of the pedicle may be gained. It should be remembered, that in this method it is necessary to have the stump so long that the whole of the constricted portion must be outside the peritoneal cavity; in which position it is to be retained by the transfixing pins, which pass through the stump just outside the wire loop and rest on the parietes on each side of the wound. While the peritoneum is being reflected, the tumor should be held up by the assistant, and thus it rises gradually out of the pelvis with the uterus. One precaution to be observed very carefully in these cases, is to transfix with the pins before cutting away the tumors. He once lost a patient through the non-observance of this precaution. The last steps are to cut away the uterine tissue to within a quarter of an inch of the pins, and to trim the loose peritoneum by cutting it away to within half an inch of the loop and then stitching it from the opposite side across the surface of the stump, to hold it all well together. Before closing the wound give the screw a final turn if it will allow of it. Remember that the distal portion of the stump must slough off, that it is desirable that the amount of this tissue should be as small as possible, and that it is necessary to keep it out of the peritoneal cavity.

You may have heard great stress being laid upon the character of the mucus in the uterus and cervical canal, and you may have observed great care used in wiping it away and setting aside the sponge employed for the purpose. On operator has gone so far as to pass an iodoform pessary down the canal for the purpose of disinfecting. This is a practice with which he has no sympathy; nor is it rational or founded on any sound reasoning. He looked on it as a bugbear, and regarded it as a means of withdrawing attention from other and more important matters of detail. As to comparative results, Martin had just reported 84 cases with a mortality of 25; while Dr. Bantock was able to point to 72 cases with only 12 deaths.

There is some misapprehension of the value of terms. Some operations are termed aseptic, but the result only can prove any operation to have been aseptic. All operations are or are not performed upon an antiseptic method. Dr. Bantock has now discarded all antiseptic agents. When Listerism was first introduced, he used it in all its details, and continued to do so until he lost a patient, and had others affected by what he felt sure was carbolic poisoning. An easy and sure test for this is the absence of sulphates from the urine. In one case of carbolic poisoning the temperature rose to 107° and the patient was almost moribund; by means of wet sheets and ice-packing the temperature was brought down to normal in eight hours, and she recovered.

In one fatal case the kidneys were found congested; there had been acute suppression of urine. After this experience he gradually reduced the strength of the carbolic washing fluids to one per cent. Coincidently the proportion of sulphates in the urine increased and there was an absence of high temperature and other symptoms of hitherto unknown origin. Now as 1 to 40 is the weakest solution that can be useful as a germicide, a one per cent. solution could serve no good purpose, and the carbolic acid was omitted altogether. Afterward he tried doing without the spray, and results steadily improved. Of his last one hundred ovariotomies only three have been lost, and of the last seventy-eight only one was lost. But ovarian statistics do not apply to uterine operations.

Dr. W. H. Parish was present at the operation yesterday morning, and it was a complete illustration of what is necessary in all operations. First, in saving blood; Dr. Bantock was very careful to use hemostatic forceps to secure every bleeding point in the abdominal wound before opening the peritoneum. The same economy of blood was observable in every step of the operation. Great care was also taken to avoid shock from cooling the intestines by the contact of air and consequent evaporation. Large, flat sponges were pressed in to cover the intestines and prevent their escape or the entrance of blood or discharges into the peritoneal cavity. He is extremely careful about the cleansing of his sponges before reintroducing them into the wound. In placing sutures, he first passed several silkworm-gut stitches close to one another near the stump. After the wound was entirely closed it was covered with clean absorbent gauze—a pile of this was placed over the stump. The whole was secured with a cotton binder, using no adhesive plaster. So, while using no germicide at any time, every care was taken to make the operation an aseptic one. Would Dr. Bantock consider it safe to transfix, ligate, and drop the pedicle in case of a uterine fibroid having a thin pedicle as long as a finger? Dr. Parish had done so on one occasion and the patient died.

Dr. Bantock replied that a uterine fibroid with a finger-like pedicle, he had never seen. He has observed

bone smaller than half his wrist. He thinks the extra-peritoneal method safer in every case.

Dr. Longaker made some remarks about securing the peritoneum over the base of the stump, and asked what kind of suture Dr. Bantock preferred for that purpose.

Dr. Bantock said that any kind of suture would do, it was merely to secure a neat stump that would not spread out over the wound. He prefers fine silkworm-gut for sutures. He introduces his needle from within, close to the edge of the peritoneum, and makes sure of a hold in muscle or aponeurosis, and then through the subcutaneous fat and skin to secure a firm hold and prevent future hernia.

Stated Meeting, October 6, 1887.

The President, Thomas M. Drysdale, M.D., in the Chair.

Dr. M. Price reported a case of

ADHERENT INTESTINES FROM PERITONITIS, SIMULATING FIBROID TUMOR.

Mary J., colored, aged seventeen years, received a kick in the belly from a horse, about eighteen months ago. She was confined to her bed for a number of weeks, and was a confirmed invalid up to the time of operation, suffering great pain in the lower part of the abdomen, the region of the injury. She was unable to work or do anything toward her own maintenance. Upon examination, a hard mass was found high up and to the right of the uterus. Owing to her condition and the repeated efforts for her relief, it was decided to open her and see if the offending cause could be removed. This was done June 17, 1887. Drs. C. Penrose and J. Price, assisting, and Dr. W. Welsh present. The bowels were found completely matted together with an ill defined mass at the right side. Nothing was found that could be removed. The omentum could not be found. Dr. J. Price suggested the separation of all the old adhesions of the bowels, peritoneum, and mesentery. These adhesions involved the entire length of the small intestine; binding the folds of the mesentery and knuckles of intestine in one solid mass. The adhesions were of such strength that many of them had to be cut through with scissors. The scissors, hand, and sponge were the instruments used in the separation of the adhesions. This method was followed until every knuckle of intestine and fold of peritoneum and omentum was separated. The bowel was almost completely occluded by the bands. Irrigation with distilled water at a temperature of 110° completed the operation. After this operation was finished, the indurated mass could not be found. She reacted well, and was freely purged with epsom salts. She made an uninterrupted recovery, and said she had less pain the day after operation than at any time after the kick.

She is now perfectly well and able to be about her work. As a distinct surgical procedure, Dr. Price knows of no similar case on record. He opened a man a year ago for great pain in the region of the gall-bladder, and tore loose the adherent viscera from the abdominal wall so as to complete his examination, but finding nothing wrong, closed up the incision; the pain was cured! but this operation was not performed with the same object in view as in the first case. Dr. Duncan in his book on *Diseases of Women*, page 49, gives a case in point. "I remember a case diagnosed as a fibrous tumor of the uterus, a hard rounded mass as big as a child's head, above the brim of the pelvis, very slightly tender, and fixing the uterus. The young lady died, and at the post-mortem examination it was found that there was no fibrous tumor at all. It was adhesive perimetritis, a pocket of coherent intestines, which formed a hard mass and had led to the deception of eminent and experienced gynecologists."

SPINDLE-CELLED SARCOMA OF THE OVARY.

Dr. M. Price also reported the case of Mrs. M., aged forty-four years. Married twenty years, sterile; always regular; had always enjoyed good health up to January 1, 1887, when she was greatly troubled with inability to hold her water and with constant pelvic pain, with a feeling of fulness, and an entire suppression of the menstrual flow, which had been regular up to that date. The incontinence of urine was relieved about the middle of February by the escape of the tumor into the abdominal cavity. The tumor grew rapidly, and when it had reached some two inches above the umbilicus, the patient thought she might be pregnant, and sought advice as to her condition. Upon examination I found the uterus small, the left ovary and tube healthy and posterior to the tumor. The right ovary could not be found, but in its position the pedicle of the tumor could be mapped out. The removal of the tumor was advised. Operation June 11, 1887, with assistance of Drs. J. Price, Burns, and Penrose. A spindle-celled sarcoma of the ovary, weighing five pounds, was removed. The patient reacted well. On the evening of the second day there was a slight rise of temperature and quickening of the pulse. Fearing peritonitis, I ordered a tablespoonful of epsom salts every two hours until the bowels were freely moved. Six doses were given; the next day the pains had disappeared and temperature and pulse were normal. She has made a perfect recovery.

Dr. Drysdale remarked that the successful result of the operation in this case was a proof of its justifiability, but he thought that, generally speaking, it would be of doubtful advantage to perform abdominal section for the relief of the consequences of peritonitis, as adhesions would be likely to reform immediately after the operation.

Dr. Price explained that the active movements excited by the epsom salts prevented new adhesions from forming. He made some remarks on ovarian tumors, and stated that although seeming to be of fibroid character and called fibroid at time of removal, microscopic examination had, in his experience, uniformly shown them to be spindle-celled sarcomata.

Dr. Parish remarked that it is always allowable to break up inflammatory adhesions in abdominal operations. The new adhesions formed are not firm.

Dr. H. A. Kelly said that a year ago he had examined a small tumor, about the size of a pea, distinctly arising from the ovary, and found it to be a fibroid; it was quite hard. He had, three months ago, removed from a girl of eleven years, a large sarcoma of the ovary; she recovered. The intestines might be bound together into a mass by plastic lymph, and if there was no unnatural position of any portion, no kink nor strangulation, no symptoms would be developed. The patient would feel no pain and would be conscious of nothing

wrong. In an operation all bands and local adhesions should be broken up and kinks or knuckles should be liberated.

Dr. J. Price said that trouble will sometimes follow breaking up of old adhesions in the removal of cystomata, local pain and alarming local and general symptoms. He thinks the matting together of the intestines resulting from general peritonitis a cause of death in some few cases, and could be averted by prompt surgical interference. He described a case which he had seen recently as consultant, and in which he advised immediate operation. The attending physician would not consent until he thought his patient dying from peritonitis. The abdomen was now opened and the pus and lymph removed by irrigation and sponging; all adhesions were freed, and the patient commenced to improve immediately and is to-day a well woman. The operation was the only way in which her life could be saved. In his brother's case the intestines were freed by free dissection, pressure was applied afterward to hold the intestines back in the loins and keep them immobilized. The hemorrhage during these operations was very slight. Dr. J. Hoffmann had, in a recent operation in which Dr. Price assisted him, found fourteen inches of the large intestine adherent in an operation for the relief of an umbilical hernia, requiring a long and masterly dissection. If such adhesions are not liberated, the operation of dividing the stricture and simply liberating the strangulated portion may be a failure in saving life. Here, again, Mr. Tait, in his deep surgical wisdom recognizes the importance of opening the abdomen for strangulated hernia in the median line, that inflammatory adhesions and strictures may be liberated in the most scientific manner. Adhesions in pelvic inflammations are very common, and in operations they should always be released. Hard bodies are frequently discovered in the tube and ovaries. Their appearance suggests fibroid growths, but they are In reality sarcomatous. The round ligaments alone do not seem liable to disease.

Dr. Montgomery was very much interested in the subject of this paper. The method of first breaking up the adhesions and then preventing their reproduction by peristaltic motion excited by saline purgatives is similar in principle to the treatment of ankylosis in joints; breaking up adhesions and passive motion subsequently. Doubtless all present can bear witness to the beneficial action of saline laxatives in dysentery and other inflammatory intestinal affections. He had recently assisted Dr. Warder in the removal of an abdominal growth. The diagnosis had been uterine fibroid, but when the abdomen was opened the tumor was found to be of ovarian origin. It was very large and hard. Dr. Daland had made an examination of it and reported it to be fibroid in character. There was considerable ascitic fluid.

Dr. Longaker made some remarks on the clinical history of adhesions. Some months ago, the specimens from a case of obstruction of the bowels ending in death were shown by him at the Pathological Society, This was a case of encysted, retro-uterine hæmatocele, the appendages on both sides being involved in the mass of adhesions, from which mass there passed a band to the lower portion of the descending colon about nine inches above the sigmoid flexure, where it was so attached as to form an acute flexure. At this point the bowel was in a gangrenous state and the colon above was greatly distended while the portion below the obstruction had a lumen just admitting the passage of the little finger. The patient manifested no symptom of difficulty until four or five days after labor, when some nausea and vomiting occurred, The points of interest are, that while the autopsy demonstrated the feasibility of an operation, the symptoms were at no time sufficiently definite to warrant a diagnosis. The patient must have had the trouble a long time without it giving rise to any but vague and indefinite symptoms. As involution of the uterus took place this knuckle of bowel was slowly dragged down into the pelvis.

Dr. M. Price, in closing, said that the appearance of his first described patient was remarkable. The long-continued suffering from peritonitis had so wasted her that she looked as if she had passed through a wringing-machine; her chest and belly were flattened out. If no symptoms resulted from the adhesions, there would be no call to operate for their relief. But in all cases the intestines have sharp bends and curves, and form knuckles, which are caught under lymph bands, which tie the intestines together and contract them, and sooner or later symptoms of obstruction must be developed. He does not believe in antiseptic surgery as applied to the abdomen and the peritoneum. If he did believe in microbes, tadpoles, and the other insects so much talked about, he would be afraid to operate, for their presence, if all that is said about them were true, would do more harm than the peritonitis, and more than the operation would do good.

Dr. H. A. Kelly considered this a most important subject, and one on which we are greatly in need of enlightenment. His own experience had taught him several interesting facts in regard to peritoneal adhesions. Bands of adhesion, or the adhesion of a small area of intestine in such a way as to make it liable to kink, doubling it sharply on itself, are exceedingly dangerous, and should never be allowed to remain. But there is a class of adhesions by no means dangerous, not productive of symptoms, and which should not be interfered with. We must bear in mind that the adhesion of opposing serous surfaces is a conservative process preventing the continuous pouring out of effusion, and, in event of tuberculous peritonitis, probably starving out the disease by taking away its pabulum. The least dangerous variety of adhesion is the general adhesion of the gut *in situ*. He operated two years ago on a case in which all the intestine adhered, looking like one great bag when the peritoneum was opened. It was a case of tubercular peritonitis tending to a cure in this way. He simply dried out the peritoneum, and besprinkled it with iodoform to check secretion, and the patient, who has been constantly under his eye ever since, has not had any trouble from her adhesions. Also those cases of adhesions of lesser intestines in the pelvis, in which they lie adherent in normal relative position, in full round curves without kink, do not, so far as he has been able to observe in a large number of cases, ever do harm.

Dr. H. A. Kelly read a paper on

PALPATION AND SOUNDING OF THE FEMALE URETERS,

in which he stated that he made it his routine practice

to examine all gynecological cases with reference to the condition of the ureters. Since Dr. Sänger had demonstrated to him, in the summer of 1886, the facility with which both ureters could be outlined through the antero-vaginal wall, and traced back to the posterior pelvic wall, he had made a long series of confirmatory observations, and, in some instances, demonstrated the value of such observation by finding disease of the ureter. He had added to this a method of his own, by which the ureter is picked up and handled bimanually, and with the exact knowledge thus gained as to its position, he then proceeds to catheterize it with Pawlik's catheter. He detailed a case in which the catheter was thus introduced free-hand into the ureter, and passed back to the posterior pelvic wall. The urine escaped in little gushes of from ten to fifteen drops every ten or fifteen seconds, evidently accumulating beyond the catheter until the pressure became sufficient to dilate the ureter and let the urine pass down into the eye of the instrument. About three drachms of urine were drawn in this way, and, on removing the catheter, about five ounces of urine were drawn from the bladder. A disadvantage of Pawlik's catheter is that the sharp eye sometimes catches the mucous membrane of the ureter.

Dr. Kelly showed some sounds which he had had constructed some time since, when studying the subject, but considered them inferior to Pawlik's instrument. The value of knowledge which may be thus gained was illustrated by reference to a recent case of severe operation, removing adherent, pus-containing ovaries and tubes. On the second day urine appeared in the tube, and flowed freely. The only way of determining from which kidney this flow came was by catheterization of the ureter.

Dr. Charles M. Wilson thought that such an instrument used in cases with a history of pyelitis might be the cause of serious trouble. He has tried in a number of cases to palpate the ureters by Dr. Kelly's method; in a few elderly women he has succeeded, but in nulliparæ with firm tissues he could not distinguish the ureters.

Dr. J. Price considered these methods of examining the ureters of but little practical use, for trouble does not exist in the ureters alone, but in all the pelvic organs and kidneys and when these are distorted by new growths and inflammatory products it would be very difficult to locate the ureters. The case cited by Dr. Kelly in his own experience shows how difficult it is even with the fingers in the pelvis while removing diseased appendages, to locate the ureters through one layer of peritoneum, to say nothing of the conditions when we have to deal with inflamed and thickened vaginal walls.

Dr. Montgomery thought it would require extreme skill to pass such fine instruments without doing injury to the mucous membrane. Dr. Bowman, in a paper read before the Ninth International Medical Congress recommended dilatation of the ureters and washing out of the pelves of the kidneys and ureters in pyelitis; even advising splitting of the bladder through the vagina in order to reach the orifices of the ureters.

Dr. Walker was very much interested in this subject and has been desirous of accomplishing this procedure in some patients that he had in his care in the Philadelphia Hospital. He had succeeded in palpating the ureters in males but not in females. This ability to pass a catheter into the ureter will enable the surgeon to determine in any given case which kidney is diseased.

Dr. Kelly, in closing, said that there is no danger in the exploration; the instrument must be lightly poised between thumb and forefinger and gently passed in, or not at all. The sensation when the end of the catheter is caught by the ureter and it begins to pass up the tube is characteristic. Dr. Walker is certainly correct in his high estimate of the great value of the possibility of sounding the ureters free-hand in certain puzzling renal cases. As to Dr. Price's remark, cases in which there is much pelvic cellulitis are not those in which we desire to sound the ureters. Ureteritis is a distinct, well defined disease. He treated one case which he cured by opening the base of the bladder. The whole trouble lay in the extremities of the ureters. The first to suggest splitting the vesico-vaginal septum and rolling the ureteral orifices and thus under guidance of the eye catheterizing them, was Dr. Emmet. Pawlik's work was but the culmination of a vast number of attempts to accomplish this, from Suchmanns, who attempted to clamp the orifices of the ureters, and Silbermann, who tried to choke them by a bag of quicksilver, and Simon's dilatation of the urethra, and Neumann and Grünfeld, who tried to reach it by endoscopic methods. Sänger showed how readily the ureters can be palpated, and Dr. Kelly thinks that by combining a careful palpation according to his own method and following this with catheterization of the ureters already so distinctly located, he has added a method of real value, simplifying this free-hand difficult subject. Great skill is not required thus to palpate the ureters.

Dr. Hirst reported a case of

TYPHOID FEVER IN A PREGNANT WOMAN.

The impression still prevails in some quarters among general practitioners, that typhoid fever will not attack a pregnant woman; an idea originating doubtless in the teaching of the famous Rokitansky, who believed that the condition of pregnancy granted a woman immunity from this disease. It is unnecessary, of course, to point out the fallacy of this opinion or to refer to the statistics of 322 cases of typhoid fever during pregnancy collected by Charpentier. The case now reported occurred in a young primigravida, who was admitted to the Philadelphia Hospital in the second week of the attack. The disease presented all the characteristic symptoms in a typical manner, leaving no doubt as to the diagnosis. On the tenth day after her admission she gave birth to a child which corresponded in its development to the seventh month of intrauterine life. The infant died two weeks after birth, but, unfortunately, the cause of death was not ascertained. One interesting feature in this case was the effect of labor upon the temperature. As uterine contractions began the woman's temperature was 104.2°, but it steadily lowered as labor advanced, until directly after the expulsion of the child it was only 95°. Under the influence of external heat and stimulants hypodermatically, the patient reacted and made a good recovery.

Dr. Longaker remarked that his experience taught him that high temperature in typhoid fever in the pregnant woman was incompatible with fetal life. He had

been recently associated with such a case which ended fatally.

Dr. Charles M. Wilson had under his care a pregnant woman with typhoid fever in whom the temperature rose as high as 106° and was not reducible for several hours, but the child survived and was delivered alive at term. Numerous similar cases are on record, so a temperature as high as 106° is not necessarily fatal to fœtal life.

Dr. Montgomery remarked that in the majority of cases maternal typhoid fever is fatal to fœtal life. Premature labor has occurred in all such cases that have come under his notice. In one such case the temperature rose to 105°; miscarriage occurred, and was followed by a fall of temperature to 97° with collapse, from which it was very difficult to restore her. The temperature again rose to 105°, and after a protracted illness the patient recovered.

Dr. W. S. Stewart remarked that in one case of typhoid fever, about the sixth month of pregnancy, in which the patient became emaciated to a remarkable degree, she recovered and was delivered of a living child at term. The temperature did not rise very high.

Dr. J. C. Da Costa stated that these cases do not all abort or die. He recalled one case in particular, with a temperature of 105½°, with characteristic typhoid eruption and intestinal hemorrhage; four stools containing, each, from one to two pints of blood having been passed, which went on to full term, twins being delivered alive.

Dr. Hirst, in closing, stated that although the temperature of his patient remained at 95° for over twelve hours, despite all that could be done to raise it, she did not appear in collapse, but looked and felt quite comfortable. The prevalent idea as to the danger to the fœtus of high temperature in the mother, would appear to be erroneous. Runge's well-known experiments are often quoted to support the view that the fœtus is in danger if the mother's temperature reaches 104°; but Doléris, in 1883, showed that if the maternal temperature is gradually and not quickly raised, the fœtus remains unaffected. Runge, in a second set of experiments, found that Doléris's conclusions were correct. Preyer, on one occasion, actually found a temperature of 110° in the anus of a living fetus.

Dr. Parish considered that the high temperature in disease was accompanied by blood changes which contributed to the fatal result.

Dr. J. M. Baldy read a paper on the administration of

SALINES IN PERITONITIS FOLLOWING ABDOMINAL SECTION.

Twenty-five per cent. of the deaths following abdominal section are attributable to peritonitis (Agnew). Taking the hint from Mr. Tait, he never takes any steps to prevent a movement of the bowels after operation, and routinely administers salines on the second or third day, repeated in small doses, especially when there are distention and persistent bilious vomiting. The results following this course have been most satisfactory. He had used salines in large concentrated doses (one ounce), repeated several times and aided by large (two quarts) turpentine enemata in fully developed peritonitis, with best results. The symptoms begin to subside almost immediately when the bowels commence to discharge watery stools. The treatment is in every way preferable to the use of opium, and is logically infinitely better than the narcotic. Opium only does good by relieving pain, at times, in enormous doses. The bowels are already "in splints" from the disease and do not need the aid of the drug for that purpose. Opium, however, does a world of harm. It helps keep the bowels in splints and so favors the formation of those great masses of adherent intestine and organized bands which we find so often the cause of subsequent intestinal obstruction. Still worse, it closes all the avenues of escape for the poisonous products of inflammation found in this great lymph sac, and in this manner keeps up the inflammation much more surely than the rubbing together of the peritoneal surfaces will. With salines, however, an active peristaltic movement is kept up, which tends to prevent the formation of adhesions and bands. They drain the abdominal cavity of the products of inflammation, and by depleting the blood-vessels of the intestines and peritoneum tend to prevent the throwing out and organizing of lymph to any great extent. There are, of course, dangers in the production of large, watery stools, but the treatment must be used with care and judgment. He would suggest that in the after-treatment of abdominal section the bowels be moved as a matter of routine on the second or third day after operation. That on the first access of pain and soreness with distention, a brisk purgative be given at once. In case a general peritonitis is developed, the production of large watery stools should be secured as quickly as possible, by purgation and stimulant enemata; the amount of purgation to be controlled in accordance with the strength of the patient. The salines, as suggested originally by Mr. Tait, are perhaps the best of the purgatives for the purpose.

Dr. Watson remarked that Mr. Tait had been led to the use of salines because he had always observed bloody serum in the peritoneal cavity after death from peritonitis. Dr. Watson has been in the habit of using saline laxatives whenever he has found signs of beginning peritonitis after labor. Once after ovariotomy, and again after a very difficult labor he found their use of very decided benefit in cutting short threatened attacks of peritonitis; both cases had made good recoveries.

Dr. Longaker remarked that Dr. Bantock, while in this country recently, expressed entire want of faith in any benefit to be gained from the use of salines in peritonitis.

Dr. Parish explained that peritonitis as seen by Dr. Bantock was always of septic origin, and the patients would die under any treatment. That form of peritonitis is preventible. The saline treatment is quite reasonable; it is an adaptation of an old method of treating dysentery and inflammatory diseases of the intestines.

Dr. Walker had employed salines as depleting agents in various inflammatory diseases. When the depletory action is desired, concentrated solutions should be administered. A weak solution will act simply as a laxative.

Dr. Cleemann had had success and failure with both the opium and saline methods of treating peritonitis. Salines had been recommended years ago by Dr. Meigs in the treatment of peritonitis. Several suc-

cessive attacks of typhlitis in one patient had been subdued under the use of opium. A case of peritonitis under his care had shown progressive relief after every movement of the bowels, the result of a dose of castor oil. As the opium treatment has been adopted by the majority of physicians, it is presumably the best.

Dr. Kelly believed that serious consequences will often be avoided by a timely free depletory purgation. He had used calomel and soda, but now considered salines better. All peritonitis is not, however, as the speaker would urge, to be so treated. There is a dry form, which he has verified by post-mortem examination, which corresponds to the friction dry stage of pleurisy, which is better treated by opium. We must bear in mind that the depletion of the intestinal villi only quickens the absorptive activity of the peritoneum, and a large accumulation within the peritoneum may really be too great to be thus disposed of. Here the drainage tube saves lives by disposing of the excessive and often unavoidable serous weeping from wounded peritoneal surfaces. He calls this his *fifth emunctory*, and it is better than all the natural emunctories in these cases, when properly handled, disposing of accumulations at once, without in the least taxing the powers of the patient. Next to the drainage tube, the best emunctory is that nearest the field of activity, the intestinal tract, and, next, but much inferior to this, come the kidneys, then the skin, and, lastly, the lungs.

Dr. Montgomery resorts to closely restricted food and drink and the administration of concentrated doses of salines in commencing or threatened peritonitis. He adopted this method recently in a case of peritonitis consequent on the presence of a malignant tumor which could not be removed. He did not use a drainage tube, but kept the patient on restricted diet and drink, applied a light bandage, and administered salines.

Dr. J. Price thought the preparatory treatment of paramount importance in abdominal surgery. After an operation opium is simply harmful, while salines are soothing to the patient and prevent flatulent distention. Upon the slightest indication of peritonitis, use them freely and it is simply wonderful what rapid disposition is made of the thirty-seven varieties, according to Sternberg, of rhizopods and boa-constrictors. Again the drainage tube is of the greatest importance in preventing peritonitis. It usually does its work, if managed well, in the first twelve or twenty-four hours.

Dr. Baldy does not think there is such a thing as dry peritonitis. The idea of administering salines is to deplete, and concentrated solutions should be used. The use of opium by the majority does not prove it to be correct.

NEWS ITEMS.

The Results Accomplished by the Illinois State Board of Health.—The results of the enforcement of the New Medical Practice Act in Illinois, are as follows:

The new law has required much labor, but the result has been satisfactory. Eleven suits have been pushed to successful conclusions. The most signal benefit has been in ridding the State of the itinerant nostrum-venders, with their brass-band and other accompaniments. July 1st, twenty of these shows were in the State, which tendered $1500 per month in fees for licenses, all of which were refused.

One of the evidences of the good work of the Board is the gradually falling proportion of graduates to matriculates. It is now about 31.5. In the regular schools it has fallen to 30.33.—*Sanitary News*, October 22, 1887.

A Proposed Test for Gleditschine.—Dr. Claiborne, the introducer of this substance to the profession, proposes, in the *Medical Record* of November 5, 1887, to have its genuineness tested by a committee of two experts who are to make the preparation under direction, and then to pass judgment upon it. Drs. Shrady and Foster, of New York, have agreed to select the committee.

The Health of Prisoners.—Dr. Watkins, Inspector of the State Board of Health of Louisiana, has recently examined the prisoners in the parish prison of New Orleans. He found a number of the inmates suffering from acute dropsy of the legs, arms, face, and body, due to confinement and insufficient and unwholesome food. Each prisoner is allowed a piece of bread and a pint of tea early in the morning, and one meal consisting of soup, the beef cooked in the soup, and bread. The beef is supplied by a contractor at five cents and a half per pound, and has been repeatedly condemned by the resident surgeon.—*Science*, November 4, 1887.

Hot Water in Surgery.—Possibly our readers have seen the failure in the use of hot water as a hæmostatic which Dr. Varick describes, in the *New York Medical Journal* of October 15, 1887:

An amusing instance of failure to comprehend the principles involved in the subject under discussion occurred recently in a hospital not a thousand miles from New York. A surgeon, having occasion to perform an amputation at the lower part of the leg, and after ligating the vessels, was annoyed by a somewhat free oozing which he was unable to control. A gentleman present, who had, on several occasions witnessed the hæmostatic effect of hot water in St. Francis and Jersey City hospitals, suggested its use in this case. The hot water was brought, and cold water added until it could be easily borne by the hand, then by means of a sponge it was applied for a moment several times. This proving ineffectual, the sponge, now saturated with water scarcely more than blood-warm, was held at a distance above the wound and the water allowed to trickle over the surface. It is needless to say this also failed. The verdict of the sapient operator was that "hot water is no good."

Canned Peas and Copper.—The State Board of Health of New York has decided, after securing analyses of various samples, that the following goods are within the conditions hereinafter prescribed declared to be exempt and permitted to be sold under the provisions of the said act:

Canned peas or beans in the preparation of which copper has been used, provided that the proportion of metallic copper shall not exceed three-fourths of a grain per avoirdupois pound of peas or beans equivalent to

three grains of crystallized sulphate of copper, and that the same be plainly stated on the label.

Mutilation of Children for Debt in China.—In the report of the Customs Inspector at Shanghai a case is reported in which a young man had lost an eye by puncture for his father's debt: the physician called in attendance was successful in saving the other eye, but the injured eye was lost. The practice is said to be common in some districts of China, and the attention of the Government has been called to it.

The Death of Dr. Kraus, editor of the *Wiener medicinische Zeitung* is announced, at the age of fifty-nine.

M. Pasteur's Health is said to be still so feeble as to necessitate his confinement to the house.

An International Speech.—At the visit of the Vienna Congress of Hygiene to Buda Pesth, the speech delivered by M. Sasvári was the most striking illustration of internationalism. He commenced in Magyar, and, after a few complimentary words to his Hungarian colleagues, assured the Austrian and German guests—himself speaking in good German—that the Hungarians recognized how much their civilization was due to the Germanic races. Then, speaking in French, he explained that Hungary admired the great French nation, which, marching in the vanguard of progress, had given to the world the highest and most generous ideas. Now, changing from French to Italian, he spoke of the glories of ancient Rome, to be revived at no distant date. Finally, concluding in fluent English, he greeted the brave children of Great Britain, who had borne the banner of civilization to the uttermost regions of the globe. Here the speech seemed ended, but, recognizing among the delegates the dignified features and high turban of the Mahomedan Burgomaster of Serajevo, he again rose, and, in the Servian-Croatian language, hailed the presence of this Oriental functionary as typifying the union of the East and the West for the furtherance of the cause of hygiene.—*Lancet*, November 5, 1887.

Healthy and Unhealthy Occupations.—The English Registrar-General has made a comparison between healthy and unhealthy occupations. Assuming the normal average death-rate of the community as the unit of comparison, and calling it 1000, particular occupations may be regarded as healthy or unhealthy according as the death-rates among those pursuing them fall above or below that figure. The most healthy occupation appears to be that of minister of religion, whose rate is 556. Next are gardeners and nurserymen, 599; farmers and graziers, 631; agricultural laborers, 701; schoolmasters, 719; and grocers, coal-merchants, paper, lace, and hosiery manufacturers, wheelwrights, shipbuilders, and coal-miners, with all of whom the average death-rate is under 775. The most unhealthy occupations are the trades connected with the liquor-traffic and hotel-service, with which the death-rate is 2205; following these are general laborers in London, 2020; costermongers, bankers, and street-sellers, 1879; innkeepers, etc., 1521; and brewers, 1361. After the trades concerned with alcohol, the highest rates are furnished by occupations that involve the breathing of dust—other than coal-dust—and exposure to lead-poisoning. The death-rate among butchers is also high, 1170.—*Popular Science Monthly*, October, 1887.

The Food of American Workmen.—In his American Association paper on "Food of Working-men and its Relation to Work Done," Prof. L. O. Otwater said that statistics of the dietaries of considerable numbers of Americans, mostly of the working-classes, show that their food is ample in amount, and includes large proportions of meat. Chemical examinations of the dietaries showed them to be richer in active nutritive material and potential energy than even the large quantities would imply. This is because they contain so great proportions of meat and other nitrogenous and fatty substances. Comparing the standard of diet prevailing among the working-men of Massachusetts with that of Germany, it is shown that laborers in Massachusetts average just about one-half more than the German standard requires. It thus appears that the food of the American laboring-man is much more nutritious on the average than that of his European competitors. It is also shown that he turns off much more work than the European working-man. He is better paid, better housed, better clothed, and better fed than the European. He has better opportunities for self-development, more to stimulate his ambition, and more hope of reward if his work is efficient. These factors are all connected, but the explanation of his superior capacity for work is to be found largely in his superior nourishment.—*Popular Science Monthly*, October, 1887.

The Influence of the Civil War upon the Number of Insane.—Dr. Palmer states that "the late civil war, no doubt, has contributed toward increasing the number of insane, as well as modifying the type of mental disease. But few were rendered insane by the war that would not have broken down by other exciting causes. A large proportion of the soldiers that served in the war, and lived to return home, were reduced in mental and physical vigor. The disabilities thus acquired have influenced their children, imparting to them a delicacy of organization and susceptibility to external influences, often leading to mental disease. During the past few years several of these children have been admitted into institutions. Thus it will appear that the influence of a great and momentous event, acting upon the past, is made potent through laws of transmission to the present generation by producing mental and physical degeneracy."—*American Journal of Insanity*, October, 1887.

The Hygienic Value of Gas and Electricity, as Sources of Light.—The last number of the *Gesundheits Ingenieur* contains a paper by Professor Dobroslawin, of St. Petersburg, on the comparative use of gas and electricity for lighting theatres. Referring to the interesting experiments made by Professor Pettenkofer and Dr. Renk, Professor Dobroslawin, with the assistance of Drs. Kowolkowsky and Bosaroff, made, last February, during the three days' carnival at St. Petersburg, when the largest crowds fill the theatres, experiments on the temperature and ventilation of the

"Grosse" and "Alexander" theatres, lighted with gas, and the "Mariar" theatre, lighted with electricity. These three theatres gave, each, two performances daily, and each held about 1600 people. The thermometers were so placed as to be on a level with the audience. The carbonic acid was determined by the Pettenkofer method. As every theatregoer knows, the temperature falls between the acts, and it was found that the temperature in the galleries did not fall as rapidly as in the parterre. As a result, the Professor thinks that people seated in the parterre are more apt to take a cold than those in the upper parts of the house. The highest degree of temperature by electric-lighting was 25° C. (77° F.), and with gas 33° C. (91.4 F°.) The Professor does not think that the difference of air is noticeable with either kind of lighting. Finally, the Professor concludes that electricity is far superior to gas from the standpoint of health.—*Sanitary Engineer*, November 5, 1887.

THE ANALYSIS OF A "CURE FOR CANCER."—Pharmacist MOERK reports, in the *American Journal of Pharmacy* for November, 1887, his analysis of a "specific" for cancer, which has been extensively used by the inhabitants of Pennsylvania and New Jersey. It is purported to consist largely of "horse-sorrel."

The result of the analysis is that the powder contains

Moisture	0.69
Charcoal	36.82
Carbonate	26.07
Extractive	6.40
Ash	4.35
Arsenious oxide	25.67
	100.00

The editor states that it is probable that the powder is made by mixing two parts of arsenious acid with one part of wood charcoal, and that the deviation from this proportion is simply the result of the difference in the specific gravity of the two ingredients favoring a partial separation of the heavy arsenic. This proportion gives arsenic far in excess of that contained in the arsenical powders of Swediaur, Cosme, Dupuytren, Pluckett, and others.

DRINK LEGISLATION IN AUSTRIA.—The Austrian Government have, it is stated, introduced into the Reichsrath a strong measure for the prevention of drunkenness. The reason alleged is the alarming deterioration in the physique of young men enrolled for military service, owing to the spread of spirit drinking amongst the humbler classes. It will be interesting to see if the provisions of this measure are accepted. They would be difficult to carry out in this country, where freedom even to get drunk is still jealously guarded. Spirit shops are to be closed at five on Saturday afternoon, and to remain so till five on Monday morning. Ordinary storekeepers are not to be allowed to sell spirits, the sale of which is to be restricted to public houses, confectioners, and specially licensed stores. Dealers serving spirits to intoxicated persons are to be liable to arrest or fine. No debt for spirits consumed on the premises can be recovered by law if the amount exceeds the value of five quarts. The magistrates are empowered to forbid retailers to serve spirits to habitual drunkards for any period up to twelve months. Similar legislation already exists in Galicia. The proposal now is to extend it to all Austria. The preamble of the measure sets forth that it is a direct outcome of the Hygienic Congress.—*Lancet*, November 5, 1887.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U.S. ARMY, FROM NOVEMBER 8 TO NOVEMBER 14, 1887.

GREENLEAF, CHARLES R., *Major and Surgeon*.—Par. 8, *S. O. 218, A. G. O.*, October 25, 1887, directing Surgeon Greenleaf to visit the recruiting depots and rendezvous at certain places, is amended to include Davenport, Iowa; Quincy, Ill.; and Evansville, Ind.—*S. O. 257, A. G. O.*, November 4, 1887.

LORING, LEONARD Y., *Captain and Assistant Surgeon*.—Ordered for duty at Fort Mojave, Arizona Territory, upon the expiration of his present sick leave of absence.—*S. O. 258, A. G. O.*, November 5, 1887.

BYRNE, CHARLES B., *Captain and Assistant Surgeon*.—Relieved from temporary duty at Fort McHenry, Maryland, and will return to his proper station, Washington Barracks, District of Columbia.—*S. O. 242, Division of the Atlantic*, November 11, 1887.

PETTEY, HARRY O., *Captain and Assistant Surgeon*.—Now on duty at Fort Wayne, Michigan, ordered for temporary duty with troops stationed at Highwood, near Chicago, Illinois.—*S. O. 258, A. G. O.*, November 5, 1887.

IVES, F. J., *First Lieutenant and Assistant Surgeon*.—Granted leave of absence for one month, to take effect on or about the 15th instant.—*S. O. 113, Department of the Platte*, November 5, 1887.

WALKER, F. V., *First Lieutenant and Assistant Surgeon*.—Relieved from duty at Post of San Antonio, and assigned to duty at Fort Ringgold, Texas.—*Department of Texas*, November 8, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 12, 1887.

HEATH, J. C., *Surgeon*.—Detached from the "Marion," proceed home, and wait orders.

CRAIG, J. C., *Passed Assistant Surgeon*.—Detached from the "Marion," proceed home, and wait orders.

WELLS, H. M., *Medical Inspector*.—Detached from the "Trenton," proceed home, and wait orders.

PECK, GEORGE J., *Medical Director*.—Ordered to Washington, D. C., as a member of the Examining Board.

AYRES, JOSEPH G., *Surgeon*.—Ordered to the "Galena," to relieve Surgeon F. L. DuBois.

DUBOIS, F. L., *Surgeon*.—Detached from the "Galena," proceed home, and wait orders.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, FOR THE TWO WEEKS ENDING NOVEMBER 12, 1887.

WYMAN, WALTER, *Surgeon*.—To proceed to Louisville, Ky., and Memphis, Tenn., as inspector, November 2, 1887.

URQUHART, F. W., *Passed Assistant Surgeon*.—Relieved from duty at Cape Charles Quarantine; ordered to Norfolk, Virginia, November 9, 1887.

MACKNIGHT, G. M., *Assistant Surgeon*.—When relieved, to report station at Chicago, Illinois, November 3, 1887.

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

ORIGINAL ARTICLES.

AN ANALYSIS OF TWO HUNDRED AND SEVEN CASES OF CARCINOMA OF THE BREAST.

BY SAMUEL W. GROSS, M.D., LL.D.,

PROFESSOR OF THE PRINCIPLES OF SURGERY AND CLINICAL SURGERY IN THE JEFFERSON MEDICAL COLLEGE OF PHILADELPHIA.

UP to May of the present year, I had seen in private or in hospital practice, or in consultation, and kept a record of, 14 cysts and 251 neoplasms of the female breast. Of the cysts, 10 were retention cysts—6 having been evolution and 4 involution cysts, while of the new growths, 207 were carcinomata. 19 sarcomata, 24 fibromata, and 1 was an adenoma. Hence, 82.47 per cent. of the neoplasms were carcinomatous, a proportion which closely corresponds with the records of other surgeons. Thus, of 481 tumors observed by Bryant,[1] 400, or 83.16 per cent., were carcinomatous, while of 440 from the practice of Billroth,[2] 375, or 85 per cent., were of the same nature. The object of the present communication is to present a succinct analysis of my notes of the carcinomatous growths, with the hope of throwing additional light upon their life history and proper treatment.

I have met with the disease as early as the twenty-fifth, and as late as the seventy-second year, the average being 47.6 years. Of the 207 cases,

6	first appeared between		20	and	29	years	of	age.
39	"	"	30	"	39	"	"	
78	"	"	40	"	49	"	"	
62	"	"	50	"	59	"	"	
21	"	"	60	"	69	"	"	
1	"	"	70	"	79	"	"	

Of the entire number, not one was observed during the developmental state of the mamma; 45, or 21.73 per cent., appeared during the period of its greatest activity; and 162, or 78.26 per cent., began during its functional decline.

121 women, or 58.45 per cent., were menstruating at the date of the development of the disease, and only 8.21 per cent. of the entire number had been irregular in the performance of that function.

Of 197 women in whom the social condition is noted, 175, or 88.83 per cent., were or had been married, and 22, or 11.17 per cent., were single. Of 154 in whom it is mentioned, 133, or 86.36 per cent., had borne children, and of these, rather more than nine-tenths were prolific and had nursed their children; while 21, or 13.64 per cent., were sterile. In only one did the tumor appear during pregnancy, and in none during lactation. The general health of the patients when they first came under observation was excellent in 69.56 per cent., indifferent in 17.39 per cent., and bad in 13.04 per cent., so that less than one-third were injuriously influenced by the progress of the affection. In only 10, or 4.83 per cent., was it inherited in the direct line of descent—that is to say, from parents, grandparents, or great-grandparents.

The disease was ascribable to traumatism in 20, or 9.66 per cent. of the 207 cases; but in only 9 of these did the tumor develop within six months. Of the 133 parous women, 11, or 8.27 per cent., had suffered from puerperal mastitis, but in only 2 was it clear that the tumor started from the lump or induration left by the inflammation. In 5 cases, or 2.41 per cent., there was antecedent nonpuerperal mastitis, and in 4 of these the disease developed at the site of the inflammation. In 5 cases, or 2.41 per cent., the nipples had been the seat of crusts and scales for several years—in one case for thirty-two years—before the appearance of the tumor. In 6 cases, or 2.9 per cent., it began as Paget's disease of the nipple, or as malignant papillary dermatitis.

In reviewing the foregoing facts, it is evident that my personal experience throws little light upon the causation of carcinoma, although it differs in several important points from views which have been engrafted upon, and are still held by the profession. The general nutrition of the patients was not nearly so bad as many teachers would lead us to believe, since more than two-thirds of my patients enjoyed capital health, and their appearance did not denote that they were suffering from so grave a malady. The inheritance of the disease, which is believed to be so common, not only by the laity but by medical men, is not supported by my figures. I do not mean by inheritance a family history of cancer among relatives of carcinomatous subjects, as aunts, uncles, cousins, brothers, and sisters, but an undoubted history of transmission by direct descent, that is, from parents, grandparents, or greatgrandparents. In studying the subject of cysts of the breast, I find that in not less than 5, or 7 per cent. of 70 subjects of retention cysts, there was a clear history of carcinoma in the ancestors, the mothers of two and the grandmothers of two having died of carcinoma of the breast, and the grandmother of the fifth having perished from carcinoma of the uterus. These interesting facts merely indicate to my mind that a peculiarity of structure is transmitted, through which, in the one case, the contracting fibrous stroma of the breast irritates the glandular elements, and incites an atypical growth of the epithelium, thereby giving rise to carcinoma, while in the second case the contracting fibrous tissue constricts some of the ducts, through which cysts develop. The influence of puerperal mastitis, upon which much stress has been laid, was not marked, when it is considered that in less than one per cent. was it demonstrable that

[1] Practice of Surgery, 4th Amer. ed., pp. 769 and 773.

[2] Die Krankheiten der Brustdrüsen, p. 134.

the tumor appeared at the site of the inflammation, so that if it were a factor at all, it was less efficient than was nonpuerperal mastitis. Scaly nipples, by obstructing the mouths of the ducts, may be precursors, but the evidence on this point is too limited to be of any value. Paget's disease should not be included among the causes, since histological investigations show that it is a malignant inflammation of the skin of the nipple and areola secondary to carcinoma of the orifices of the milk ducts, so that carcinoma is actually present, although in an unusual situation. Traumatism appears to be the most common of all the efficient causes, and I presume that no one will deny that it does provoke an atypical growth of epithelium in involuting breasts which results in carcinoma. There certainly can be no connection between the social condition of the patients and childbearing, since the proportion existing between married and single women, and between parous and sterile women suffering from the disease is about the same as in health. From these statements I believe that age, which simply denotes senility of the tissues of the breast, is the only factor which predisposes to the occurrence of carcinoma; that injury is the only proven existing cause; and that hereditary transmission tends to perpetuate the disease.

With the exception of 5 cases in which several tumors existed in one breast, the disease began as a solitary growth, in the right breast in 101, and in the left in 106. It was seated in

The upper hemisphere in	. . .	4 cases.
" lower "	" . .	7 "
" outer "	" . .	8 "
" inner "	" . .	6 "
The upper and outer quadrant in	. .	66 cases.
" " " inner	" " .	19 "
" lower " outer	" . .	10 "
" " " inner	" " .	12 "
The vicinity of the nipple and areola in		75 "

Hence, the seats of election were the upper and outer portions of the gland, and the immediate vicinity of the areola and nipple.

In one case a scirrhous carcinoma occupied one breast, and a fibroma its fellow, while in a second case the right breast was the seat of three fibromata, and the left contained three fibromata and a scirrhous carcinoma.

The nipple was retracted in 108, or 52.17 per cent. of the entire number, the large proportion being due to the fact that in 75 the tumor was seated near the nipple and areola. In 15, or 7.24 per cent., there was a spontaneous discharge from the nipple, the fluid being, as a rule, either watery and bloody, or thick and lactescent; while in two additional cases a milky fluid—the so-called cancer-juice—could be expressed. In one-third of the cases the discharge preceded the detection of the tumor.

In eight-tenths of the cases, pain of a sharp, intermittent character was experienced; in about 15 per cent. there was merely a sensation of discomfort; while in about 5 per cent. there was no suffering whatever. In exceptional instances it was the first symptom that attracted attention.

Invasion of the skin, the earliest sign of regional infection, was met in 155, or 74.87 per cent. of the 207 cases. The cutaneous invasion was characterized by discoloration or adhesion in 78, or 37.68 per cent.; by the formation of tubers or nodules in 33, or 15.94 per cent.; and by ulceration in 44, or 21.25 per cent. In only one case did the tubers occupy the entire surface of the chest, and undergo atrophic changes, thereby constituting the affection known as *cancer en cuirasse*. In four of the cases the lymphatic vessels of the skin constituted elevated, convex ridges, as large as crows' quills, but in three of these they were filled with lymph-cells, and in only one were they plugged with polymorphous epithelial cells.

Infection of the skin was met with as early as two weeks, and as late as twenty-nine months, the average having been 12.6 months. Adhesion occurred, on an average, in 9.5 months; discoloration in 10.1 months; nodules in 12.3 months; and ulceration in 15.8 months.

Immobility of the breast on the chest, or invasion of the pectoral fascia or muscle, was witnessed in 31, or in 15 per cent. of the cases. It occurred as early as the second, and as late as the twenty-seventh month, the average having been 16.9 months. Distinct nodules were also found in 20.93 per cent. of my operations in the pectoralis major muscle, and in one case in the pectoralis minor muscle, and in the periosteum of the sixth rib.

The opposite breast was invaded in 8, or 3.86 per cent. of all cases, the original seat of the disease having been the right mamma in 6. It was a late sign, appearing, on an average, at 21.5 months, although it was witnessed as early as five, and as late as fifty-eight months. In all of these cases it was preceded by invasion of the skin and glands associated with the first growth, and in two of these ulceration was present. Although I have included implication of the opposite breast among the signs of local extension of the disease, it is probable that in most of the examples it was an independent outbreak.

Infection of the axillary lymphatic glands was detected in 136, or 65.70 per cent. of all cases; and along with these the supraclavicular glands were involved in 15, the subclavicular in 3, and the cervical in 2. This statement does not, however, indicate the real frequency of glandular invasion, since, in my late operations, in which I always clear out the axilla, I have found that these bodies were carcinomatous in 95.35 per cent. of all instances, and Kuester[1] states that, of 117 similar operations, in only 2 was there no axillary disease. I have witnessed glandular involvement as early as three weeks, and as late as twenty-nine months, but the average date of its detection was 13.2 months. In two of my cases it was discovered by the patients before the tumor was perceived.

My opportunity for making post-mortem examinations of women dead of carcinoma have been so few that they are not of much value. In six autopsies of subjects in whom the disease had pursued a natural course, metastatic deposits were found in all.

[1] Deutsche med. Wochenschrift, 1883, No. 17, p. 258.

One was a case of atrophying scirrhus that had lasted for seventeen years and seven months. The remaining five died at periods varying from twenty months to five years and two months, the average date of death having been thirty-seven months and twenty-four days.

Of my first 100 cases, the subsequent histories are unfortunately most imperfect. Of these I can only say that 7 ran a natural course, and that their average life was 33.6 months, and metastases were discovered in the 3 cases which were inspected post-mortem; and that 55 were subjected to operation, of which 1 died; there was no recurrence in 1 in two years; 2 died with recurrence, their average life having been 44.6 months, and 9 recurred, on an average in 7 months, but their further history could not be traced. Hence, 91.75 per cent. of the cases were marked by local reproduction, and I was unable to find a single permanent recovery. In all of these cases the old operation was performed, that is to say, the nipple and a portion of the skin were circumscribed by two incisions, the mamma was dissected out of its bed of fat, any glands that were perceptible in the axilla prior to the operation were removed, and the wound was nicely approximated by sutures. These results led me to abandon the partial and inadequate operation for the thorough and complete procedure which I instituted in my second series of cases.

Of the succeeding 107 cases, I am enabled to speak with certainty in 53. Of these 10 died without, and 43 were subjected to, operation. Of the 10 which ran a natural course, all were dead, with visceral deposits in 3 as demonstrated post-mortem. These patients lived, respectively, for nine, twelve, eighteen, twenty, twenty-five, thirty-two, thirty-eight, fifty, sixty-two, and seventy-four months, their average life having been 34 months.

Of the 43 operations, 2 died—1 from fat embolism, and 1 from pneumonia, and in 5 the patients were lost sight of after recovery. Of the remaining 36, 12 died with local reproduction; 1 died with recurrence and metastases; 2 were alive with recurrence; 1 was alive with recurrence and metastases; 20 remained well, or died of some intercurrent disease, but 3 had had recurrences.

It will thus be seen that local reproduction was met with in 52.77 per cent. of the operations. Out of 17 of these 19 cases in which the date could be fixed, 10 recurred in six months, 4 in from seven to twelve months, and 3 in from thirteen to seventeen months, the average having been 7 months. The recurrent disease was seated in or near the cicatrix in 5, in the axilla alone in 8, and in both localities in 6.

Of the thirteen patients who died with recurrence the average life was 25 months, the shortest having been six and the longest sixty months. Hence, the life of these patients was shorter by nine months than was that of the ten patients who were not interfered with.

Of the 20 subjects who remain well, or who perished from other affections without recurrence, 5 were dead and 15 were alive. Of the former,

1	lived	for	7	years	and	10	months.
1	"	"	.....			23	"
1	"	"	.....			21	"
1	"	"	.....			17	"
1	"	"	.....			2	"

Of the living,

1	remains	well	for	8	years	and	3 months.
1	"	"	"	8	"	"	2 "
2	remain	"	"	5	"	"	11 "
1	remains	"	"	3	"	"	5 "
1	"	"	"	3	"	"	1 "
1	"	"	"	2	"	"	9 "
1	"	"	"	2	"	"	8 "
1	"	"	"	2	"	"	1 "
1	"	"	"	1	"	"	8 "
1	"	"	"	1	"	"	6 "
2	"	"	"	.....			12 "
1	"	"	"	.....			8 "
1	"	"	"	.....			6 "

If the permanent recoveries were based upon freedom from recurrence after seventeen months, the latest period which I have observed, these 20 cases would show 14 cures; but in determining the date at which recovery may be said to be definite, surgeons accept the dictum of Volkmann that a cure is rendered almost certain if the patient has survived over three years without local or general recurrence after the last operation, or if she has died of some intercurrent malady under the same conditions. Applying this test, it will be seen that of the 36 operations in which the result could be traced, 7, or 19.44 per cent., recovered permanently. The average time of cure was 6 years and 1 month, and the disease had existed before operation, on an average, for 9⅓ months. When I state that in all of my operations the axilla was cleared out, and that in 5 of these 7 cures the axillary glands were largely involved, the degree of success must be considered remarkable. As only 2, or 4.65 per cent., of the subjects died from the immediate effects of the operation, and 19.44 were permanently relieved, the propriety of removing the glands along with amputation of the breast cannot admit of question. That the axilla should be cleared out in every instance in which infected glands cannot be detected prior to operation, is clearly shown by the fact, that of sixteen of my cases of this nature, in only two were the glands not diseased. Hence, my experience demonstrates that the glands may be expected to be involved in 87.5 per cent. of all cases in which they cannot be felt through the integuments of the axilla. In Kuester's[1] practice the proportion of glandular implication under similar circumstances is somewhat larger, as his last sixty-five cases indicate that the glands were infected in fifty-seven, or nearly 92 per cent.

The operation which I perform, and which I was the first to advocate in my *Treatise on Tumors of the Mammary Gland*, published in 1880, is a thorough one, the object being to remove all tissues which the experience of centuries has demonstrated serve as the sources of recurrence. As the operation will be fully described and illustrated in an early number of *The American Journal of the Medical Sciences*, it need only be stated at this time that, no matter

[1] Deutsche Zeitschrift für Chirurgie, Bd. xxvi. p. 143.

what the situation of the tumor may be, or whether glands can or cannot be detected in the armpit, the entire breast, with all the skin covering it, the parammary fat, and the fascia of the pectoral muscle are cleanly dissected away, and that the axillary contents are extirpated. It need scarcely be added that aseptic precautions are strictly observed.

THE TREATMENT AND PROPHYLAXIS OF ANGINA TONSILLARIS.

By H. V. HOFFMANN, M.D.,
OF BADEN BADEN.

The tonsils are (lymphatic) glands, the numerous ducts (lacunæ and follicles) of which undergo many changes, namely, they become distended and elongated, and are thereby converted into cavities filled with viscid secretion and pus; these changes are due to inflammation. The lumen of these altered ducts, as well as those in the normal tonsils, are almost in direct continuation of the lymphatic system, as also with the venous system; this is due to the thinness of their walls, especially those that have undergone pathological changes. If the orifices of these ducts, which open into the oral cavity, become occluded, it will be readily seen how they furnish a most favorable nidus for the development of bacteria and other specific poisons, the germs of which find in these ducts a protected shelter where they develop unmolested.

During the act of deglutition, especially when respiration has been carried on through the month, a favorable opportunity is afforded for infectious particles and specific poisons to enter the orifices of the ducts, whence they penetrate the ducts, and there become tightly lodged. That the specific virus of diphtheria, as well as the infectious material of scarlet fever, likewise gains access into the system through the same channel is undoubted; and that many other infectious diseases also get into the blood in the same manner, seems to me to be very plausible.

The almost simultaneous development of a number of cases of tonsillitis in a certain locality (endemic) is, without doubt, due to the development of the germs in the ducts of the glands, there being an especial predisposition to an attack in those in whom pathological changes, as before described, have already taken place.

My therapeutics in these cases of tonsillitis consists in applying pressure (squeezing) to the tonsils (from below upward) with a wad of cotton wrapped about as thick as the little finger around the point of a dressing forceps, and dipped in a mixture of tinct. nuci vomicæ et glycerini, equal parts. The removal of the foreign matters, which have a tendency to cause inflammation, by this method at first causes some pain, but the relief obtained from it is so great that you will find your patients asking to have it repeated in a few hours. The use of a gargle of potassium chlorate, and the administration, at night, of a moderately large dose of quinine materially assist in the cure.

After the patient has recovered from the attack of tonsillitis, we begin our measures for the prevention of the return of any more attacks of tonsillitis, for the patient is bound to have relapses—and you will meet with many patients who have suffered repeatedly from attacks of angina tonsillaris.

For the purpose of putting the tonsils in a condition to resist attacks of angina the ordinary blunt hook will be almost the only instrument required. If you simply inspect the tonsils by using only a tongue depressor, you will not be able to give a positive opinion of the condition of the glands—if they are filled with pus, or if they have become impregnated with substances which are more or less deleterious to the blood; to give a positive opinion you must make use of some hooked instrument (tenaculum). When the blunt hook is made use of in closer examinations of the tonsils and is allowed to glide over the tonsils from above downward it will be found to enter depressions in the gland caused by previous attacks of tonsillitis. From these depressions there will often well up, unexpectedly, a fluid, yellow pus, or the normal secretion of the tonsils which has become converted into thick, hard, caseous particles, and which is often possessed of such a penetrating odor that the fetor which issues from the mouth nauseates the patient and those with whom he comes in contact. In these cases it is best to allow the tenaculum to sink to the base of the depressions and then to perforate the mucous membrane, allowing the opening to appear on the oral mucous membrane and then with a quick motion tear through the intervening membrane; by this means the previously existing cavity or recess becomes converted into a slit or cleft, which, during every act of swallowing, opens, and thereby empties itself, so that no inflammatory products can attach themselves.

The principle of the practice of this trifling operation for the prophylaxis of tonsillitis, is based on the view that there shall not exist, either in the tonsils or posterior thereto, any opening which has not been thoroughly explored to its base and then laid open and converted into a cleft through which the blunt hook must pass smoothly without becoming caught in any pocket.

In some few serious cases, or in some of long standing, it may be found necessary, in addition to the above procedure, to remove a part, or the entire tonsil. In other cases it will be necessary to remove only a piece of the mucous membrane. This latter must be done in those cases in which, in the act of swallowing, the mucous membrane will act as a lid to the fissure or slit, and thereby prevent it from emptying "itself of its contents. It is, however, advisable to endeavor to preserve as much of the tonsil as possible, as it is my belief that the fermenting properties of the tonsillar secretion are at least a great help if not an important agent in the process of digestion.

For the purpose of removal there will be required a long hooked forceps, or a dressing forceps, a tonsil bistoury, and a pair of curved scissors for the purpose of cutting down to the base of any pus passage, the base of which is not permeable owing to the presence of a tough scar tissue which may be so dense that it will be found impossible to lacerate it

with the blunt hook, and which must therefore be cut open with the scissors. It is, however, much better to tear through than to cut with the scissors (although this may be accomplished, as I have shown, by using a blunt hook, which has its inner edges sharpened), because the wound produced by the scissors will heal up in an undesirable manner. The little operation is finished by applying to the wound—from which there is but little bleeding—a pledget of cotton dipped in a mixture of iodine and glycerine, after which the patient must abstain from the use of warm victuals and drinks, as they may cause pain. A lukewarm gargle, composed of a weak solution of common salt, or one composed of a weak solution of potass. chlorate should be used; during the summer (if the operation is performed during this time) small pieces of ice may be taken into the mouth; often, however, nothing at all is requisite, because the following day the patients seldom experience any discomfort.

It happens but seldom and then only in patients of a nervous disposition, that both tonsils cannot be operated upon at one sitting, and these cases seldom require more than two or three sittings. This operation is soon followed by the disappearance of the chronic redness of the gums, a symptom which is always coexisting and a positive proof of the presence of pus accumulations in the tonsils, and any chronic pharyngitis that may have been present will also be found to have greatly improved or entirely disappeared without the use of any medicaments whatsoever.

It is very desirable and favorable to a rapid radical cure that the patient should frequently have the tonsils swabbed with iod. glycerin., so that a healthy mucous membrane results, and one that does not easily bleed and which shall act as a resisting barrier between the blood and lymph systems and the outer world.

There still remains to be discussed the question, whether the prevention of inflammation could not be as readily if not better accomplished by the use of the galvano-cautery, scarification with a knife, or by performing tonsillotomy! The first two of these procedures are without doubt beneficial, because the cavities in the tonsils are thereby laid bare and cauterized. But if this result is achieved, it is more due to "blind luck" than anything else, and still more depending upon chance is the formation of a scar, for after the use of the galvano-cautery it is not always that cicatrization readily occurs owing to the continual contraction; and even if the scar is well formed it is often the cause of the development of new recesses and pus-filled cavities, which, on account of the scar tissue, it will be found very difficult to lay bare.

My argument against the removal of the tonsils with the tonsillotome is, that by this method there is removed more of the secreting mucous membrane of the gland than there is with the galvano-cautery, and also the circumstance, that after the removal of the tonsil it is still necessary to look for and to open the cavities which are sure to remain after the performance of tonsillotomy, and this becomes so much more difficult on account of the dense scar that remains after the use of the tonsillotome. The partial excision for the purpose of laying bare a deep cavity which may exist behind the gland is often imperatively demanded, but may be more easily reached by the use of the blunt hook.

It is advisable (especially in those patients who want to feel assured that they are thoroughly protected against angina tonsillaris) to have them come to your office about six months after the operation for the purpose of inspection, and it is well to recommend them to call again after the lapse of another six months—preferably during spring or fall—in order to be absolutely certain.

It is in the laying open of the normal ducts of the tonsils in young children who have never had an attack of angina, herpetic or diphtheritic affection of the glands, but who are predisposed thereto on account of the congenitally thick spongy condition of the tonsils, as also by reason of the history of tonsillar inflammation in their families, that we achieve the happiest results. In these cases in children, the ducts may be very readily laid bare, as they do not penetrate very deeply into the gland; the operation may be made absolutely painless by first applying cocaine. The thickened tonsils rapidly shrink, and their immunity against inflammations seems, according to my observations, up to the present time, to be thoroughly established. It is my belief that children thus treated have also less to fear from an attack of diphtheria, than those who receive the most devoted care and attention during such an attack; just as in traumatic diphtheria, here it is surely easier to prevent an attack of it by the use of antiseptic treatment, than it is to cure a case.

I was led to make this investigation by finding in my endeavors to learn the origin of diminution in the power of accommodation, that it was so constantly associated with tonsillitis, and that on the latter being removed the accommodation also improved.

SURGICAL CONSIDERATIONS OF THE ABDOMINAL COMPLICATIONS OF TYPHOID FEVER.

By THOMAS S. K. MORTON, M.D.,
MEMBER OUT-DEPARTMENT STAFF PENNSYLVANIA HOSPITAL; ASSISTANT SURGEON TO THE ORTHOPŒDIC HOSPITAL.

DURING a recent surgical survey of Europe I took pains to interrogate those whom I met upon various subjects which have had more than ordinary interest for me. Perhaps most interesting has been the topic of which I now propose to speak, namely, the question of surgical interference in the abdominal complications of typhoid fever.

My inquiries met with but one affirmative response—that was in Birmingham. There Mr. T. H. Bartleet during the past winter had operated for perforating typhoid ulcer. Perforation was diagnosed by the resident physician, at whose urgent request the attending physician gave sanction for surgical interference, and Mr. Bartleet was called in. He made a median incision, and great fecal extravasation was discovered upon opening the peritoneal cavity. An unsuccessful hurried search was made for the bowel

opening, the cavity irrigated, a drain put in, and the parietal incision closed. The patient died during the second day after operation.

Since my return a single contribution upon this subject has appeared in literature: the report of a case operated upon in 1885, by Prof. Kussmaul, of Strasburg, and reported by Lücke in the *Deutsche Zeitschr. für Chirurg.*, 1886–87, xxv. 1–4. I give an abstract of the important points of this, to be, historic case:

A woman, aged twenty-eight years, was admitted to the Strasburg Obstetrical Clinic, on September 22, 1885, and very shortly afterward confined normally. The puerperium was tardy, and she gradually developed a typhoid condition. This became so marked on October 14th as to justify a positive diagnosis of typhoid fever. All went well until the night of the 22d of October, when she was suddenly taken with agonizing pain in the abdomen, and symptoms of collapse. In ten minutes she was seized with continuous chills, was cold, pale, and bathed with cold perspiration; pulse 180, and small; much vomiting, pain upon palpation of abdomen, and tenesmus present. The patient was a few hours later transferred to the surgical clinic with the accompanying diagnosis of perforated typhoid ulcer.

Prof. Kussmaul saw the case almost immediately, and determined upon abdominal section. Upon commencing operation the patient's condition showed: cold extremities, pulse small and weak, belly moderately distended and painful, great shock. Precautions were: warm room, legs carefully wrapped, rigid antisepsis. An incision was then carried from the umbilicus to the symphysis pubis. The incised tissues were found œdematous, and upon opening the peritoneum much dark, flaky, feculent fluid escaped. The intestines were pasted together and covered with fibrinous exudate. The coils of the small intestine were carefully drawn out, examined, and covered with hot moist towels: they were found quite adherent to one another. One small perforation was found about a foot and a half above the ileo-cæcal valve. From it flowed yellow feculent material. The cæcum and vermiform appendix were negative; mesenteric glands enlarged. That portion of the gut including the perforation was excised and stitched with Lembert sutures, the peritoneal cavity cleansed thoroughly by irrigation with salicylic solution and sponging, a large drain placed in position, and the abdominal wound closed. The patient died in eleven hours without reacting from shock.

Necropsy proved the presence of broncho-pneumonia and hypostatic congestions, foul pus in Douglas's cul-de-sac, and fibrinous exudate everywhere in the peritoneum, while the drain tube was totally obstructed by a kink. The belly-wound was in excellent condition. The site of resection was found to be nineteen inches above the ileo-cæcal valve, while on either side of the intestinal incision circular necrosis and inflammation were well advanced.

As far as my knowledge and search go, these two cases represent the history of surgical interference with the peritoneal complications of typhoid fever. In the *Philadelphia Medical Times* of December 11, 1886, Dr. James C. Wilson, after recounting a case of recovery from peritonitis following supposed typhoid perforation, impressively asks whether operation in certain of these cases would not be justifiable, and pleads for its judgment by trial. This article called forth an approving editorial in THE MEDICAL NEWS, but since then the subject has remained dormant and received no further public attention. Whether the future will present more brilliant and encouraging results remains to be seen, certainly they can become no worse in record, and just as certainly there would seem to be chance of improvement.

The etiology of the conditions which might indicate operation appears well understood, and we have no additional modern knowledge which will, by making more clear the exact etiological factors, possibly also assist in diagnosis. For upon the latter depends *everything* concerning surgical interruption of the typhoid pathological process.

There are practically but two conditions which we could have any hope of benefiting by operation. They are, perforation of the intestine with intra-peritoneal extravasation; and rupture of a suppurating gland or other abscess into the abdominal cavity.

Now, granted that either of these conditions has been correctly diagnosed, and the patient not moribund, I should consider it imperative duty to interfere surgically. In the light of present medical science I think everyone will agree with me that the condition *diagnosis* being allowed, we should so proceed until it is proved either that operation can be of no avail, or that an occasional life, otherwise condemned, can be saved.

Diagnosis being our starting-point and foundation, what then may be our powers in that direction? First, however, a word as to the etiological factors which give rise to the conditions which we would improve. Typhoid perforations and mesenteric gland abscess occur more frequently in men than in women—almost never in children. About 1 per cent. of cases in adults perforate, and 10 per cent. of typhoid fever deaths occur from this complication. From the beginning of the third week until the end of the fifth week is the period when such complications are most apt to take place. Either of the chief complications of which we are speaking, but especially perforation, may arise at even a very long period after the subsidence of apparent symptoms, perhaps from a resultant chronic ulcer, but this latter would scarce come under the strict limits of our caption. Perforation may be the result of primary slough of a Peyer's patch early in the course of disease, but usually, and at a later stage, secondary ulceration is responsible. Completely formed ulcers have been observed as early as the seventh day. The mesenteric glands are always enlarged, frequently inflamed, and occasionally slough during the course of typhoid fever. This is the result of conveyance to them of absorbed septic matter by the intestinal lymphatics. The exact nature of this irritating substance we do not understand, nor does its constitution concern the limited scope of this article.

Suppurative peritonitis may, in the typhoid state, develop from one or more of three causes: from irritation of the peritoneum by proximatous inflammation of gland, intestine, or other organ; from the perforation of an ulcer, or from rupture of a gland or other abscess into the peritoneal cavity. The earliest sloughing and ulceration, as a rule, will be found close to the ileo-cæcal valve, and in this same region are to be found the most violent septic changes and extensive ulcerations, although, on the

other hand, it is not a fact that most perforations there occur; which may depend upon the peculiar bowel structure in that region.

Hoffmann states that the ulcerative process rarely extends more than nine and a half feet above the valve; it *can* occur, however, in any place where intestinal glands are to be found, from the upper duodenum to the lower colon, but ulceration at these extremes must be very infrequent. Perforation of the vermiform appendix from involvement of its follicles is to be remembered as a possibility, but I have no knowledge of an example.

The immediate causes of perforation are: imprudence in diet, muscular exertion, and, occasionally, the movements of entozoæ.

Liebermeister states that an apparent diphtheria of the mucous membranes—including the intestinal—occasionally follows upon recovery from typhoid fever, but regards the process more as a breaking down from malnutrition than as a true diphtheria. Perforation of intestine from violent inflammation has been known to follow this condition of its mucous membrane.

Rupture of the spleen occurs rarely, as does peritonitis also, from proximity to, or rupture of, abscesses of the same, or other abdominal organs. Gangrene of more or less intestinal wall is also an infrequent complication. Peritonitis may arise at any time from the onset of an attack of typhoid fever until an indefinite period after the establishment of convalescence. Originating before the end of the first week it cannot be caused by perforation or abscess, unless the former be due to the breaking down of an old ulcer cicatrix, etc., caused by the general devitalization of tissues. In fact, before the end of the second week, any peritonitis starting up is probably of the irritative or sympathetic type, or due to the general constitutional depreciation incident to the disease. This form is liable to come on at any time during the course of the malady in question, and must be dealt with as we would with a similar state of affairs in a non-typhoid individual; with the difference that some of the special considerations hereafter to be mentioned must be kept in mind before operative interference is undertaken. Of course, surgical treatment would always at least be considered in any case of peritonitis in these times. Sudden onset of peritonitis of violent type or with concomitant or quickly succeeding great shock or collapse, during the time limits when perforation, etc., are likely to occur, would indicate with great probability that some such accident had taken place: gradual onset and increase might be caused by either the more grave complications, or by irritative or sympathetic lesion—most probably the latter. Cases are on record where perforation has taken place, a very small amount of bowel contents escaped, the pathological orifice had been almost at once closed by fibrinous exudate, and *gradually* increasing fatal purulent peritonitis set up.

Great shock or collapse without concurrent peritonitic symptoms may indicate hemorrhage, or even the most desperate septic peritonitis from perforation. One case under my care not long since became greatly shocked, complained of a little more pain in his ileo-cæcal region than he had been having, had copious bloody stools, and died in about twelve hours. Post-mortem showed that perforation had taken place at a higher level of intestine, coincidently with hemorrhage from a separating slough lower down, and that purulent peritonitis had already started and made considerable headway. No symptoms of the latter complication were discernible during life, and I hope that the combination is, and will continue, unique; and that we shall soon possess some means by which accurately to differentiate the occasional shock of beginning peritonitis from hemorrhage. Investigations into the by no means trite subject of the symptoms of certain forms of peritonitis are most urgently needed. Within a year I saw a man die of universal purulent peritonitis from traumatic rupture of intestine, without presenting a single conventional symptom of that "inflammation."

May means be forthcoming to tell positively the presence or absence of peritonitis under all circumstances? Those who have had most experience will, I think, agree with me in being in a very anxious receptive condition for the advent of such pathognomonic signs. Upon the occurrence of perforation, patients usually become conscious, if they have not been so before; but, unfortunately, this sign holds good for hemorrhage also.

Sudden agonizing pain in the right lower abdomen, quickly increasing and extending, chill or coldness, particularly of the extremities, fall of temperature, small, rapid pulse, hurried, shallow breathing, haggard appearance, and perhaps tympany and diminished liver dulness—these symptoms strongly indicate perforation; none is positive, but the combination, in absence of hemorrhage, is *almost* so. According to Hoffmann, violent general peritonitis without perforation took place in 16 instances out of 2000 cases of typhoid fever. Liebermeister has twice observed the same conditions arise, in similar cases, from rupture of the gall-bladder, and the discharge of calculi and bile into the peritoneum. The same author also mentions cases dying of perforative peritonitis which, during life, presented no symptoms of it. Infarctions of the liver, spleen, and ovary are said, likewise, to have originated these same conditions, with and without symptoms. Rupture of the spleen, and consequent death from hemorrhage or subsequent peritonitis, has been reported more than once. A very small perforation may cause gradual onset, or limited peritonitis. Reported cases of recovery from general peritonitis, due to typhoid perforation, are most probably ones of mistaken diagnosis. Flint says that peritonitis from perforation is almost certainly fatal.

Let me quote Dr. Wilson's impressive remarks. "Granted that the chances of a successful issue are greatly against you; that the patient is in the midst or at the end of a long sickness; that his tissues are in the worst state to stand the injuries of the surgeon's knife; that the lesions of the gut may be very extensive; that the vital forces are at the lowest ebb. No one yet has hesitated to perform tracheotomy in the laryngeal complications of enteric fever, which require it to save life for these reasons. The opera-

tive treatment of purulent peritonitis has been performed many times successfully by gynecologists in conditions scarcely less unpromising. In point of fact, the objections which may be urged against laparotomy in intestinal perforation in enteric fever are no more tenable than those which would have been made use of at first against the same operation in gunshot-wounds of the abdomen. . . . The courage to perform it will come of the knowledge that the only alternative is the patient's death. Certainly *a priori* reasoning will not help us. We must not, however, overlook the fact that while a few cases of perforation occur in the second week of the disease, while the infective process has yet some time to run, a far larger proportion take place in the period of convalescence when the condition of the patient, except for deep ulceration, often single, is tending toward recovery."

If satisfied then that in certain of these cases operation is positively indicated and demanded, we should think over what course of procedure to adopt in carrying out the operation, that we may be prepared to deal with them when called upon to do so. All usual precautions taken in abdominal sections should be observed. The surroundings and atmosphere should be as cleanly as possible. The patient must be stimulated, if necessary, and extraordinary pains taken to keep him warm, such as surrounding him with hot bottles, wrapping the limbs with warm blankets, using hot solutions, and having the temperature and moisture of the apartment at just as high a point as the surgeon and his assistants can withstand—a collapsed patient can bear with benefit considerably more moist heat than can the operator.

If there is time and opportunity, a hot bath will not only cleanse the patient, but also improve his condition if he is shocked. Every unnecessary movement or manipulation of his body should be strenuously avoided before, during, and after the operation. The abdominal walls, and everything liable to come in contact with the wound, must be surgically clean, and in convenient order before the operation is begun. Median incision will undoubtedly prove best in almost every case. It should be as long as is necessary for efficient work, and commence a little more above the pubes than is usual in such incisions. Extreme gentleness will be required throughout, as otherwise, perhaps in any case, other ulcers may be broken through. Let systematic search for lesions commence at once upon gaining admission to the peritoneal cavity, starting, in order, at the points most liable to involvement. We should examine the cæcum and its appendage, then carefully go over the entire length of the small intestine continuously from its termination in the cæcum to its origin at the pylorus, by passing it between the fingers. This finished, in like manner the colon should be examined; then the mesentery, ovaries, liver, etc.

What shall be done with lesions when found? This is a vital, and not an altogether answerable question.

Perforations, in the great majority of cases, will be found in the small intestine corresponding to the position of Peyer's patches. Occasionally a follicle ulcer will perforate near the mesenteric border, but probably never so close to it as to produce the trying injuries which are made by a bullet or knife. In the cæcum, or colon, perforation is equally liable to occur anywhere, except close to the meso-colon attachments. The usual position of these lesions is fortuitous, as the situation permits of most easy reparative treatment.

Shall we resect a perforated bowel, simply turn in the borders of the perforation, or attempt the production of an artificial anus?

In the lack of experience, nothing positive can yet be said upon this point. We do know that circular gangrene of intestine occurred in the single instance where exsection has been done, but this may possibly have been due to some defect of operation. A large perforation, or a small opening through the base of a very large, deeply excavated ulcer, would probably require excision of a portion of bowel. Such an ulcer occurring in the small intestine would be in its longitudinal diameter, hence, it can be turned into the bowel entire by Lembert sutures introduced beyond its lateral borders. This I should be inclined to think the best method of dealing with most perforations, or ulcers about to perforate. The possibility of narrowing the bowel immoderately must be kept in constant view, and, where the above suggested mode of repair would undoubtedly give rise to it, resection or artificial anus must be substituted.

It is possible that the necrosis of bowel already alluded to resulted from the absence of resistance in tissues so profoundly poisoned and malnourished as, of necessity, are those of a typhoid individual. We do not even know what course the parietal incision itself would follow, but I deem it probable that, with thorough cleanliness, such wounds could be induced to heal kindly. At the worst, happen what may, the patient can be in no more deplorable condition than before operative interference was carried out. We know nothing of what possibilities there may be in this direction, and I would plead for an attempt to reduce a mortality of one hundred per cent. If resection cannot successfully be done, and the affected area is too large for efficient stitching, then artificial anus would be another resource.

Whether any one of these three methods of treatment is *the* one, or whether all will have occasional use, must be determined by trial and experience. The order in which I should suppose them valuable would be: stitching by Lembert's method, resection, and, lastly, artificial anus.

In the examination of the intestine I should also be inclined to turn into the bowel lumen, by the same method of stitching, any seats of disease which appeared likely soon to perforate, or to approach dangerously that condition. Cæcum and colon lesions could, probably in every case, be treated by simple stitching. The principles of modern abdominal and general surgery must be our guide in treating the rare abscesses of mesentery, liver, spleen, and ovaries which complicate typhoid fever. The point which I wish to reiterate is that, these having ruptured into the peritoneum, and being so diagnosed, it is our imperative duty to open the abdomen and treat what

we may find according to our knowledge, unless the future shall demonstrate that no good can ever be accomplished by surgical interference in these desperate and, at least heretofore, necessarily fatal cases.

Large irrigations with very hot distilled or medicated water are indispensable before closing the abdomen. Just as important will it be to drain these cases thoroughly, and for this purpose nothing answers so well as the leaving in of a Keith glass-drain. This tube can best be kept in working order, as suggested by Dr. Joseph Price, by carrying a rope of absorbent cotton (medicated, if preferred) to its bottom, and removing it as often as a wad of cotton placed over the outlet becomes saturated. The rope and superimposed cotton must be renewed as it becomes saturated, even as frequently perhaps as every couple of hours for the first day; afterward, at less frequent intervals, according to circumstances.

The oncoming of symptoms of a second perforation would call for a repetition of the whole process.

CÆSAREAN OPERATION,

FOR THE RELIEF OF AN OBSTRUCTION, CAUSED BY A UTERINE FIBROMA IMPACTED IN THE PELVIS.

BY THOMAS M. DRYSDALE, A.M., M.D.,
OF PHILADELPHIA.

The attention of the profession has repeatedly been called by Dr. Robert P. Harris to the unsatisfactory results of the Cæsarean section in the United States, caused mainly, as he has clearly proved, by the delay in operating, and very recently an able article by him on this subject was published in The Medical News.

This stirring appeal to improve the results of the operation in our country must meet with a hearty response, and a God-speed in the good work from every obstetrician and surgeon. In the article referred to, Dr. Harris appears to lay the blame for this delay mainly upon the medical attendants' ignorance of pelvimetry. "If our obstetricians," says he, "had as good a knowledge of pelvimetry as prevails in the maternities of Austria, France, Germany, and Italy, there would be much less delay, and fewer attempts to deliver, either by forceps or craniotomy, in cases of pelvic deformity or other forms of obstruction."

This is undoubtedly true in many instances, yet the delay is not always owing to the want of such skill, for, even when the diameters of the pelvis are known to be normal, cases occur in which eminent practitioners are in such doubt that every resource of the art is appealed to before the Cæsarean section is decided upon. Witness the case reported by Dr. Parish, at the meeting of the American Gynecological Society, in 1886, or the one published by Prof. T. Gaillard Thomas, in the *American Journal of Obstetrics* for February, 1876, p. 612. In both of these pelvimetry was not at fault, nor was skill absent, yet delivery by section was not determined upon until all other hopeful means were fruitlessly used. It is clear then that the obstetrician is not invariably to blame in such cases, for an honest difference of opinion may unhappily lead to such delay that a disastrous result is inevitable. And while in the main Dr. Harris is correct in the statement which I have quoted, yet instances will occasionally present themselves where we are foiled in our desire for an early, and therefore successful, operation by the misleading character or the obscurity of the symptoms, resulting in an erroneous diagnosis, or causing such doubts that an operation is only undertaken under protest from some of the attendants, as in the following case.

I was sent for, November 5, 1884, by Dr. Emil Fischer, to "aid him in a case of abnormal labor," and received this history. Mrs. I. P. R., a native of Germany, a small, delicate looking blonde, thirty-five years old, said she first menstruated at the age of twelve, without pain or trouble of any kind, and had always been regular both as to time and quantity until she became pregnant. The only exceptions to this were that five or six years previous she had a profuse flow, accompanied with clots, which lasted eight or nine days; and for some months before marriage she had noticed that the discharge was growing scanty.

She was married January 16, 1884, and thought she became pregnant at once, as she last menstruated from the 10th to the 14th of the month. The abdomen enlarged regularly, and the motions of the child were strong from the time of quickening until a week before the pains commenced; since then the motions had been weaker, but were still felt. For the first seven months she had constant nausea and frequent vomiting, for the relief of which she had early applied to Dr Fischer, and at the same time engaged him to attend her in her confinement, which she expected to occur in October. Ten days before my visit the uterine tumor fell lower in the abdomen, and her waist became smaller. The functions of the bowels and bladder were normal.

During the night of November 4th she was seized with strong bearing-down pains, coming at regular intervals, and accompanied with gushes of blood from the vagina, but without any escape of liquor amnii. In the absence of Dr. Fischer, Dr. Bricker was sent for, who, to arrest the bleeding, gave her fluid extract of ergot and used a tampon. Dr. Fischer saw her about 10 P.M.

With the exception of the prolonged period of gestation, which Dr. Fischer thought could be readily accounted for by an error of calculation, nothing had occurred up to this time to indicate anything abnormal in the pregnancy. Now, however, the doctor discovered, on examination, a body which appeared to be the child's head, occupying Douglas's pouch, and diagnosed extrauterine fœtation. As the hemorrhage continued at his visit, and the first tampon had escaped, he inserted another.

I saw her at 12, noon. The pain and hemorrhage had ceased about 11 o'clock the night before; she had taken nourishment and appeared comfortable and cheerful. Her pulse was 112; temperature 98½°. On examination I found that a hard mass occupied Douglas's pouch, and, in fact, the whole true pelvis. The finger came in contact with it about an inch within the vagina. It was globular

and resembled in shape and feeling a child's head, covered with a thin layer of uterine tissue. It filled the pelvis so completely that there was only room for a finger to pass between it and the pubic bone. A careful search failed to detect the cervix or os uteri. A uterine sound was passed along the vagina and entered until the handle was buried within the labia, before it met with resistance. Its point could be felt through the abdominal wall, as if just under the skin below the umbilicus. The breasts were small and soft, and although the areolæ were dark, no enlarged follicles were seen. No milk could be obtained from them.

The abdomen was occupied by a tumor of the size of a fully pregnant uterus. It was hard and resisting to pressure, and, in fact, felt like a uterine fibroid. This resemblance was strengthened by a number of small, hard tumors, some of them movable, which projected from the surface of the mass. It was impossible to find anything like the outlines of a fœtus within it. A prolonged examination failed to reveal the fœtal heart sounds, but while listening for them, I detected an occasional slight uterine contraction.

I diagnosed pregnancy, complicated by a fibroma of the uterus, developed in its posterior wall, which had been forced down and occupied the pelvis. Taking this view of the case, I proposed attempting to free the pelvis of the tumor, and, failing in this, to perform the Cæsarean section. The patient was placed in the genu-pectoral position, and a vigorous and prolonged attempt made to raise the mass, but without success.

After this, she remained free from pain, and did well until the night of November 8th, when there was a return of active labor, accompanied with some discharge of blood and dark clots from the vagina. Dr. Fischer gave her a half grain of morphia, which quieted the pains.

I saw her with Dr. Fischer November 9th, when she complained of feeling weak and of soreness over the lower part of the abdomen. She had lost her appetite, but her tongue was clean and moist; pulse 112; temperature 98°. Her bowels had moved freely, and she had frequent desire to pass water. Another and equally fruitless attempt was made to dislodge the tumor.

From this time until the operation, she had no return of expulsive pains. Her general condition remained the same. The upper part of the abdominal enlargement became softer, but the pelvic portion continued hard. She again asserted that the motion of the child could still be felt, but much fainter than it was a week before.

I operated, with the usual antiseptic precautions, except the spray, November 12th, at 11 A. M., in the presence of Drs. Parvin, W. S. Stewart, Robert P. Harris, Emil Fischer, C. R. Prall, C. E. Bricker, Frank Fisher, and my son. After a hypodermatic injection of ergotine, the patient was placed in the usual position for laparotomy, and an incision made from the umbilicus downward, about six inches in length. The uterine section was made rather shorter, commencing near the fundus and passing downward. The membranes, stained with meconium, bulged through the wound. On opening them, the child, which was large, was seen to lie with its back to the incision, and the vertex downward. Seizing its legs, it was readily extracted. The placenta occupied the fundus, from which it was detached. This was followed by a pretty free hemorrhage, which was quickly arrested by the uterine contractions. The inner surface of the uterus was of a dark green color to the depth of one-eighth of an inch, and presented a gangrenous appearance as if its vitality had been destroyed by its contact with the dead matter. It was disinfected as thoroughly as possible by sponging with a five per cent. solution of carbolic acid.

The pelvic tumor was now examined and found to spring from the posterior wall of the uterus. It still remained firmly fixed in the pelvis, from which, after some difficulty, it was dislodged by drawing on it from above while it was forcibly pressed upward through the vagina.

Wishing to ascertain the condition of the os, a uterine sound was passed; no opening of it had occurred and a short cervix still existed. Before closing the wound in the uterus the cervical canal was dilated and a drainage tube passed through it into the vagina.

When the uterus was emptied, arterial blood was seen to be flowing freely from the upper angle of the wound near its peritoneal coating, over the site of the placental attachment. On attempting to secure the vessels the uterine tissue proved to be so soft and friable that the ligatures cut through it, leaving a bleeding surface. As the vessels could not be ligated, they were secured by bringing the edges of the wound together by a silk suture, passed under them through the entire thickness of the uterine wall, which at once arrested the bleeding. Ten other deep sutures were introduced in the same way and the wound in the uterus closed. Ten fine sutures were then used between these to secure the peritoneal coat; these were made in such a way as to turn in and bring the peritoneal surfaces in apposition. The external wound was closed with silk sutures, a compress and bandage applied, and the patient put in bed. She soon came from under the anæsthetic, made no complaint and presented no evidence of shock. The pulse was 98 and of good character.

She did well until 5 P. M., when she complained of soreness in the lower part of the abdomen and severe after-pains, for which I ordered an injection of half a drachm of denarcotized tincture of opium, to be given every hour. Her pulse was 96, temperature 100°: 10 P. M., pulse 112; axillary temperature 100°, in vagina 102°. She was sweating so profusely that her pillow and clothes were wet. As she still suffered from the intermittent uterine pains, I ordered a quarter of a grain of sulphate of morphia in half an ounce of camphor water, to be given every half hour until she was relieved. Soon after my visit she vomited, and continued to do so until 4 A. M., when Dr. Bricker was sent for, who, finding her pain unrelieved, gave her a hypodermatic injection of half a grain of sulphate of morphia. Nov. 13, 10½ A. M., her pulse was 140 and weak; temperature 105; breathing irregular and gasping; surface decidedly cyanosed. Ordered ten grains of

quinine and an ounce of whiskey by injection, and again washed out the uterus with carbolized water.

She continued to sink and died at 1.50 P. M. At the autopsy, made the next day, the uterus was found firmly contracted, and already the peritoneal lips of the wound in it were adherent, but the muscular wall showed no signs of healing and was thickened by fibroid degeneration. Its cavity contained some dark blood. The tumor was seen to originate by a broad base involving the cervix and about one-half of the posterior wall of the uterus. Its surface was mottled, but presented no signs of inflammation. The entire peritoneum was healthy, except on the anterior portion of the uterus, which was adherent to the abdominal wall for the space of an inch on each side of the incision in this organ. Douglas's pouch contained about two ounces of bloody serum.

Her death was undoubtedly owing to septicæmia, as there was no evidence of peritonitis beyond that already described. The septic poisoning probably occurred by the uterine contraction forcing the dead matter from the interior of the uterus between the edges of the wound where it could be readily absorbed by the freshly cut surface, or even enter the uterine sinuses.

This case is chiefly remarkable for the difficulties it presented in arriving at a correct diagnosis, which can be best appreciated by a brief review of its main features. After marriage, the patient, who had menstruated regularly, ceased to do so: morning sickness occurred and proved obstinate; the abdomen enlarged regularly; the fœtal movements were asserted to be active, and at the end of the tenth month she was seized with the usual signs of labor.

The history and symptoms, so far, then, were clearly those of pregnancy, although the duration was unusual, but this Dr. Fischer thought might be owing to an error of calculation. As nothing unusual in the condition of the patient had presented itself, the doctor had made no examination until the pains commenced and the patient supposed herself to be in labor. Then the pelvis was found to be occupied by a mass in Douglas's pouch, which he believed to be the head of the child, and so diagnosed extrauterine pregnancy and sent for me. Up to this time no doubt had been felt as to the fact of pregnancy, but further examination showed the breasts undeveloped and the areolæ unchanged, and *although the mother asserted that the fœtal movements could still be felt* none could be detected, while prolonged auscultation failed to reveal the sound of the fœtal heart. The abdomen was occupied by a solid tumor of the usual size of a pregnant uterus at full term, but conveying to the touch the sensation of a solid body like a uterine fibroid, in whose surface could be perceived imbedded several small movable tumors, but nothing resembling any part of a child could be detected. The mass in the pelvis so thoroughly filled it that only a finger could be passed with difficulty between it and the pubic bone. The finger thus inserted could detect no portion of the uterus or child within reach, while a uterine sound measuring eleven and a half inches was introduced until its handle was buried within the vulva, when its end could be felt as if just under the skin below the umbilicus. It will be seen, then, that the child was in a thoroughly inaccessible position. It could not be reached from below, neither could its form be made out through the uterine walls above, owing to the broad, smooth back of the child and the placenta being closely applied to them. There was, therefore, no opportunity of verifying the diagnosis by the usual methods.

The pelvic tumor was hard, and closely resembled the head of a child, the deep sulci in it simulating the sutures. So deceptive was it to the touch that two obstetricians of large experience believed it to be a child's head in a retroverted, pregnant uterus. To add to the obscurity of the case, the pains which occurred the night of November 5th left her until the 8th, when they yielded readily to morphia, and never returned.

There were no constitutional symptoms present, except a rapid pulse, for which the loss of blood would account. Apart then from the history of the case, which was not entirely reliable, and the absence of menstruation, there was absolutely nothing to distinguish it from a rapidly growing, uterine myoma, except the intermittent uterine contractions. It is evident that such a condition of things is rarely met with, as I can find no similar case on record. This one, therefore, differs in that respect from any others reported, for in them a correct diagnosis could be made at once, as the uterus was within reach, and, in most of the cases, the presenting part of the child could be felt.

MEDICAL PROGRESS.

Laryngeal Phthisis and its Connection with the Tubercle Bacillus.—Korkünoff reports his results from his study of this subject as follows: His material consisted of fourteen larynxes taken from cases of pulmonary, peritoneal, and general miliary tuberculosis. In twelve of these laryngeal phthisis was also present, while the remaining two did not present any structural changes either to the naked eye or microscopically. The specimens were hardened in alcohol, and then placed in paraffin, the slides being treated after the Koch-Ehrlich plan. Dr. Korkünoff's results may be summed up as follows: 1. In the twelve phthisical specimens tubercle bacilli were found in the tissues. They were absent in the tissues of the remaining two, in which there was no laryngeal disease, though the secretion collected in the ventricles contained numerous Koch's rods. 2. The number of the latter varied, but bore no relation whatever to the extent and intensity of the morbid process—that is to say, they were often very scanty in number in an extensive tuberculous mass, and *vice versâ*. Further, in some cases he was unable to detect any bacilli within or around an ulcerated region, while he found them in some recent tubercular formations in the same larynx. This shows the importance of examining in each case as many sections as possible taken from different situations. 3. So far as histological changes are concerned, the tuberculous ulcer of the larynx originates in the following way. Mostly in the subepithelial layer, but not infrequently in some deeper

one, one or more tubercles, each of which is often enclosed in a connective tissue capsule, make their appearance, the epithelial covering and intermediate layer remaining yet intact. The tubercles contain Koch's bacilli, which are also seen in the surrounding infiltrated tissue, but never in the epithelium or the still healthy intermediate layer. The latter, with the gradual increase of lacteolar infiltration, becomes ever narrower, and ultimately disappears, so that the new growth comes into close contact with the epithelium. At this stage copious infiltration of the epithelial covering with leucocytes invariably takes place, and spaces become apparent between its cells, which are filled with white blood-corpuscles and tubercle rods. These spaces are nothing else than lymph spaces, which are also present in normal epithelium, but which may become dilated under morbid conditions. The nutrition of the epithelial covering now fails, its superficial strata become fissured, the infiltration with leucocytes increases, the lymph spaces grow larger, and finally the diseased portion separates, leaving a denuded or ulcerated surface. The ulcer continues to spread in the same way, that is, by infiltration with leucocytes, formation of spaces, sloughing, etc. Its parts covered with cylindrical epithelium, which is comparatively softer, the process goes on more rapidly than in those covered with the flat variety; consequently the tuberculous ulcers are deep in the former situation, and superficial in the latter, as Biefel had already pointed out. 4. The primary cause of the process is tubercle bacillus. Having appeared in the subepithelial tissue, the microbes, by their presence and multiplication, give rise to all the changes described above. 5. The microbes enter into the subepithelial tissue from the patient's expectoration, but from his own vessels or lymphatics, which carry them thither from primary tuberculous foci. No bacilli are met with in the epithelium of the intact larynx in a phthisical patient, though that epithelium is in constant contact with the expectoration containing tubercle bacilli. Again, no bacilli are found in a still intact epithelial covering, when tubercles, together with bacilli, are present in the subepithelial stratum. Microbes appear in the epithelium only at places where a tubercle with bacilli in its immediate contact with the epithelium, and ulcerates, or may be in greatest numbers in the deeper layers of the epithelium, and become more and more scanty as the surface is approached. Lastly, Koch's microbes have no enzymic or fermentative action."—*British Medical Journal*, November 5, 1887.

LUMINOUS CATARACT.—LAWFORD, of St. Thomas' Hospital, reports on the following case: "On October 1887, I was asked to see a patient, after excision, was presented to me in Mulleg's shed, for a month, and the ground in the usual manner, and examined. As regards the posterior parts of the eye, it will suffice to say that there was some hemorrhage in the vitreous, and between the choroid and sclerotic, and in the retina at the yellow spot. The lens was very slightly displaced, to a much less degree than appeared possible before removal of the eyeball. It was, however, dislocated slightly upwards, and more a little backward, at its upper edge. The pupil had a free way at this point, and the vitreous was bulging forward between the ciliary processes and the lens margin. The rupture of the iris was in this situation also. The lens was less uniformly opaque when seen from behind than it appeared to be anteriorly. Its circumference was rendered irregular by a slight prominence at the upper edge. Its posterior surface showed some unevenness, the middle part being raised a little above the lateral parts, and nearly in the centre of the posterior capsule was a small vertical gap, with a protrusion of semi-opaque lens substance through it. There was no other breach in the capsule. The whole lens was imbedded in celloidin, and sections were made transversely so as to cut across the rupture in the capsule. On microscopic examination of the sections, the rent in the posterior capsule was very well seen; it was a little to one side of the midline of the posterior surface of the lens, and the capsule on one side (probably the temporal) of the gap was curled outward upon itself, with two nearly complete turns, in an exactly similar way to that which occurs when the anterior capsule of a fresh lens is opened. At the opposite edge of the rent no such curling had occurred. The capsule elsewhere was intact. The changes in the lens substance were most noticeable in the posterior cortical layers. Here the fibres had undergone considerable change, and there were numerous globular particles among them. In the part immediately adjoining the rupture nothing but irregularly globular (or nearly globular) masses, quite structureless in appearance, could be made out, the small notch in the lens being almost filled by them. Anteriorly, there were numerous small bubbles or vacuoles among the lens fibres, which were evidently loosened and separated to a moderate extent. The nuclear part of the lens presented an almost homogeneous appearance, the outline of the fibres being completely lost. The anterior subcapsular epithelium was unaltered.

DIPHTHERITIC CONJUNCTIVITIS.—COUTANCES, of Paris, writes as follows in a recent thesis on this subject: Diphtheria may manifest itself locally on the conjunctiva just as on other mucous membranes. Diphtheritic ophthalmia may be met with at all ages; every cause leading to debility, and especially hereditary syphilis, predisposes to it. Cold may be regarded as an adjuvant cause, but the ocular affection declares itself especially when the conjunctiva is previously unhealthy, the pathogenic microbe having an action only upon an injured mucous membrane. Diphtheritic conjunctivitis differs essentially from purulent ophthalmia by its general symptoms and also from conjunctival croup. The malignancy of the affection varies much according as the ocular affection is an isolated case, or occurs epidemically.—*Journal of Laryngology*, November, 1887.

PARASITIC INFECTION FROM DOGS.—DR. OLLIVIER, of Paris, is quoted as follows on this subject by the *British Medical Journal* of November 5, 1887:

The number of hydatid cysts in a country is in direct proportion to the number of dogs. Facts seem to confirm this theory, for they show that there are more hydatid cysts in hill districts than in the low lands, in the country than in towns. The author cites several cases observed by him, in which the cyst was plainly traceable to previous intercourse with dogs, in patients

fond of these animals. A long period, sometimes years, may elapse before the ecchinococcus develops itself, but the cause is none the less evident. Children are always fond of dogs, and like to play with them, and these pets are affectionate and caressing, and have a bad habit of licking; in this way the animal's tongue may prove a ready means of propagation of the eggs of tænia. It is also possible that they may be inhaled, when, in very dry weather, these eggs are carried about by the wind. This would explain certain cysts in the respiratory organs. The penetration into the human organism, however, generally takes place through the digestive organs by means of salads, green vegetables, fruit, and other aliments imperfectly cleaned; or by water from ponds, reservoirs, or wells contaminated by dogs resorting there to drink. The author points out the precautions which should be taken to diminish the danger of propagation of this parasite: greater care in the choice and cleanliness in the preparation of certain articles of food; avoidance of unfiltered water, and particularly of stagnant water of any kind; and, above all, less intimacy with dogs, particularly in the case of children, who should be carefully watched. He condemns altogether house dogs of all kinds, as being a source of continual danger as regards the propagation of the eggs of *tænia echinococcus*.

Nasal Tuberculosis.—Cartaz believes that though the nasal mucosa cannot escape this condition, it is rare, if one puts on one side lupoid affections, as to which great diversity of opinion exists. Cartaz has been able to find only eighteen cases of this disease, of which one came under his own observation. Nasal tuberculosis occurs under two forms, one consisting of ulceration, the other neoplastic. Ulceration, which is usually unilateral, is situated on the septum, a little distant from the nasal meatus. The ulcer has a diameter of about half an inch, and a form more or less rounded. The base is pale reddish gray, and covered with muco-pus; caseous masses are seen embedded on certain anfractuosities of the ulcer, or fine gray granulations are seen in relief. The edges of the ulcer are sometimes projecting, sometimes forming, sometimes a light gray ring, sometimes sharply cut and toothed with small excavations. There is little pain, or interference with nasal respiration.

In the second form there is usually a tumor, and coincident coryza, interference with respiration, and the diagnosis will be uncertain unless pulmonary signs are present. Cartaz recommends galvanocaustic applications, lactic acid, and iodoform.—*Journal of Laryngology*, November, 1887.

The Question of Operation for Peritonitis.—At a discussion of this subject before a recent meeting of the Clinical Society of London, Mr. Treves expressed his views as follows: He said that other inflamed serous cavities, such as the pleura and the joints, are amenable to extensive surgical interference, and the same general principles of treatment are now being applied to the largest serous sac of the body. Already Truc had collected a series of ninety-seven cases of deliberate surgical interference with the peritoneum, and this numerical statement alone sufficed to show the rapidity with which this treatment had spread. As to the claim of priority of the deliberate treatment of peritonitis by washing out the sac, he could only say that he did not gather from a rather verbose correspondence with Mr. Lawson Tait that that gentleman was the first who deliberately performed the operation of abdominal section for the purpose of healing a case of supposed simple peritonitis. The operation had been done in previous cases as the consequence of a mistaken diagnosis, as in Sir Spencer Wells' historical case of tubercular peritonitis. Then, again, Mr. Luke Hancock's writings show that his conception of the treatment of peritonitis was a utopian idea. Just as the poetical outburst of Addison foretold the origin of the telephone, so in an excess of surgical exuberance Hancock had predicted this mode of treatment of the peritoneum. In Mr. Barwell's case six days had elapsed before surgical interference. As a rule, such a time would have seen the termination of the career of many cases of acute peritonitis. Moreover, in Mr. Barweel's case but a small part of the peritoneum appeared to have been diseased. The necessity of thorough washing out is made evident by the reflection that the peritoneum is so large a cavity with so many recesses in which fluid might accumulate. He hoped Mr. Barwell would amend his views as to the use of the drainage tube, for if ever there be a case for the use of the drainage tube, surely it is when the peritoneum is the seat of suppurative peritonitis. The principle that underlays the practice is perfect cleanliness. And in some cases he would wash out the stomach if the vomits had been offensive. Next, as to tubercular peritonitis. Kümmell, at the recent Congress of German Surgeons, had collected thirty cases of this disease treated by laparotomy, and others who discussed the paper added six more. Of the whole number, six cases ended fatally; twenty-five recovered of the first series of thirty, and only one died of the second series of six. In many cases the operation was done practically by accident on the mistaken diagnosis, as in Dr. L. Knagg's case of encysted peritonitis. Most of the cases occurred in others than young children, and between the ages of fifteen and twenty. It seemed that it was a matter of perfect indifference how the peritoneum was treated so long as it was opened. In young children the treatment was not encouraging. Reference was made to a case of his own in a child fourteen months old; there was so much ascites that the child was almost suffocated by the attendant dyspnœa. At the operation of section peritoneal tubercles were seen. It appeared that the treatment tended to alter the character of the inflammation, and for a time this case did well; but the fatal termination was only averted. Some improvement followed the injection of one pint of a solution of two drachms of tincture of iodine in hot water, at a temperature of 100° F., and for three weeks the child seemed better. At the necropsy general miliary tuberculosis was found. The influence of the ascitic fluid on the growth and nature of tuberculosis was discussed.—*Lancet*, November 5, 1887.

Diphtheria in a Prison.—Kionig, of Christiania, is quoted by the *Journal of Laryngology* for November, 1887, as reporting the following case:

A prisoner, aged twenty, who had been a year and a half in prison, was attacked with diphtheria of the fauces. After the patient had begun to recover, serious paretic

symptoms of the throat and gullet supervened, paresis of accommodation and later on, palsies of the muscles of the neck and arms, with subsequent atrophy of the muscles and extreme emaciation. He recovered, however, at last. There was no other case of diphtheria in the prison, and the only probable explanation of the way in which the contagion had reached the patient was that the prisoner had worked in a shed where a man from outside, whose child suffered from diphtheria, had previously been.

INTERNATIONAL LEGISLATION FOR THE PREVENTION OF EPIDEMICS.—At the Vienna Congress for Hygiene Professor von Pettenkofer said that as long as the etiology of cholera was not thoroughly known, the practical conclusions at which they might arrive would not be accepted as having much weight. All measures which restricted intercourse and interfered with commerce, and quarantine of all kinds, were worthless. The proposed practical prophylactic measures, such as disinfection and isolation, could prevent the spread of cholera just as little as the omission of them would propagate it. This was proved in Bavaria, in 1836, when no measures whatever were taken to stop the spread of the epidemic, and the course of the disease was, nevertheless, milder than ever before. After once more citing the example of England, Professor Pettenkofer expressed a hope that the system of quarantine would be altogether abandoned.

Dr. Angelo di Mosso, of Turin, stated that the preventive measures which had been taken in Italy, in 1884 (cordons, quarantine, isolation) had completely failed to check the disease, whilst causing much inconvenience and suffering to the country, whereas the present epidemic, though, in accordance with the order of the Minister, Signor Crispi, no such precautions had been taken, had run a much milder course, and had already nearly died out.

Dr. Stekoulis, of Constantinople, and Professor Conradi, of Bologna, also spoke against the utility of quarantine, the former particularly condemning the blockade of the Suez Canal.

A resolution as to the proposed international legislation for the prevention of epidemics, which had been drawn up by the reporters, Drs. Sonderegger, Vallin, Murphy, and Finkelsburg, was then read. It was in the following terms: The Third Section of the Congress expresses the desire that an international convention should be arranged between the different States for their common protection against cholera, yellow fever, plague, etc., the said convention to be based on the following principles: 1. Compulsory notification of each case of the above-mentioned diseases to be made without delay. 2. In a neutral European State an office should be established which should be a centre of information to which the first cases of epidemics, and regular accounts as to their course, should be forwarded by telegraph; these accounts should then be transmitted by the office to all the States which participated in the convention. 3. The convention should lay down rules for the proper sanitation of seaports and centres of commerce, etc. 4. The States taking part in the convention should take all necessary steps to prevent the shipping of persons or goods from localities in which any of the above-specified diseases were prevalent. 5. Vessels arriving from infected places should be so arranged that the patients could be isolated on board, and the necessary disinfection performed. 6. Ships coming from infected places should be submitted to a medical examination at the port where they arrive. 7. When cases of cholera had occurred on board the ship, the patients should be disembarked and isolated, and those who were suspected should be kept under observation until the true nature of the disease was established. 8. The ship should be kept under observation until disinfection had been duly carried out and it was certain that no epidemic was to be met with on board the ship. 9. At the ports of the Suez Canal an international board of medical supervision should be established, and the officials should be appointed by the Sanitary Council of Alexandria. This proposition was, after some discussion, carried by a large majority.

A proposal brought forward by MM. Ruysch, Brouardel, and Silva, that the Austrian Government should be asked to call the Sanitary Conference of Rome once more into existence, or to summon such a Conference at Vienna or elsewhere, was also accepted.—*British Medical Journal*, November 5, 1887.

POSTURE IN SLEEP.—The *Lancet* of November 5, 1887, writes as follows on this subject:

It would seem on the first blush of the matter that the posture for—that is, to favor—sleep must be generally the same as that voluntarily or instinctively assumed during sleep; but a little consideration will make it apparent that this is not correct. It may be granted that, supposing a person to be sleeping lightly and uncomfortably, the posture will be changed half-consciously to one of comfort. It would be more correct to say that it is changed in the endeavor to avoid distress or discomfort; but even the fact that sleep is quieter in the new position, will not suffice to prove that this is a better one, because the sleep may meanwhile have become deeper. It is, on the whole, impossible to ascertain, either by experience or observation, which is the posture most conducive to sleep, and attempts to lay down rules for the guidance of bad sleepers are always arbitrary, generally empirical, and rarely of any practical value. Those who think "anæmia of the cerebrum" is the cause of sleep, and those who think that, though not the cause, a diminution in the quantity of blood in the vessels of the encephalon is a necessary concomitant of sleep, prefer, and recommend, that the head should be higher than the feet; while those who adopt the opposite view, and think passive congestion causes or promotes somnolence, would have the feet raised and the head lowered. The confounding of stupor with sleep may, and probably has, something to do with these differences of opinion. Meanwhile, a common-sense view of the subject would conclude that, as there is evidently some change in the blood-state when the brain falls asleep, the best plan must seem to be to place the body in such position that the flow of blood through the vessels of the head and neck may be especially easy and free. The way to secure this, is to allow the head to lie in a posture and on a level that cannot offer any obstacle to the free return of blood through the veins of the neck, and does not tend to make the blood flow specially in any particular direction, but leaves Nature at liberty to act as she will.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.

SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, NOVEMBER 26, 1887.

THE CONTAGION OF SCARLET FEVER.

ONE of the most important questions now before the profession is that of the nature and properties of the contagious principle of scarlet fever. In common with all the eruptive fevers, it has long been supposed that the exciting cause of this disease would be found in a microörganism; and, indeed, in its mode of onset, course, and decline, it produces in an impressive degree all the characteristics of a disease caused by the invasion of organized beings and their subsequent development.

Although numerous scattered attempts to discover the supposed germ have been made during the last few years, they have been so imperfectly and faultily carried out that they attracted little or no attention. Recently, on account of the epidemic proportions assumed by the disease in England, the subject has acquired new prominence, and, as a result, a number of investigations have been recently made, the most important of which are those of JAMIESON and EDINGTON, and KLEIN, and a study of their work is valuable in showing what must be done by future investigators to settle definitely the subject.

Dr. Klein's researches were directed mainly to a disease among cows in a certain dairy, the milk of which was supposed to have caused an epidemic of scarlet fever. His conclusions were justly criticised, and it has been shown that the cows in question did not have scarlet fever, while the real cause of the human disease seems to have been found elsewhere, as shown by THIN, in the *Brit. Med. Journ.* of August 20, 1887. Edington studied the bacteriological side of the disease in the human being, and found in a number of cases several forms of microbes. One of these, provisionally named by him *bacillus scarlatinæ*, was found in the blood in all cases examined before the third day, and in the desquamation of all after the thirtieth. The deductions from the latter statement are difficult to reconcile with our present knowledge. Edington's report has been made the subject of inquiry by a special committee of the Edinburgh Medico-Chirurgical Society, the final report of which has not yet been issued. We can, however, from the facts already in our possession, point out certain things which must be thoroughly explained before any real advance can be made.

First, in regard to scarlet fever in the lower animals, especially calves. It has long been believed that cows, horses, and some other domestic animals, under favorable circumstances, could acquire a disease identical with human scarlatina. This has been flatly contradicted by intelligent men of large experience in stock-raising, and by physicians, and this negative testimony has been strengthened by the experiments of the Edinburgh committee, which obtained negative results in two inoculation experiments with scarlatinous blood, and one attempt at feeding the desquamated scales in calves. If this be so, and applies to all available animals, the difficulty of proving any specific cause in man will be greatly increased.

In regard to Edington's bacillus, it is evident that his observations were too few in number to permit of generalization even if his investigation had more intrinsic merit, for its precise nature is not yet known, and it has been asserted to be nothing more than a non-pathogenic organism. To make out the causal connection, the organism must be found in all of a large number of cases, by different observers in different localities. It must be shown to be present in the blood, or tissues, or both, of the affected persons in one or all stages. It must not be a commonly occurring parasite or saprophyte which has gained access to the body in an early stage. According to the strict rules laid down by Koch, the organism would have to be cultivated pure, and the pure cultures possess the power of reproducing the disease in men or animals susceptible to it.

These are the lines that must be followed to discover the cause. Whether Edington's investigations and those of the Committee will achieve this, the near future will tell. With the earnest work the subject is now receiving, it is fair to hope the desired information will not be long delayed.

The question of contagion associates itself narrowly with attempts made to discover the cause of the disease by examinations of the desquamation. Any results based on these must be received with great caution. Before any scientific work can be done in that direction, an immense amount of research must be accomplished with the organisms of the healthy skin. As

a result of his investigations, Jamieson recommends the use of baths and antiseptic ointments to prevent contagion. In the absence of any more positive knowledge of the nature of the contagion and the duration of its activity, these precautions may well be followed, and all the more since they were indicated by experience and observation in days when the contagion was supposed to be of a much more impalpable nature than at present. Jamieson advises the use of an ointment of carbolic acid in the proportion of one to thirty-two, as the result of culture experiments with the bacillus scarlatinæ, and continues its use until the thirtieth day of the disease, a period which might be lengthened with advantage to patient and all others exposed.

PTOMAINES AND SUPPURATION.

Some observations of Grawitz, in the October number of Virchow's *Archiv*, if confirmed, will add a great deal to our knowledge of suppuration. From some earlier experiments Grawitz was led to believe that in subcutaneous inflammations in which bacteria were actively concerned, suppuration was caused, not by the bacteria directly, but by chemical products—ptomaines—resulting from the metabolic activity of the bacteria. According to him, therefore, the rule would hold good that, aside from artificial phlegmons caused by the injection of ammonia or turpentine, in abscess of the subcutaneous fatty tissue, the tissues are first prepared, as it were, by the chemical products of the so-called pyogenic bacteria (staphylococcus pyogenes aureus, albus, streptococcus), and then the bacteria multiply and carry the process further by the formation of new alkaloids.

Experiments have shown that many organisms not usually considered pyogenic—e. g., micrococcus prodigiosus—furnish chemical products capable of exciting inflammation and suppuration; but as these substances have not yet been thoroughly studied, it is better to begin research in the new field with those ptomaines which have already been isolated. For this reason Grawitz used in the experiments now under consideration *cadaverine*, a non-poisonous alkaloid discovered by Brieger as the result of putrefaction in various substances from different causes, and the morbific effects of which had not previously been accurately studied. This alkaloid occurs as a colorless liquid, soluble in water, and in dilution of one per cent. has a strong alkaline reaction. The pure alkaloid contains no bacteria, so that dilutions with sterilized water are easily prepared. A 2.5 per cent. solution kills staphylococcus aureus in an hour, while extremely small amounts retard or check the growth of these bacteria. All cadaverine producers, therefore, may be considered as antagonistic to the pyogenic cocci in the sense of Garré, though practically this fact has not the value the latter observer seems to impute to it, for Grawitz's experiments show that cadaverine is itself pyogenic. By the subcutaneous injection of solutions of cadaverine which were free from germs the result was, according to amount and concentration, either escharotic action or inflammation followed by suppuration or inflammatory œdema, with subsequent absorption and simple healing.

For the details we must refer the reader to the original paper. The experiment, which is quoted at length, seems to prove beyond doubt that the alkaloid caused suppuration without the presence of bacteria. Most of the cases are without bearing on the question, as necrosis of the skin came on so soon that bacteria were able to penetrate it. In some cases the bacteria—large bacilli—were found in large numbers. They could not be successfully cultivated in agar-agar. That they were not the cause of the suppuration is evident from the fact that pus containing them injected into dogs was absorbed without any evil consequence, and when the cadaverine had exerted its greatest escharotic effect no suppuration followed, though then the bacilli could enter with least difficulty. That the bacilli or their spores were introduced at the time of injection is rendered improbable by the fact that weak solutions were absorbed both in dogs and rabbits. The effect was, therefore, as stated above, in proportion to the quantity and concentration of the alkaloid. Injections of mixtures of staphylococcus aureus and cadaverine were absorbed when the dilution was carried far enough, while strong solutions killed the microbes before the inflammatory exudation could cause a further dilution. In the resulting abscesses only the bacilli spoken of above were found, and no culture of the yellow coccus could be made.

In one group of cases injection of cadaverine with staphylococcus aureus caused phlegmon in the surrounding tissue beside the necrosis of the skin, and in the pus of the phlegmon were found the staphylococcus and various other bacteria. It follows that cadaverine can cause purulent inflammation, and when pyogenic microbes are present they can still further promote the suppurative action.

It is of great practical importance, as shown by Grawitz, that cadaverine, a common result of putrefaction, when introduced into the tissues can cause inflammation and suppuration. For it proves that the old views, according to which putrefaction of wound secretions caused pyæmic disease, are still valid. These observations, by so competent an investigator as Grawitz, deserve careful study and repetition. As said before, they have an important bearing on the subject of suppuration. That they will alter the well-grounded belief that in nature all suppurations are caused by bacteria—in other words, "with-

out microbes no suppuration"—is not probable. It is quite evident there are a number of microörganisms beside the few with the specific name "pyogenic" that in some way or other cause suppuration, and as the putrefactive alkaloids are the results of bacterial action, it is only making another step in the process and not altering the conditions, to unite the alkaloid directly with the suppuration.

Although in these experiments no general effect on the animals used could be made out, we have no doubt that further research with the putrefactive alkaloids will lead to an immense increase of our knowledge of infectious diseases in the narrower sense.

A novel experiment in medical teaching is to be tried at the University this coming week. All medical men have felt the great need of practical instruction in what may be called "Medical Dietetics," the lack of which has often sorely tried the young practitioner when asked by his patients such questions as how to make beef tea, wine whey, and the various delicate foods so needed by the sick. As a matter of fact, how can one give directions unless some previous training has made him competent to do so?

Dr. George Strawbridge, assisted by Miss Davis, proposes to give a course of illustrated lectures on every Wednesday afternoon to cover this ground.

The first lecture will be next Wednesday, at 4.30 P.M., at the University Hospital. *The preparation of milk foods* will be the subject, and the lecture will be illustrated by practical demonstrations.

The second lecture, on the following Wednesday, will be on the *preparation of beef tea, broths, etc.*, the *proper method of cooking meats, vegetables, etc.*; and like subjects will be taken up in order.

The course is open to the medical profession without fee.

The patient upon whom Prof. John G. Jay, of Baltimore, performed the Sänger-Cæsarean section four weeks ago, has now recovered, so far as the operation is concerned. There has been but little rise of temperature during the course of the case, and, it might be said, no unfavorable symptom. The secret of success is early operation, close suturing of the uterine wound, and surgical cleanliness. We are informed that six operations, with four recoveries, have been performed in this country during this year.

At the meeting of the Berlin Medical Society on October 12, 1887, a communication from Secretary-General Hamilton was read, announcing to the Society the choice of Berlin as the meeting place for the next International Medical Congress.

Professor Virchow, president of the Society, read the communication, which had been also sent to von Bergmann and Waldeyer.

Professor von Bergmann succeeds von Langenbeck as editor-in-chief of the *Archiv für klinische Chirurgie*.

The Death of Dr. Robert Greenhalgh, formerly accoucheur and lecturer to St. Bartholomew's Hospital, is announced. Twenty years ago he performed a successful Cæsarean section for epithelioma of the cervix, and he was one of the earliest advocates of measures of surgical treatment in contracted pelvis, now acknowledged to be correct.

SOCIETY PROCEEDINGS.

OBSTETRICAL SOCIETY OF PHILADELPHIA.

Stated Meeting, November 3, 1887.

The President, T. M. Drysdale, M.D., in the Chair.

CATHETERIZATION OF THE URETERS.

Dr. B. C. Hirst said that, after seeing the urethral catheters that were shown by Dr. Kelly at the last meeting of the Society, and hearing his commendation of them, a case came under his observation in the Maternity Hospital which seemed eminently suitable for the application of these instruments as an aid in arriving at a correct diagnosis. The clinical history of the case is briefly as follow: A young primagravida was found to have both pus and albumen in her urine, which condition persisted after delivery. The case was treated as one of cystitis, by vesical injections, but without much benefit. Some three weeks after delivery, the quantity of urine excreted in twenty-four hours became decidedly lessened, while the amount of pus became both actually and relatively much decreased. At the same time the temperature rose to 104°, and there was considerable pain over the region of the right kidney. This history would, of course, have led one to suspect "lithogenic pyelitis," resulting in the formation of a stone in the pelvis of the right kidney, which had suddenly plugged up the outlet from the kidney and has thus diminished the quantity of urine and decreased the amount of pus. Answers to the following questions were desirable: 1. Was the *right kidney* chiefly affected, or was the pain on the right side referable to a morbid condition of the left kidney? a possibility to which attention has been called, especially by Knowlsley Thornton. 2. Were both kidneys diseased, or was one healthy? 3. Did the pus really come from the kidneys, or was it confined to the bladder? He was able to solve these problems by the use of the ureteral catheters. The ureters were made out without difficulty by abdominal palpation, and then the catheters, first the metal and then the flexible, were introduced with ease, the flexible catheter being pushed up the right ureter a distance of eight and a half inches. The specimens of urine collected in separate test tubes from each kidney, showed, on inspection, a much greater turbidity in that from the right than in that from the left kidney. A microscopic examination

revealed pus in both specimens, but in that from the right side in much larger amounts than in the specimen from the left kidney. In the urine from the left side a well-defined granular cast was found. He could say, then, 1. That the pus came from the kidneys. 2. That both kidneys are diseased, but the right is most markedly affected. 3. That there is not only pyelitis, but pyelonephritis in the left kidney; arriving thus at a precision in diagnosis that would be impossible without the use of the ureteral catheter.

Dr. Hamill had, since the last meeting, palpated the ureters without difficulty, and had passed the catheter into them. The ureters were about the size of the little finger.

Dr. Kelly has, since the last meeting, operated successfully for the relief of a ureteritis in an unmarried young woman; the pelvic organs were healthy. The inflammation was confined to the orifices of the ureters. He experienced no difficulty in passing the catheters.

Dr. Philip M. Schiedt read a paper on

THE DELIVERY OF THE AFTER-COMING HEAD.

"Time is the great factor in these cases. It is generally conceded that if the head is not delivered in from five to eight minutes after the delivery of the body, the child will be stillborn." Dr. Schiedt took up the history of the literature of the subject from the time of Celsus, and the method of "expression" by suprapubic pressure, down through the various manual methods. He deprecated the neglect of this subject by American and English authors, and entered very fully into a criticism of the methods advocated by German and French writers. His own deduction from an analysis and comparison of these authorities, who widely differ in their teachings, and from his own experience, is that the forceps constitute "the best, quickest, and safest treatment."

Dr. William Goodell had been struck by what seemed to him a great, although common mistake, trying to secure flexion of the head in breech deliveries. In a flattened pelvis it is better for the head to descend in a transverse position, so as to enable its shortest diameter, the bitemporal, to correspond to the short diameter of the pelvis, the antero-posterior. In a juxtominor pelvis the operator would be justified in trying to secure flexion. The fingers in the fœtal mouth are useless for good, and there is danger of breaking the jaw. The forceps is the only proper aid in the expulsion of the after-coming head. One objection often made to their use is the loss of time involved in their application, but this does not hold. The accoucheur should be acquainted with the form of the patient's pelvis. The body of the child should be held away, so that the forceps can be applied to the sides of the head, the handles being on the anterior aspect of the child's body. Another point to bear in mind in a flattened pelvis, is the problem of bringing the head safely around the promontory of the sacrum. The hand should grasp the neck of the child, the thumb being on one side and the fingers on the other, and traction should be made so as to ease the head around the promontory base, securing rotation of the face into the hollow of the sacrum. After this it would be easy to make the chin engage or to apply the forceps.

Dr. Longaker laid great stress upon the necessity of avoiding mismanagement in the early stages of a breech delivery; there should be no immediate haste. If the legs are seized and drawn down upon, the body is quickly delivered without securing dilatation of the os uteri and the arms become extended beside the head in the grasp of the lower segment of the uterus; forcible extraction at this stage is a frequent cause of extensive laceration and has caused death of the mother. He agreed with Dr. Goodell as to the treatment of these cases in flattened pelves; the adaptation of the bitemporal diameter to the direct conjugate should be secured and the obliquity of Nagele should be maintained until the anterior base has well descended into the cavity of the pelvis. The late Dr. A. H. Smith laid great stress on the propriety of using the forceps to assist in the delivery of the after-coming head. In applying the forceps, flex the body of the child toward the dorsum, and the handles of the forceps should be on its anterior aspect. Pressure over the head of the child, while the body is swept toward the belly of the mother is not a good or safe method; the amount of traction required to extract the head is too great for the neck to bear. The forceps should be in readiness to apply as soon as the body has escaped from the vulva.

Dr. Ellwood Wilson thought it a common mistake to hurry the delivery of the body of the child. When dilatation of the os is complete the child will descend with the arms folded on the body. He is as strong an advocate of the application of the forceps to the after-coming head as any man can possibly be.

Dr. Thomas M. Drysdale reported a

CÆSAREAN OPERATION

(see p. 621),

made necessary by the presence of a uterine fibroma impacted in the pelvis.

NEW YORK SURGICAL SOCIETY.

Stated Meeting, November 9, 1887.

The President, Charles McBurney, M.D., in the Chair.

SUCCESSFUL CASE OF LAPAROTOMY FOR BULLET-WOUND OF THE INTESTINE.

Dr. Lange reported the following case: On the 12th of October he saw at the German Hospital a boy, fourteen years of age, who, twenty-four hours before, while playing with a small revolver (22 calibre), shot himself in the abdomen, the ball entering about one and a quarter inches below the navel, and about one inch to the left of the median line. He did not look as if he was suffering from shock. His pulse was 112 to 120, his temperature 101°, and he did not have much pain, although there was marked tenderness on making pressure over the left hypogastrium. There was some tympanites, and the abdominal wall was tense; the breathing was almost entirely costal. The normal liver-dulness was preserved, and there was no change in the ordinary percussion sounds. There was evidently commencing peritonitis, thus far limited to the left hypogastric region.

Laparotomy was performed at once, the abdomen being opened in a line with the point of entrance of the

bullet. The track of the latter could not be traced through the muscles, nor could any wound be found in the peritoneum, although there was a small extravasation in the retroperitoneal space. On opening the peritoneum, about an ounce of brownish, sanguinolent fluid escaped. The wound was enlarged to about six inches, and the intestines were lifted out and carefully examined. Seven perforations were found in the gut, both walls being pierced in three places, while the fourth wound involved only one wall. About four ounces of bloody fluid were discovered at the deepest point of the abdominal cavity, but it did not have a fecal odor, nor was any fecal matter mingled with it. The openings in the intestinal wall appeared as small, grayish spots surrounded by zones of hyperæmia. The mucous membrane was nowhere everted, but all the openings seemed to be firmly closed. At one point the track of the ball was visible in the wall of the gut. Six of the perforations were closed with three or four interrupted sutures of iodoform catgut, while the seventh was not touched, as it seemed to be firmly united.

The boy made a good recovery. The temperature did not rise above 101°, and became normal on the twelfth day, after evacuation of a mural abscess. The bowels moved spontaneously on the third day, in spite of opium, the discharge being dark in color and very fetid, this being probably due to decomposed blood. During the next four days they moved three or four times daily. The ball was not found in the stools, although search was made for it.

The interesting question in the case was: Might the boy have recovered if no operation had been performed? The exudation and extravasation might have been absorbed, and the peritonitis localized. To what degree, the reporter was asked, did the danger from gunshot wounds increase in proportion to the size of the projectile? There were cases on record in which spontaneous recovery had followed wounds from small bullets. In the one reported there was no evidence that fecal extravasation had occurred, and apparently the closure of the small wounds had taken place so promptly and accurately, that under proper care and treatment, without operation, the danger of secondary escape of the contents of the gut could naturally have been avoided.

Dr. Stimson recalled the case of a man who received a bullet wound of the abdomen, the ball, which was of moderate size, entering a little to the left of the median line, midway between the border of the ribs and the umbilicus. He saw the patient on the following day, and found a slight elevation of temperature, with marked tympanites. The wound was not probed, but there was good reason to believe that the bullet had passed into the abdominal cavity. Opium was administered, and the patient made a good recovery.

Dr. Wyeth said that in July, 1887, he had been called to a neighboring city to see a boy, aged sixteen years, who had been wounded by a rifle-ball (38 calibre), which entered the abdomen at a point two inches above the crest of the right ilium, and half-way between that spot and the spines of the vertebræ, and came out one inch below and to the left of the umbilicus. The boy complained of severe pain and suffered from shock, lasting for four or five hours, after which he rallied, and was in good condition from 10 P.M. until 6 the next morning, when symptoms of peritonitis developed. Dr. Wyeth saw him at 1 P.M., nineteen hours after the accident, and found him delirious, with a pulse of 160, a high temperature, and a tympanitic abdomen. He declined to operate, as death was inevitable. The patient died two hours later. The boy was strong and hearty, and would probably have recovered if laparotomy had been performed at once. Although an autopsy could not be obtained, the intestine was doubtless perforated.

Dr. Hall said that he had seen two cases of recovery from bullet wounds made with a 22-calibre revolver ball. He asked if any of the members had seen a fatal case.

Dr. Abbe replied in the affirmative. He had had under his care a strong man, who had received a wound in the abdomen from a bullet of 22 calibre. The ball entered just below the umbilicus, and exactly in the median line, perforating the intestine in four places, and the wall of the bladder in one; it remained within the latter viscus. Laparotomy was performed six hours after the injury occurred, and a pint of greenish fluid, mixed with fecal matter, was found just underneath the parietal wound, and surrounded by adhesions. The man died of shock fifteen hours after the accident. Uræmia doubtless contributed to his death, as complete suppression of urine occurred several hours before.

Dr. Wyeth cited an instance of the rapid formation of adhesions after a secondary laparotomy for volvulus of the intestine. The gut was so distended that it was necessary to puncture it in several places, the punctures being closed with sutures of black silk. The patient died in three hours, and even in that short time the sutures had become almost entirely concealed by plastic lymph.

Dr. Stimson said that about a year ago he had seen a gentleman who had accidentally shot himself with a revolver of 45 calibre, the ball entering the body a little to the left of the xiphoid cartilage and emerging at a lower point in the back, near the vertebral column. When seen he had paroxysmal dyspnœa with extreme pain. The wound was not probed, except to a sufficient depth to establish the fact that the ball had perforated the seventh costal cartilage; it was plugged with iodoform gauze. Under the use of opium, with rest, the patient recovered in three weeks. The bullet probably traversed the anterior part of the diaphragm, perhaps also the abdominal cavity, and certainly perforated the pleura, as the man had all the symptoms of perforation of the lung—hæmoptysis, with dulness over the lower part of the chest.

Dr. Lange thought that it was important to gather further experience about the question how soon after an average perforation of the intestine, with fecal extravasation, symptoms of septic peritonitis appeared, and, whether perhaps in a case like the one reported, where twenty-four hours after the injury only localized peritonitis existed, without particularly alarming symptoms, the assumption might be justified that the peritonitis was not due to the escape of the contents of the gut into the peritoneal cavity. The operation, which became necessary in searching for bullet-wounds in the gut, would always be a serious surgical interference, carrying danger in itself, to avoid which might, in a given case, be of the greatest importance.

Dr. Sands said that laparotomy in gunshot wounds

or the abdomen ought to be performed before the occurrence of grave symptoms. Experience must show how far we may safely explore the abdomen in order to ascertain the exact nature of an injury. Many patients doubtless lose their lives because the surgeon waits too long. Recovery, to be sure, is possible in the case of wounds made by small projectiles, but even these of small calibre may cause fatal extravasation. If it can be shown that laparotomy is not in itself very dangerous, it may obtain the preference in nearly every doubtful case, even when the bullet is very small. Until we know just what the risks of operation are, most surgeons will favor laparotomy. It may subsequently be shown that laparotomy for gunshot wounds of the abdomen is a very dangerous procedure, and the statistics will perhaps never bear comparison with the operations performed for the removal of ovarian tumors.

Dr. Stimson thought it equally important to collect evidence to show the danger following perforation of the abdomen by bullets of small calibre, for if that danger is less than that of exploratory laparotomy, the operation may still be controvertible.

Dr. Wyeth thought that the reason why wounds of intestine made by small projectiles do not invariably prove fatal, is due to the fact that the gut was not filled with gas at the time of the injury. If gas be present, it may escape into the peritoneal cavity, no matter how small the perforation.

Dr. Abbe called attention to the fact that in his case fecal extravasation had clearly taken place from one wound in the free border of the intestine. At every inspiration of the patient fluid was forced out at this point. It was evident that extravasation through such openings is inevitable as soon as the gut becomes full; whereas, when the perforations are at or near the attached border this is not apt to occur.

Dr. Hall said that he could recall only a single case in which recovery had occurred after fecal extravasation. In one instance (reported by Mikulicz) some pieces of potato, but apparently no feces, escaped through a perforation resulting from a typhoid ulcer.

Dr. Lange was sure that there were several cases on record in which recovery occurred after extravasation.

MARKED DIMINUTION IN THE SIZE OF A UTERINE FIBROID FOLLOWING REMOVAL OF THE APPENDAGES.

Dr. Abbe showed photographs of a patient upon whom he had operated a year before. She was a colored woman, aged twenty-four years, who had a uterine fibroid as large as a man's head, of three or four years' growth, which occasioned severe pain and attacks of flooding. Laparotomy was performed, with the assistance of Dr. Peters. It was necessary to lift the growth out of the pelvis before the appendages could be reached and removed, so that an intelligent idea of its size was gained. She made a good recovery, and had been perfectly well since the operation, so that she was able to work hard as a laundress. Menstruation returned regularly at intervals of twenty-eight days, but there was neither pain nor flooding. Her sexual feelings were not impaired. The girl was examined a day or two since, and it was found that the tumor had diminished in size, at least, one-half.

Dr. Lange said that he had had two patients under observation for upward of a year, upon whom he had performed the same operation. In both cases the growth had diminished to one-half the former size. One patient had not menstruated at all; the other had continued to menstruate for some time, and then had epistaxis every month instead.

Dr. Briddon asked if the persistent menstruation could not be explained by reference to the presence of a third ovary.

Dr. Abbe thought that this explanation could not be generally urged, because the recorded cases of supernumerary ovaries are comparatively few, while persistent menstruation after removal of the appendages, is not uncommon.

CALCULUS OF PECULIAR SHAPE.

The President exhibited two calculi which he had removed by the lateral section, from a boy, aged eleven years. One stone was almond-shaped, while the other was larger and presented two concave surfaces, which had apparently resulted from alternate friction against the other calculus. There was nothing peculiar about the shape of the bladder.

Dr. Lange asked if the biconcave stone might not contain a foreign body.

The President did not see how this would account for the peculiar shape of the calculus.

Dr. Briddon said that if a foreign body formed the nucleus it would be apt to have concentric layers completely surrounding it.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, November 7, 1887.

The President, D. Hayes Agnew, M.D., in the Chair.

Dr. Thomas G. Morton reported

THREE CASES OF LAPAROTOMY

which he had performed in the last five weeks, all of which recovered.

Case I.—A colored woman, aged twenty-six years, admitted to the Pennsylvania Hospital, September 20th, complaining of intense pain. The history was that two years prior to admission she had an abortion and that since then there have been many attacks of undoubted gonorrhœal infection. At the time of admission her features were pinched and temperature was 102°. Shortly afterward she had a sharp chill with a rigor which lasted half an hour. The right Fallopian tube was found much enlarged and there was evidently an abscess of considerable size connected with it. The left tube was also much enlarged, but he could not make out any distinct abscess connected with it.

Early the following morning the abdomen was thoroughly cleansed and an incision made. The left ovary, which was enormously enlarged, was bound down by adhesions, and an abscess, which was as large as a goose egg and connected with the right ovary, ruptured during the operation, the contents of the

abscess escaping into the peritoneal cavity. The tubes and ovaries were removed, the cavity thoroughly washed out with hot distilled water, and a drainage tube inserted in the lowest part of the abdominal cavity. In the tube was placed, as has been suggested by Dr. Joseph Price, a rope of absorbent cotton, which can be replaced as often as it becomes saturated with the discharge. This patient made a rapid recovery. Within twenty-four hours the temperature dropped from 102° to 99°. She is now perfectly well.

Case II.—Oct. 11th, a mulatto seamstress, aged twenty-seven, married, was admitted with prolapse of the right ovary. She complained of pain in the hypogastrium, the small of the back, the occiput, the vertex, and under the left breast, increased by motion, by defecation, by urination, and on the appearance of the menses, which had been irregular. Her general health had failed and for more than a year she had been unable to do any work. She has been married eleven years, but does not live with her husband. Has never had children. The uterus was normal, retroverted, and retroflexed. The right ovary was prolapsed, slightly enlarged, moderately fixed, and exquisitely tender. She was ordered hot vaginal douches twice a day with quinine. October 16th, the abdomen and pubes were shaved and washed with turpentine, soap, and water, and were covered with towels wet with the bichloride solution. Fifteen grains of quinine were given in the evening. The following day laparotomy was performed, an incision two and a half inches in length being made. The right ovary and tube were brought out after a few adhesions had been separated. Irrigation with boiled distilled water was then practised, and a glass drainage tube introduced. The wound was closed with catgut sutures. The cotton rope in the tube was changed as frequently as it became saturated with the bloody serum. The tube was left in until October 31st. On one occasion the temperature went up to 101.5°; this was due to constipation, and promptly dropped upon free exhibition of laxatives.

Case III. was interesting from the fact that it was unattended by symptoms from first to last. A colored woman, aged twenty, had been stabbed whilst at a ball, and was admitted to the hospital on the evening of Oct. 24th. The knife entered on the left side between the umbilicus and the anterior superior spinous process of the ilium, two and one-half inches from the latter. At the time of admission a mass of omentum protruded from the wound. He saw her about 11 P.M.; she was in fairly good condition. As there was undoubted penetration of the peritoneal cavity, he had no hesitancy in at once making a median incision five inches long. The intestines were carefully examined throughout their whole length, but no injury was found. The omentum was returned, and the abdominal wound closed with four silk and seven catgut sutures. No drainage tube was employed. The next morning she got out of bed, and insisted on going home. She was constrained to remain until the sixth day, when she went home and resumed her usual duties. Five days later she returned to the hospital and had the stitches removed. The temperature never went above 99°. He has visited her twice since, and she was perfectly well when last seen, a couple of days ago.

There is one point with reference to the drainage tube to which he desired to allude. When a drainage tube is introduced, it is, of course, surrounded by intestines, and it seems remarkable that there should be no inflammatory action about it, other than sufficient to cause the exudation of the column of lymph which surrounds the tube.

Dr. D. Hayes Agnew said that he recently saw a case where an attempt had been made to remove an abscess, the result of perituterine cellulitis. In cutting down the bowel was opened. A tube was then put in, and when removed, a short time after the operation, there was left a perfect canal communicating with the bowel, through which feces escaped. The tube had been allowed to remain ten days.

Dr. William Hunt said that the rapidity with which this exudation takes place explains many cases of recovery after wounds of the intestine where laparotomy has not been performed.

Dr. O. H. Allis pointed out that in stab-wounds of the abdomen it is often difficult to say what damage has been done. A party of children were playing football in a neighboring town. While one of the children was repairing the ball some one pushed him, and the blade of a penknife penetrated the abdomen. The wound did not cause any pain, and nothing was known of it until the development of peritonitis.

Dr. J. M. Barton said that it is often claimed that there is no danger from a laparotomy, but there is a certain element of risk. He thought that it is a matter of great importance not to open the abdomen unless there are symptoms calling for it. He has now under observation a young man who, a short time ago, while gunning, slept in an unfinished club-house. During the night he got up and walked out of an open doorway in the second story, falling a distance of twelve feet and striking the abdomen on the edge of a rafter. He was considerably shocked and lay in the club-house until morning, when he walked a distance of a mile and a half to the railroad station. That evening he had decided peritonitis. When seen in consultation the following morning, the question arose as to the advisability of opening the abdomen. From the fact that the man had been able to walk a long distance, he concluded that there had been no rupture of the intestine. If there had been, he should have expected decided collapse. The peritonitis was violent and the temperature high. Under ordinary treatment the man recovered in a week's time.

Dr. Thomas G. Morton said that in connection with suppurative disease of the tubes, he would refer similar disease attacking the testicle to extension by continuity of specific inflammation of the urethra. He recently had a case of great enlargement, the result, apparently, of ordinary inflammation of the testicle, in a man, fifty years of age, who had a hernia on the affected side and was unable to wear a truss on account of the condition of the testicle. He decided to remove the testicle, believing that there was degeneration of the gland. In the centre of the testicle a cavity containing two and one-half drachms of pus was found. He had another similar case, convalescent, in which he pursued the same treatment, and found similar conditions. There is no reason why suppurative inflammation should not analogously travel along the tube in the one case as well as in the other.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, November 7, 1887.

THE PRESIDENT, J. SOLIS-COHEN, M.D., IN THE CHAIR.

DR. SOLOMON SOLIS-COHEN read a paper on

LAVAGE IN THE TREATMENT OF GASTRIC AFFECTIONS.

Any agent, or any method which promises to enlarge our therapeutic resources against those obstinate conditions of "gastric catarrh," "functional dyspepsia," etc., which are a source of distress to the patient, of annoyance to the physician, and of profit to the pepsin and patent-medicine manufacturers, deserves at least a respectful consideration. The method of lavage, or irrigation of the stomach, has been employed for many years in Europe, so that it can no longer be considered to be merely on trial. In America, however, it has not won general introduction.

In the treatment of the more readily accessible mucous surfaces, whether of the eye, the nose, the throat, the vagina, or the urethra, the importance of keeping the parts free from morbid secretions, from the products of desquamation, and other sources of irritation, is not a matter for debate. The extension of the same principle to the treatment of affections of the gastric mucous membrane, is but a question of mechanical detail, not of therapeutic justification. Kussmaul, in 1867, employed a doubly-acting stomach pump to irrigate the stomach with alkaline solutions (Carlsbad water), and it is to this observer that we are principally indebted for a study of the method, mechanically and therapeutically.

The apparatus and its employment are sufficiently simple. An œsophageal tube with blunt, double-eyed extremity, of flexible rubber, about twenty-eight inches long, and from one-quarter of an inch to a little less than half an inch in diameter, is attached by a small section of glass tubing to a soft-rubber tube about one yard in length, into the free extremity of which a glass or rubber funnel, of from six ounces to eight ounces capacity, is inserted. Sometimes the free extremity of the œsophageal tube is slightly stiffened. The œsophageal tube having been dipped into warm water or warm milk, is placed within the entrance of the œsophagus, and is then propelled by successive pushes into the stomach; the process being facilitated by efforts at deglutition on the part of the patient.

The funnel is then elevated to the level of the patient's forehead, and from a pint to a quart or more of the lavage solution is slowly poured in; the glass junction tube permitting its passage to be watched, and obstruction or attempted regurgitation to be detected. The patient's sensations will usually inform us when a sufficient quantity of the solution has entered the stomach. As the last portion of liquid disappears from the funnel, the soft-rubber tube is pinched near the extremity, the funnel is rapidly inverted over a receptacle placed upon the floor; and the contents of the stomach are thus removed by siphonage. These manœuvres are repeated until the returned fluid is clear. Sometimes during the withdrawal of the solution, solid particles of food (grains of corn in one of my cases) may become impacted in the eyes of the tube, and the flow of liquid will cease. A little more of the solution must then be introduced, both to wash away the obstruction and to reëstablish the siphon current. If the tube should be pushed too far into the cavity of the stomach, it may curve upon itself and the siphon will not work. Withdrawal of the tube for a few inches will remedy this.

When *lavation* alone (washing) is the object of the procedure, a weak alkaline solution is employed; a drachm or two of sodium sulphate, sodium chloride, sodium borate, or sodium bicarbonate, in a quart of warm water, at about 100° F. Should it be considered necessary, however, various sedative or antiseptic medicaments may be added to the lavage solution. Those most highly recommended are resorcin (one per cent.), boric acid (one per cent.), creasote (one per cent.), carbon disulphide water (one part of a solution containing fifteen grains to the quart, to two parts of water), charcoal powder (two to four tablespoonfuls), chloroform water (saturated), bismuth subnitrate (two tablespoonfuls to the pint). In the use of agents like resorcin, carbolic acid, etc., the liability to absorption if the solution be not all removed, must not be forgotten.

The effects are said to be most marked in cases of dilatation of the stomach, in which delayed digestion, retention and putrid fermentation of the contents of the stomach, give rise to distressing symptoms. In all cases where the gastric mucous membrane is in a catarrhal condition, coated with the glairy mucus which is seen amid vomited matters, or bathed in the sour liquid ejected as "water-brash;" where the production of gastric juice is impeded, or the secretion altered in quality by an abnormal condition of the membrane, extending perhaps into the tubules, or by the presence of irritative matters; where fermentation of ingested and retained matters takes place; in short, in the typical case of chronic gastric catarrh or acid dyspepsia, lavage will be found highly useful. It removes any undigested matters remaining in the viscus, cleanses it from products of desquamation and morbid secretion, and gently stimulates the glands and absorbents to healthy action.

In the chronic gastritis of drunkards, the measure is said to be an excellent palliative, nor is hæmatemesis considered a counter-indication, unless actual ulceration exists. In cancer of the stomach it is useful as a palliative measure.

Within the last few years two new applications of the lavage method have been found. In 1885, at Kussmaul's clinic, and subsequently by Senator, Rosenthal, and other observers, it has been successfully employed in the treatment of ileus. Kussmaul explains this result by the theory of relief to the tension above the point of constriction, caused by gases and accumulated feces; with concomitant restoration of normal peristaltic action.

While the practice is usually confined to chronic cases, Dr. Cohen had occasion to resort to it in one case of acute indigestion with obstinate vomiting, in a phthisical, slightly hysterical female; with gratifying result—in that the vomiting, rebellious to diet and medication, yielded to two applications of the stomach tube. In this case, before withdrawing the tube, warm milk was introduced into the stomach. Indeed, there can be little doubt that, in connection with *gavage*, or forced feeding, irrigation of the stomach assists in maintaining nutrition in phthisis and other wasting diseases.

DR. J. TYSON said that in one case of dilatation of the

stomach he had used lavage with a great deal of comfort to the patient. In a second case in which he employed it, the result was not so satisfactory, and it caused great discomfort.

Dr. W. Osler said he should like to state his experience in the use of irrigation, as this is a measure in which he has been interested for several years. In the first place, there is serious objection made to the procedure by at least one-half of the patients, on account of the discomfort experienced in the introduction of the tube. The soft tube is sometimes very difficult to pass, and sometimes it is necessary to resort to the stiffer tube. Where the patient himself performs the operation, it is, of course, better that he should have the soft tube. He is of the opinion that this measure has a much narrower field than the statements of French and German writers would lead one to infer. He would not hesitate to predict that within a few years, when the fashion has subsided, this measure will be confined entirely to cases of obstinate gastric catarrh in which it is of inestimable service, and to cases of dilatation of the stomach, in which it is not only of service but absolutely indispensable, as we have no satisfactory treatment for dilatation of the stomach other than irrigation.

Dr. J. P. C. Griffith said that during the past year he had been much interested in lavage in the diagnosis of diseases of the stomach. We, in America, are, however, unable to study the matter to any great extent, owing to the rebellion of patients to this method of examination. German patients appear to be more tractable, and Riegel reports that during the year 1885 he made over 1300 examinations of the gastric juice in 122 cases; and in 1886, tested 134 cases in a similar way. Every patient presenting evidences of disease of the stomach was submitted to lavage, and the gastric contents thus obtained were subjected to a chemical examination. Riegel's method is to administer to the patient an ordinary mixed meal, and after about six hours—the stomach should be empty at the end of seven hours—to remove the gastric contents, if possible, undiluted by the employment of water, and to filter them. He then tests the filtrate in order to determine especially the presence or absence of hydrochloric acid, and the peptic strength. The tests are at once simple and very delicate. He employs a variety of these, but the ones which have proved most satisfactory in the speaker's hands, and with which he feels most familiar, are the reactions with methyl-violet and Congo-red for hydrochloric acid; and Uffelmann's carbolated iron test, for lactic acid. In the presence of a small amount of free hydrochloric acid a dilute solution of methyl-violet will turn to a blue color, and Congo-red will also be changed by the acid to a blue.

The results of Riegel's experiments are very interesting, and have been fully confirmed by Korczinski and Jaworski, and by Sansoni. It has been found that in carcinoma of the stomach hydrochloric acid is almost invariably absent, and that the peptic strength of the gastric juice is wanting; so that the attempt to digest albumen artificially with the filtrate fails. In dilatation of the stomach there is always a large amount of lactic and butyric acids, though hydrochloric acid and pepsin are also present. In dilatation, therefore, the trouble is not due to lack of digestive power, but to stenosis or to want of muscular power. Gastric ulcer is almost always preceded and accompanied by a hyper-secretion of hydrochloric acid. In cases of ordinary dyspepsia there is not a diminution of the gastric juice, but usually a hyper-secretion. Riegel claims, therefore, that it is bad therapy to put every case of dyspepsia on a routine treatment of hydrochloric acid and pepsin; and that the chemical examination of the gastric contents is a *sine qua non*.

A case recently in the University Hospital illustrates the value of this aid to diagnosis. A man was admitted in an extremely anæmic and emaciated condition, and with subjective and objective symptoms of gastrectasia. The signs of this disappeared, however, when the diet was carefully regulated; but in spite of the apparent digestion and absorption of food, he became more anæmic and weaker. The diagnosis of carcinoma of the stomach was entertained, and it was thought that some induration could be detected in the pyloric region; but the contents of the stomach were removed with the tube, and the filtrate found to contain an abundant supply of free hydrochloric acid, and to digest albumen perfectly. On this ground carcinoma of the stomach was excluded. The man subsequently died, and cancer was found to be absent; the source of the induration being a thickened and somewhat stenosed pylorus, due to a duodenal ulcer.

There is at the present time another case in the hospital, where gastric ulcer has been suspected, but the examination of the contents of his stomach has shown that digestion is retarded, and that there is no reaction for hydrochloric acid with the methyl-violet test. Assuming that the German observers are correct, the presence of ulcer is excluded in this case.

The President said that he could personally speak of the value of lavage in the treatment of dilatation of the stomach and in carcinoma. For the past twelve years, at least, he has been in the habit of using this measure, from time to time, during his terms of service at the German Hospital. Following the example of Kussmaul, he has usually used a solution of the Carlsbad salt of the strength of the natural water. In cases of dyspepsia he has more recently preferred to use copious draughts of hot water to wash the contents of the stomach into the bowel. In the introduction of the tube into the stomach a great deal depends upon the skill and experience of the manipulator. He suggested that the tube could probably be swallowed with greater ease, if its lower end were weighted with a ring of lead.

Dr. S. S. Cohen said that his experience has been that it is difficult to get patients to submit to this measure. If, however, the first three or four times can be bridged over, the relief afforded is so great that the patient will allow it to be continued as long as necessary. The results obtained in cases of obstinate gastric catarrh, after the failure of all medication and regulation of diet, have been so satisfactory in the relief of symptoms, and in the almost reëstablishment of the normal condition, that he is encouraged to continue the use of the procedure. In dilatation of the stomach it is especially recommended, and is the only thing to be done. It would seem that in cases of vomiting due to the presence of sarcinæ, washing out of the stomach, with the subsequent introduction of a sufficient quantity of some safe antiseptic solution, would be one of the best plans of treatment. The tube has also been used in cases of poisoning, where the stomach-pump was not at hand.

Dr. E. T. [illegible]ren reported the following case of

LAPAROTOMY FOR TUBERCULAR PERITONITIS.

John B., aged thirty-four. Admitted to the Philadelphia Hospital May 8, 1887, with the physical signs of dry pleurisy, and of diffused thickening of the lower portion of the right lung. The sputa contained numerous bacilli of tuberculosis. The abdomen was prominent and distended with fluid in the central portion. The fluid in the central portions of the abdominal cavity was apparently confined in a species of sac, owing to adhesions formed between the peritoneum and the viscera, since changing the position of the patient did not change the distribution of the fluid. The liver and spleen were also enlarged, and there was marked dulness in the flanks and lumbar regions posteriorly. The abdominal distention rapidly increased, uninfluenced by any treatment which was instituted. On June 18th a gallon of clear serum, with some few shreds of lymph, was withdrawn. Unfortunately, paracentesis was necessitated about every three weeks thereafter on account of the rapid accumulation of the fluid, and the dyspnœa occasioned by it. The pulmonary process being latent, and the general condition of the patient excellent, laparotomy was suggested, and it was thought that possibly by irrigation of the abdominal cavity with antiseptic solutions the character of the inflammatory processes might be modified and the reaccumulation of fluid prevented. On June 28th Dr. Deaver opened the peritoneal cavity evacuating a large amount of serum, but no pus.

The peritoneal surface was injected, dark red in color, roughened and covered with flakes of plastic lymph. After drainage, iodoform was dusted freely over the peritoneal surfaces and the wound closed. The patient's subsequent history was unsatisfactory. Vomiting was a continuous symptom, and death occurred July 6th, nine days after the operation.

At the autopsy it was found that an acute attack of peritonitis had followed the operation. Extensive adhesions existed along the course of the colon; the diaphragm on the right side was welded to the liver, and on the upper surface extensive adhesions to the pulmonary pleura had been formed. The lower lobe of the right lung was infiltrated with nodules of miliary tubercle, the left lung was normal.

This case is reported because the number of cases of chronic peritonitis on record is limited in which abdominal section has been performed. While tubercular peritonitis is a most serious disease, yet the process may become latent, as is so fain bar in tubercular pleurisies in the course of phthisis. Just as the gravity of tubercular pleurisy depends upon the pulmonary lesion, so the gravity of tubercular peritonitis depends upon the extent of the frequent antecedent lesions present in the bowels and to the impairment of the functional activity of the digestive tract by the adhesions.

The indications for laparotomy would seem to be the same as those which guide us in the inflammation of neighboring serous membranes, the pleura, and the pericardium. Incision should be avoided in tubercular peritonitis unless the inflammation is purulent. Not only so, but when the tubercular process is present even paracentesis should be practised only in those cases in which dyspnœa, from over-distention of the serous sac with fluid, threatens life. The danger of operative interference in tubercular inflammation of serous sacs is, that the inflammatory process nearly always becomes purulent.

Dr. Osler did not believe that surgical interference will ever come into vogue in the treatment of this condition, as the general condition of the patient is, as a rule, such as not to warrant surgical interference. In the case reported, the rapid reaccumulation of the fluid brought in an element which rendered it more probable that incision would be of service.

Dr. W. G. Porter said that some six months ago a patient was admitted to the Presbyterian Hospital with a considerable collection of fluid in the abdomen, and on palpation a growth could be felt, the exact nature of which he could not determine. It was decided to make an exploratory incision. On opening the abdomen an extensive tubercular peritonitis was found. Since the operation, the woman has remained in about the same condition as previous to it.

Dr. DeForest Willard read a paper on

REMOVAL OF FOREIGN BODIES IN THE URETHRA AND BLADDER BY LITHOLAPAXY EVACUATOR WITH LARGE, STRAIGHT, OPEN-ENDED CANULA.

His object in bringing before the Society the subject of urethral and vesical foreign bodies was simply to emphasize the value of the evacuator (ordinarily used in rapid lithotrity to extract the calculous fragments) for removing other more or less solid substances that have found their way into the urinary tract, either by accident or design.

About one-tenth of inserted foreign bodies will be spontaneously expelled, but when the *vis a tergo* of the urine fails to wash out either a calculus or an object inserted through the meatus, the safest and surest plan is to attach to an ordinary litholapaxy evacuator (Bigelow's or other improved pattern) a large, straight tube, which is open at both ends. It contains a movable stylet for ease of introduction. The size should be the largest that the urethra will possibly admit (after nicking the meatus, if necessary), say French, No. 29 or 30; American, No. 19; English, No. 16, for adults; children in proportion. The possibility of the passage of the body through the tube should be determined, if possible, by actual trial, provided a similar piece can be obtained. Rarely will any bougie larger than the above-named size be found in the bladder or urethra.

The method has been so satisfactory in his hands, that he always resorts to it with confidence, to the exclusion of all other primary devices.

If lodgement has occurred in the urethra, the canal must be firmly closed by finger pressure behind the object, while the metallic tube is slid down and carefully caused to engage the catheter or other mass within its calibre, when the bulb of the instrument is slowly compressed until the water has distended the urethra to its fullest limit, thus liberating the body, when suction is suddenly applied while the penis is stretched forward. Unless the mass be firmly caught and imbedded in a pocket, this manœuvre rarely fails after a few trials. The quantity of water that can be contained in the urethra is so small that the body may require two or three efforts to withdraw it the whole length of the instrument. The water should be injected very slowly,

but the suction current must be made forcibly. Inspection of the rubber tube can be made through the upper opening without detachment of the catheter.

Avoid employing forceps until unsuccessful with the above method, but when necessary to be used, the superiority of the canula again asserts itself. The forceps can be manipulated through its calibre, and if the object be compressible enough to pass the bore, withdrawal can be accomplished without the slightest injury to the mucous membrane. Objects of larger size than this tube can seldom be withdrawn with safety by any method save cutting. Hairpins can be compressed through the walls of the urethra, and their points passed into the calibre, when they can be completely pushed within the bore and easily withdrawn. Beads, peas, pebbles, etc., will easily enter the canula by suction. Catheters, wires, etc., will usually require the assistance of forceps. Barbed heads of grain can also be ensheathed and withdrawn by this device.

If the object has passed into the bladder, the evacuator becomes an even more essential aid. A straight instrument is not always easy of introduction, but the security gained against subsequent urethral injury abundantly repays for the trouble. If a flexible or spirally cut obturator is used, the introduction is rendered much easier. The tube is used first as a sound to discover the offending body, when the bulb of the evacuator is first slowly compressed, so as not to disturb the fragment. Suction should always be made quickly, so as to draw the body with force. Failing, the water is next ejected with more energy, so as to move the fragment into better line with the calibre, suction being again rapidly applied. The hard substances will not be driven against the sides of the bladder with any more power than are calculous fragments, and unless consisting of broken glass will not be as angular. If the body is rounded, and of size that can pass the bore, it will in a few moments be found in the bulb. If very long, like a catheter, or pencil, or wire, the chances are not so good that it can be brought into line with the calibre of the tube. As a bougie ordinarily breaks at or near the eye, however, its passage is more than probable. Failing, after ten minutes of gentle trial, a lithotrite should be introduced if the body is a bougie or pencil, and is capable of being cut or pinched in two, and the division made. A cutting lithotrite, like Caudemont's, is manufactured, but is seldom found among the paraphernalia of surgeons, and the fenestrated instrument of Thompson is far safer. If the bougie is old and brittle, as is presumptively the case, such division with a lithotrite is easily accomplished. The segments can then be sucked out, and their total length carefully compared with the remaining portion or lost body. Every particle must be secured, lest it form the nucleus of a future calculus. Even the broken jaw of a lithotrite might be drawn into the bore.

Should these manipulations fail, there are two forms of forceps which he has had made of just sufficient length to be slightly protruded from the end of the tube. In the one, the jaws open by a spring, as in the old Halles' forceps; and in the other, the jaws are worked by handles, as in the Mathieu and Gross, and "alligator" patterns. Careful attempts can now be made to seize the body and extract it through the catheter. If small enough to be brought through, it is a great satisfaction to know that no possible injury can be done to either the neck of the bladder or the urethra, as is so likely to occur when a body is extracted in the jaws of a lithotrite. Necessarily only a small proportion of introduced objects can be removed per urethram, and Dr. Willard holds that any foreign body too large to pass the calibre of this No. 29 tube, unless it be very soft and pliable, should be removed by cystotomy, either perineal or suprapubic.

He summarized his views as follows:

1. The litholapaxy evacuating tube, large, straight, and with open end, is the surest and safest instrument for the removal of foreign bodies from either urethra or bladder.

2. The fenestrated lithotrite should be employed to break up all bodies capable of division.

3. Incision of urethra or bladder is safer than a tear of the neck of the viscus or of the canal.

4. The suprapubic and median perineal are the safest routes of entrance to the bladder when suction fails.

5. Forceps should be used with the greatest care, and always through a straight tube, which insures protection both to the urethra and neck of the bladder during both exploration and extraction.

CORRESPONDENCE.

THE AMERICAN PUBLIC HEALTH ASSOCIATION MEETING.

The fifteenth annual meeting of the American Public Health Association at Memphis, had before it papers and discussions that cannot but be of great service for the progress of sanitary science and art. The presidential address of Surgeon Sternberg had in it many suggestions as to practical administration, besides its valuable outline of the progress of knowledge as to the relations of microörganisms to disease. As it is published in The News, we need not enlarge upon it.

The list of general subjects opened with two brief papers by Dr. E. M. Hunt, of New Jersey. The first of these, on the "Origin of Some Diseases," also appears in The News. Its contentions as to the possible origins of some diseases caused a lively debate, in which various views of agreement or dissent were expressed. The second paper discussed prophylaxis as applied to some diseases. It sought to show that antecedent medication had in practice prevented or limited some diseases and was to be reckoned as one of the methods for checking many diseases and preventing them from becoming epidemic. In addition to citations from individual experience, the experiments in preventing anthrax which were tried by Dr. Cast for the Local Government Board, were debated with the facts as to their successful issue. Two short papers followed, by Dr. Hiersch, of New Hampshire. The one treated of the care of deceased bodies and the modes of protection from too rapid interments, and the other advocated the inspection of all animals slaughtered and of all animal foods, in the interest of health.

A paper of much value was presented by Surgeon J. S. Billings on "Some Forms of Vital Statistics, with Special Reference to the Needs of the Health Department of a City." The paper especially commended

the machine for tabulating statistics recently invented by H. Hallerett, which, by means of an electric arrangement and a punched card system greatly facilitates the various combinations into tables.

On the second day the first paper offered was "On the Importance of Protection to the Meat Supply of the Country." Dr. Azel Ames presented many statistical facts and arguments showing that the meat supply was decreasing in quantity and quality and that animal diseases were causing great ravages. It is certainly time that the subject should be considered in its sanitary as well as in its economic bearings.

The most of the day was devoted to the consideration of quarantine systems. Dr. Rauch, of Illinois, opened with a paper presenting some of the defects of our present system and the shortcomings of particular stations. He urged a closer relation between the States and the General Government, contending that each quarantine was of National rather than of State import and urging for consideration the question whether a National system should not be adopted. He was followed by Dr. Montizambert, the Health Officer who guards the St. Lawrence. He showed how the Canadian system was placed under the charge of the Dominion Government instead of being left to one province. The powers of quarantine are large, the provisions therefore good, and the administration accurate. They have separate hospitals on the ships for certain contagious diseases. No passenger can be landed unless vaccinated within seven years or unless he has had the smallpox. There is a defect, that this does not apply to cabin passengers. A compact battery of nine furnaces is employed for the disinfection of vessels with sulphur dioxide. The quarantine steamer is provided with the most complete appliances for speedy renovation of ships and all that appertains thereunto.

Dr. Bell, of New York, followed in explanation and in partial defence of the New York quarantine. He admitted many defects which had been long urged by the Health Officer, but claimed that Dr. Smith had not only made good use of what he had, but that he has rapidly and successfully improvised methods for the thorough handling of ships and passengers. Dr. Bell had himself superintended the steaming of clothing and the general fumigation. The discussion was shared by many others, and brought out most serious facts as to the defects in appliances in most of our Atlantic coast stations. In the evening, Dr. Holt, of New Orleans, gave an address as to the system at New Orleans, accompanied by a descriptive pamphlet. While the steaming and disinfecting methods are not new with him, he has shown admirable dexterity in perfecting appliances and in accurate administration. This port is probably now better protected than any other, and the States and their quarantine officers would do well to familiarize themselves with all the methods there used.

The same subject was continued the next morning in a special discussion directed by the State Boards of Health as to the feasibility of securing a National instead of a State quarantine system. It was opened by a paper read by Dr. Wyman, of the Marine Hospital Service, which was excellent, except that it had some special pleading as to the adaptability of the Marine-Hospital Service for the handling of a quarantine system. This led Dr. Holt and others to show that that service was intended for the hospital care of sick sailors, which is very different from the preventive administration needed for general sanitary service; and also to show how with the best intent there had been failure in many instances. The general sentiment did not seem to favor a national system, although it was admitted to be theoretically best. The prevalent conviction was that the General Government should put itself in close supervision or inspection of all stations; that by courtesy it should be able to find out by experts and to state all defects, and that so far as fitting up is concerned it should be a liberal contributor. For, as it was well urged, New York quarantine, for instance, is an interest to Illinois or Michigan as well as New York and is for National as well as for State defence, and so quarantines like rivers and harbors should have national appropriations.

The discussion was participated in by nearly every quarantine health officer present as well as by others well informed on the subject. It cannot but result in drawing the attention of Congress and of the whole country to the necessity of perfecting the sanitary seacoast cordon against the invasion of pestilential diseases. It is in vain to protect some sea-ports and leave others defenceless. It is in vain to have half measures and the mere forms of isolation and disinfection without the substance. The two great and possible protections against epidemics are isolation together with such cleanliness of persons and surroundings as will prevent the fertilization of disease. Both are alike important. We thus keep double guard. As to foreign diseases, isolation comes into special prominence. If the system is perfect, it is much easier to prevent diseases from transmission from the sea than upon the land. There must be systematized espionage over stations. There must be thorough fitting up with all the apparatus for isolation, disinfection, good air, good water, good food, good care, and sustained cleanliness. There must be effective administration, and we hope that sanitarians, that physicians, that Congress, that the people will not lie down at any one's bidding until the service is perfected and utterly divorced from the spoils system.

In addition to the address of Dr. Holt a part of the same evening was occupied by Prof. W. T. Councilman, of Johns Hopkins University, on the subject of malaria, with special reference to the microörganism of Laveran. His many culture experiments and inoculation tests confirm the descriptions of Laveran as well as those of Marchiafava and Celli. The changes in the blood and the different stages of the germ were well portrayed. It is pleasant to see that the work of Sternberg, Prudden, Salmon, Reeves, and others is being supplemented by new and original observations.

Next in importance was the subject of disposal of garbage as presented in the paper of Dr. Labergé, Medical Health Officer of Montreal, and in discussions and statements by Dr. Kennedy, of Iowa, Mr. Smith, of Pittsburg, and others. The chief contention was in favor of methods of cremation or incineration. Besides the forty incinerators now in use in Great Britain, some of which were described by Dr. Oldright and Dr. Hunt, descriptions were given of those operated in Des Moines, Milwaukee, Pittsburg, and Montreal. Their capacity to do the work effectually and economically and with-

out offensive gases seemed to be shown. The original cost is not far from $2000. They supply mostly their own fuel. They deal with night soil as well as with surface garbage. In our larger cities they will ere long come into use, especially in those so situated as that the refuse is greatly polluting the soil and the streams.

This subject of pollution of streams was also ably presented in the report of a committee on "The Pollution of Water Supply," by Surgeon Smart, of the Army, and by Prof. W. S. Williston, of Connecticut. These showed that in deciding as to pollution we must avail ourselves of all the facts as to quantity of sewage actually received, its relation as to distance to the intake of water-supply, the flow of the stream, and all the facts of the chemist, the bacteriologist, and the physician. Rudolph Hering, C. E., in a brief paper urged that the time had come for gathering accurate facts as to degree of dilution and effects of changes, and for the proposal of standards as to what are the limits of the use of streams and for determining which are to be used for sewerage only. Generally, rivers are not the best sources of potable water supply.

The Committee on Disinfectants reported progress, and now look upon their report as covering our present knowledge so nearly that they asked and received permission to incorporate their work in an additional volume of the *Transactions* of the Association.

For lack of time, or from the special and technical characters of the papers, some others that were offered and accepted by the Executive Committee were read by title or abstract.

From year to year the Association increases in its sphere of usefulness. While it has to do in part with popular information and with questions of practical administration, it also presents a fair share of original investigation and of the results of close observation and experience. Sanitary science and art are more and more dealing with thorough analysis and classified facts, and securing a basis for effective administration. This means results that will not only aid in the prevention of disease, but add much in the direction of skilled treatment.

Memphis, November, 1887.

IS LEPROSY A CONTAGIOUS DISEASE?

To the Editor of The Medical News,

Sir: I would offer an amendment of Terence's familiar line—*Medicus sum: medicini nihil a me alienum puto*—as my apology for trespassing on your columns in the case of Dr. Van Harlingen (whom I have not the pleasure of knowing), some cases of leprosy he was treating, and the Board of Health of your city, Philadelphia.

I learn from the reports in the daily newspapers of this city, that the Health Officer of Philadelphia had insisted upon the removal and isolation of some cases of leprosy which were under the care of Dr. Van Harlingen.

It would seem, from the action taken, that leprosy is regarded by the health authorities of Philadelphia as somewhat more contagious than smallpox, or the other exanthemata, and consequently I would offer the following in testimony against such an idea.

In 1880 a case of leprosy was admitted into the U. S. Marine Hospital wards at Hotel-Dieu, New Orleans. Subsequently the case was transferred to the U. S. Marine Hospital at Mobile. He was exposed to other patients, subjected to no rigorous quarantine or isolation, and no case developed among other patients.

I have often seen, during the years I was on duty in New Orleans, cases of leprosy in Charity Hospital of that city, On referring to the reports of that institution it may be found that, in 1885, there were of the different varieties of leprosy, six white and one colored patient treated. In 1884 two white patients were treated. In 1883 two white and one colored patient. In 1882 four white patients. In 1881 four white and one colored patient. The cases are treated in the hospital wards.

While on duty in Key West, Florida, in 1883, I treated a case of tubercular leprosy in a mulatto child, no isolation being considered.

In the Report of the Louisiana Board of Health for 1880, Dr. Joseph Jones has a paper on leprosy in Louisiana, and, though President of the Board of Health, does not insist upon the exclusion authorized by biblical law.

At any rate, it does not seem that the public alarm, and consequent unjust criticism of a professional man, are warranted by the lack of evidence regarding the existence in the United States of the environment, race dyscrasia, and other genetic factors which have served to make this disease the scourge of certain localities.

Very respectfully,

S. P. Armstrong, M.D.,
P. A. Surgeon U. S. Marine Hospital Service.

New York, November 22, 1887.

NEWS ITEMS.

The Officers of the American Public Health Association for the ensuing year are:

President.—Charles N. Hewitt, M.D., of Red Wing, Minn.

First Vice-President.—G. B. Thornton, M.D., of Memphis.

Second Vice-President.—Joseph Holt, M.D., of New Orleans.

Treasurer.—J. Berrien Lindsley, M.D., of Nashville, Tenn.

Executive Committee.—Henry D. Baker, M.D., of Lansing, Mich.; S. H. Durgin, M.D., of Boston; J. N. McCormack, M.D.

The next meeting will be held at Milwaukee.—*Sanitary News*, November 19, 1887.

The Quarantine at Baltimore.—The *Maryland Medical Journal* of November 12, 1887, writes that the Health Officer of that city thinks the committee of the College of Physicians of Philadelphia has formed an imperfect judgment concerning the quarantine facilities at the port of Baltimore. He argues that the present accommodations are adequate for the proper protection of the city against the introduction of cholera at this port. We are unable to agree with the opinion of our efficient Health Officer. We fail to see how the present arrangements at Hawkin's Point could provide a suitable quarantine for a steamship load of immigrants arriving at this port with cholera on board. Seventy-five hospital beds and any number of army tents, will not comfortably

protect six or eight hundred immigrants. Unless the quarantine establishments of all American ports are taken out of the hands of our State and Municipal authorities and placed under the control of the General Government, the present shortcomings pointed out by the committee of the College of Physicians are not likely to be corrected.

THE COMMITTEE ON DISINFECTION, OF THE AMERICAN PUBLIC HEALTH ASSOCIATION, at its recent meeting, advised essentially the same disinfectants recommended in 1885; the solution of chloride of lime was made $6\frac{2}{3}$ to the gallon instead of $4\frac{2}{3}$, as previously ordered.

PRIZE ESSAYS ON HYGIENIC COOKING.—MR. H. LOMB, of Rochester, offers one prize of $500 and one of $200 for the best essays on practical, sanitary and economic cooking, adapted for persons of moderate and small means. The award is under the auspices of the American Public Health Association.

PREGNANCY AFTER OVARIOTOMY.—A recent writer in the *Lancet* reports his attendance upon a woman in her seventh confinement since the removal of an ovarian tumor by Sir Spencer Wells, in 1875.

AMERICAN PATENT MEDICINES ABROAD.—We are informed that under the Austrian laws regulating pharmacy American patented preparations of hops and also of hypophosphites have been prohibited from sale in Vienna. A Berlin merchant was lately sentenced to eight days imprisonment for selling "St. Jacob's Oil" as a medicine.

THE TELEPHONE IN MEDICINE.—The very common use of the telephone in the business world affords a sufficient guarantee that, in spite of occasional difficulties, inconveniences, and failures in its working, there remains a substantial balance of advantage. The facilities which it has introduced into the ordinary course of domestic life have also been considerable, though the time is probably far distant when even the majority of households will possess the luxury of a telephone communication. In the emergencies of illness, particularly, there is much to be said in favor of this mode of intercourse. It is, above every other, simple, swift, and safe, and must commend itself alike for the expeditious conduct of practice and the treatment of disease. In the management of joint medical practices which cover a considerable area it is very obviously useful. Of its proved value in cases of special urgency, we need say little. A particular interest, however, attaches at the present time to what is probably its latest application. This is its employment as a part of the system of isolation, so imperative in the management of infectious illnesses. We are informed that one of the effects of the recent scarlatinal outbreak in the metropolis has been to establish, in some instances, an in-door telephone system, which, without the slightest risk of infection, brings a patient, so to speak, within touch of his friends and relatives. Whether it is to be an unmixed advantage must, of course, depend upon the discretion of those concerned. Rightly used, it may even prove a boon of some considerable curative influence. A certain gain which it confers is, of course, the comparative leisure allowed to attendants on the sick. There is no answering bells to find out what is needed, the door of the sick-room is less frequently opened, and fatigue generally, as also the risk of infection, is materially lessened. The value of this form of communication in hospitals is obvious. We would suggest its more general adoption were it not that we fear that in many cases the cost might prove a barrier. It would be easy to speak at greater length upon this topic, but it is hardly necessary when the public already recognize, at least in theory, the position of this useful invention among the amenities of life.—*Lancet*, November 5, 1887.

SOUND-BLINDNESS.—The phenomena of color-blindness are well known, and have been carefully investigated. We know that some persons can see to great distances, discern minute objects, enjoy works of art, and yet are unable to distinguish certain colors. Physiologists, and especially psychologists, have also found that there is a similar series of phenomena to be observed in connection with the sense of hearing. If a word were coined to describe these phenomena, it would naturally be "sound-deafness," but many who have written on this subject seem to prefer the term "sound-blindness."

A writer in the London *Journal of Education* uses the term "sound-blindness," and seems to have come to the subject from a pedagogic standpoint. He states that the difficulties which some persons have in learning to spell and in learning how to pronounce foreign languages suggested to him the possibility of the existence of such a thing as sound-blindness—an inability to distinguish particular shades of sound, arising from some organic defect in the ear which is distinct from deafness, as that term is commonly understood.—*Science*, November 18, 1887.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM NOVEMBER 15 TO NOVEMBER 21, 1887.

PERIN, GLOVER, *Colonel and Assistant Surgeon-General.*—Retired from active service, November 17, 1887, by operation of law.—*S. O. 268, A. G. O.*, November 17, 1887.

SMITH, A. K., *Lieutenant-Colonel and Surgeon.*—Assigned to duty as attending surgeon in New York City.—*S. O. 269, A. G. O.*, November 18, 1887.

SMITH, J. R., *Lieutenant-Colonel and Surgeon.*—Ordered for duty as Medical Director, Department of Dakota.—*S. O. 269, A. G. O.*, November 18, 1887.

HORTON, S. M., *Major and Surgeon.*—Granted six months' leave of absence on surgeon's certificate of disability.—*S. O. 269, A. G. O.*, November 18, 1887.

ARTHUR, W. H., *Captain and Assistant Surgeon.*—Granted two months' leave of absence, with permission to apply for two months' extension, to take effect on the arrival at Fort Niagara, New York, of Assistant Surgeon Paul R. Brown.—*S. O. 269, A. G. O.*, November 18, 1887.

KEAN, J. R., *First Lieutenant and Assistant Surgeon.*—Granted two months' leave of absence, to take effect about December 1st.—*S. O. 269, A. G. O.*, November 18, 1887.

OFFICIAL LIST OF CHANGES IN THE MEDICAL CORPS OF THE U. S. NAVY FOR THE WEEK ENDING NOVEMBER 19, 1887.

RINEY, P. M., *Passed Assistant Surgeon.*—Ordered to the Naval Dispensary, Washington, D. C.

ORIGINAL LECTURES.

CHRONIC BRIGHT'S DISEASE.

A Clinical Lecture Delivered at the Good Samaritan Hospital, November 23, 1887.

BY JAMES T. WHITTAKER, M.D.,

PROFESSOR OF THEORY AND PRACTICE OF MEDICINE AT THE MEDICAL COLLEGE OF OHIO.

Reported by JAMES M. FRENCH, M.D.

Wm. H. McD., grocer, Irish, admitted to the hospital May 24, 1887. Had been ill about six weeks. First noticed disorder of stomach and bowels; constipation, vomiting, and headache. After short treatment outside of hospital, he improved, and was able to be around. About two weeks after the first attack swelling of the legs set in below the knees and above the ankles; this swelling increased and extended upward. At the time he entered the hospital the scrotum was beginning to swell, as also the abdomen. The face was puffed, especially under the eyes; he was pale and waxy-looking. Constipation continued and was relieved by hydragogues given to reduce the dropsy. The swelling of the feet, legs, scrotum, and penis increased in spite of treatment.

June 5th the feet were punctured with a needle. The reduction thus obtained was but temporary. June 7th, the feet, scrotum, and penis were punctured with antiseptic precautions. This operation allowed the escape of a large quantity of water, and gave much relief, since the swelling of the penis had interfered with the passage of urine. About June 20th he began to suffer from violent headaches and vomiting. These symptoms were relieved, to some extent, by active purging. July 1st, he began to take hot baths daily at 105° F., lasting twenty minutes. This treatment rapidly relieved the headaches and vomiting, and reduced the general dropsy. His general condition improved decidedly. About August 1st, he began to cough, and cough has continued since. Some dyspnœa existed at the same time. August 16th, he left the hospital to visit near Maysville, Ky. While there the baths were discontinued. About two weeks after leaving he began to feel worse; the cough became more annoying, the dyspnœa increased, and he had pain in the region of the heart. Now for the first time attacks of palpitation of moderate severity began.

September 11th, he reëntered the hospital. The dropsical condition was as marked as at any time before. His chief complaint now was of the cough and dyspnœa. The latter was so severe at times as to prevent his lying down. Both cough and dyspnœa were worse at night. He was again given hot baths every night at a temperature of 110° F. These baths now seemed to depress him greatly and excited attacks of dyspnœa, which lasted several hours. The third bath induced an attack from which he was with difficulty revived. The action of the heart became labored and irregular. This last was the most severe attack he had had, and lasted six hours. The baths were then discontinued. Since then the swelling of the feet, legs, scrotum, and penis has gradually increased, so that at present urination is somewhat interfered with. His appetite has been continuously good. When he entered the house the urine contained a large amount of albumen, No casts were found. June 15th, he passed seventy-two ounces of urine in twenty-four hours. Albumen was still abundant, no casts. Specific gravity 1.020. Since then the urine has been examined a number of times; albumen has always been abundant, but no casts have been found. During the last twenty-four hours he has passed forty-four ounces of urine; albumen undiminished; hyaline casts found for the first time. Specific gravity 1.015. September 25th, he passed fifty-four ounces. Since then he has not taken so much fluid. The heart's dulness is increased downward and to the left. Pulse 120, feeble.

The patient's habits before his illness have been good. He has not been a drinker. For some time before he had slept in a damp, cold, partly underground room.

Gentlemen: We have before us, I need hardly say, a severe case of chronic nephritis. Seven months ago this man was first taken ill with symptoms on the part of the alimentary canal, anorexia, nausea, and vomiting. How many cases of this kind show symptoms of this character, which are diagnosticated and treated as simple cases of gastric catarrh. This is, perhaps, proper enough in the majority of such cases, but when the case does not yield to this treatment, we at once should think of two conditions as explaining the nature of the case, namely, tuberculosis and Bright's disease. Tuberculosis we could exclude in this case, not because of the absence of cough, for some cough exists, but because the cough is found to arise from œdema of the lungs. Then, what would first lead us to suspect Bright's disease in this case, is the fact that this man suffered from persistent violent headache. The first symptoms to show themselves in these cases are generally headaches, neuralgias, more or less vertigo, and œdema of the lower eyelids in addition to the disorders of digestion which we have already noticed.

Let us consider the dropsy which plays such a prominent rôle in his history. In order to understand this subject we must transport ourselves to the early part of this century. At this time dropsy was treated as a distinct malady. Now, nobody thinks of treating dropsy as a disease, it is known to be merely a symptom. In the present case, as in most cases, it was not the first symptom presenting itself, but followed others fully as important. First of all, there were disturbances of digestion. A disturbance of digestion characterizes more or less every case of Bright's disease. The case before us is an exceptional one, in the fact that the individual has had a good appetite during the whole course of the disease. One of the most distressing

symptoms you will have to treat in Bright's disease is obstinate vomiting, both dyspepsia and emesis being so often dependent upon œdema of the alimentary canal. Next in this case, as you heard in the history, there showed itself a headache. Headache has been a prominent symptom of the case. The patient has never had convulsions. When you stand in the presence of Bright's disease you will interrogate your patient with reference to three distinct sets of symptoms: the disturbances of the nervous system, the occurrence of dropsy, and the condition of the urine. The only nervous manifestation this man has shown is headache. There has never been any disturbance of vision. Sometimes these patients present themselves to the oculist first to be treated for blindness. An examination of the fundus oculi in these cases will sometimes establish the diagnosis. The oculist sees by the side of dilated veins white patches or stripes about the optic disk associated often with minute patches or rather stripes of a dark color due to hemorrhage. The white spots are believed to be a fatty degeneration. Sometimes there is an absolute amaurosis without discoverable lesions, but this is not so common in this form of disease as in the shrunken kidney to which it properly belongs. But this man has never had any but trivial symptoms on the part of the nervous system; and the fact that the nervous symptoms in this case have been conspicuous by their absence speaks for the particular form of Bright's disease before us. We have here the chronic parenchymatous form of the disease; it is more in the acute parenchymatous, the cirrhotic, or the contracted kidney that the nervous symptoms predominate. Moreover, this individual has never had any asthma. This same dropsy—to return now to the dropsy with which we started—which is present here in the scrotum to such a degree as to interfere with micturition, as you see and as we have heard in his history, is present also in the course of time in the lungs, and from this cause the individual suffers from dyspnœa. We see asthma most marked, however, in those cases in which there is very little or no dropsy. That is the true renal asthma, nervous in its origin. We might say of the nervous symptoms that they show themselves in inverse proportion to the dropsy. Dropsical accumulations seem to serve the purpose of reservoirs into which the noxious elements are eliminated. Although the individual becomes helpless and suffers great distress by the occlusion of the lungs, it is merely a mechanical occlusion. The noxious elements find their escape not through the urine, but into the serous sacs and into the lungs. Other things being equal, then, we say that the immediate prognosis is rather more favorable in those cases which show us a great deal of dropsy. Sometimes, however, the dropsy causes serious phenomena, as when it swells up the vocal cords to occlude the air-passages, or sometimes it accumulates so greatly in the serous sacs and lungs as literally to drown the patient in his own fluids.

Many a patient will come to you to be treated, first of all, for dropsy. He will show you his feet. He will say that in the morning when he gets up the swelling is gone and he can walk, but that it comes again during the day. Other cases will have their attention first called to the disease by the œdematous condition of the lower eyelids. As a rule, however, the swelling first takes place about the feet. Sometimes you will be able to notice it about the loins, especially in individuals who are confined to their beds, though you may by no means explain the localization of the dropsy by gravity. If a man presents himself for your opinion with a sallow skin, with puffy eyelids, and says that he has headache, you at once examine his urine; at once you suspect Bright's disease. The amyloid kidney may also present some of these symptoms, but it generally shows no dropsy, or but little, throughout the entire course of the disease. In parenchymatous nephritis, however, it is the rule. The acute form, especially that following scarlet fever, shows it, and the chronic form always shows it. This great accumulation of fluid is characteristic of the acute and chronic forms of parenchymatous nephritis. You can generally distinguish between these two forms of the affection by the symptoms which accompany the dropsy. The fact that this individual has had the disease so long, that he has had few nervous symptoms, but has had great dropsy, even invading the lungs to such an extent as to render orthopnœa a necessity, bespeaks this form of the disease.

We might be willing to make a diagnosis and to rest our treatment upon these points alone, but there is a third cardinal factor—one which is equally important with any of any of the others and which is sometimes the sole index of the character of the affection. The urine is a fluid which comes directly from the seat of the disease. The quantity which is passed in this form of nephritis fluctuates. This man is now passing forty-four ounces of urine in twenty-four hours. He has passed as high as seventy-two ounces, however, as you have heard in the history. That was when his heart was strong in its hypertrophy. Three pints we say is the average quantity which a healthy man should pass in twenty-four hours. The specific gravity in this disease is high; it varies from 1.020 to 1.030—you might put down the average at 1.025. The first point to notice in connection with the urine is that it is generally reduced in quantity. With this reduction you would expect a change of color, it is darker, and it is also more or less turbid. Slight agitation produces froth. From this alone you might suspect that it would contain albumen, although this would by no means be a sufficient test. After the specimen has remained stationary for a little while there will be a sediment. This sediment is not the healthy sediment of urates; it has not the red color of the urates, but is of a whitish, muddy color. I now we put a little of this sediment under the microscope, we will find that it is made up of the detritus of blood corpuscles, much more of the white than red, and more especially of fat granules. After examining into the gross appearance of the urine the next thing is to inquire whether the urine contains albumen. We will subject a little of this specimen to the test of heat and nitric acid. We will have the urine boiled and then add a little nitric acid; if albumen is present, it will, of course, coagulate. If, however, there is a coagulation, does that necessarily mean that we have Bright's disease to deal with? By no means. We have a physiological albuminuria which is not connected with Bright's disease. There are certain other conditions which produce albuminuria. Pressure on the thorax will produce abundant albumen in the urine. The urine of a newborn child always con-

tains albumen, probably on account of an interference with the circulation of the blood in the thoracic cavity. Fever, and any retardation of the circulation will show it. I have said that there is a physiological albuminuria; so there is, but it is seldom encountered, is transitory, and the albumen is present, except in the pressure cases referred to, only in very slight quantity. Albumen in any quantity always indicates some disturbance of the epithelial cells of the kidney. These cells have the function of preventing the exosmosis of albumen; but if they become diseased in any way, only cloudy or opaque, they will permit the escape of albumen; you may put it down as a law that albumen in the urine in any quantity means disease of the kidney.

In executing the test for albumen, it is best to heat only the upper stratum of the liquid in order to discern by comparison the presence of only a small quantity; the boiling process should be continued at least one minute. Again, you should take a sample from all the urine that is passed in twenty-four hours, for in that space of time you will be more certain to find albumen if there be parenchymatous disease of the kidney. Sometimes, after heating—that is, boiling, I repeat, and adding nitric acid you will find that the contents of the entire test tube set into clot. You may then hear it stated that the urine was all albumen, or that it contained 50 per cent. of albumen. This is a mistake, for if it sets solid in the test tube, it indicates only 5 to 7 per cent. You must always take the precaution to add nitric acid to it as well as to boil it. It matters little which you do first, but you must always do both. Then, it is best to add quite a quantity of nitric acid—from one-tenth to one-fifth of the volume of urine to be tested.

There are a great many varieties of albumen. There is a serum albumen, there is a peptone albumen, a propeptone, and a globulin, and there are occasionally met other albumens which we are just beginning to recognize. Only two of them, however, have practical significance as yet; one is serum albumen and the other peptone albumen. The peptone albumen has nothing to do with Bright's disease. It never occurs in Bright's disease. It indicates to us that there is suppuration present somewhere in the body. It indicates to us sepsis that we can sometimes find in no other way. It is of value in the diagnosis of ulcers of the intestine, inflammations of the lung, and cerebro-spinal, as distinct from tuberculous meningitis.

There are many tests for albumen, but this heat and nitric acid test is sufficiently accurate if properly made. The mistakes which occur are for the most part in cases not examined at all. Boil the urine and see that it has an acid reaction; add plenty of acid.

The quantity of albumen is not indicative of the gravity of the disease. Most of the cases of acute parenchymatous nephritis or chronic nephritis show large quantities of albumen, but a case of cirrhotic kidney may disclose no albumen in even a dozen examinations, so that if you rely upon albuminuria only you will often be deceived. Suppose you have albumen, the question then is, Does this albumen come from the kidneys? Is the case one of renal albuminuria, or is it one of accidental albuminuria? Does it come from the kidney or from some other source? Does it come from the pelvis of the kidney, from the ureter, or from the bladder? Cases of accidental albuminuria distinguish themselves by the presence of pus, as a rule, and albuminuria due to affections of other parts distinguish themselves by the presence of epithelial cells from these parts, disease of which shows other signs. Albuminuria from the kidney is generally distinguishable by the great quantity of albumen as well as by the presence of tube casts, fat granules, and epithelial cells or débris. The presence of fat is valuable, but not so valuable as the presence of tube-casts. We have in most cases the granular, fatty, and epithelial casts, but in many cases we find only clear hyaline casts, such as are exhibited here under the microscope.

We have now interrogated this patient from three standpoints; namely, the nervous system, the dropsy, and the urine—the latter with reference to changes in its quantity, color, and composition. We find in it albumen, fat granules, and hyaline casts. The diagnosis is clear.

How Bright's disease came to attack this man we do not know. Some cases of chronic parenchymatous nephritis do follow the acute form of the disease, follow scarlet fever or some other acute infection, but only a small minority of cases are of this origin. Most cases are chronic from the start. The individuals begin gradually to suffer malaise. They feel low spirited, as a rule, suffer occasional headache and vertigo; then disturbances of digestion occur; and, finally, the patient presents himself to a physician, who examines his urine, to find in it the peculiar features mentioned, and be the first to recognize the disease. It is said that malaria and syphilis are diseases which often result in chronic Bright's disease. We know that individuals who suffer from malaria and syphilis are not infrequently affected with this disease; but you will find that most cases of Bright's disease cannot be ascribed to either of these affections, or to any cause, in fact, except to cold. Whether the cold is really the cause, or whether it is only the exciting factor acting with some other cause which existed previously in the body, we do not know. This much we know, however, that the microörganisms of the acute infections do not escape through the kidney, if the kidney be sound. They are not locked up in the kidney as they are in the liver, spleen, and bones. But they may be liberated from a latent state in these organs to affect the kidney at a later date, on or after long-continued or insidious exposure to cold.

The prognosis is always grave. We base our prognosis largely upon the length of time that the disease has lasted. If the individual has had the disease only a year, we may say that he has a good chance to recover. The average duration of the disease runs from a year to a year and a half. Many cases last longer under favorable hygienic surroundings, and some are cut short even in a few months. These patients are not so likely to die suddenly as those who suffer from the cirrhotic kidney. Patients sometimes fall down comatose in the latter affection, without having ever shown any symptoms of the disease. If you interrogate these cases, however, you will find that the individuals have been ill with vague feelings of distress, feeling below par, as they say, for some time; though not sufficiently so to take them to the office of a physician for advice. You must examine the urine in these cases. If necessary, draw it off with a catheter. A little albumen may be present in any case of coma, so that you

must look for fat granules and tube-casts, whereby you make your diagnosis. Look also in all cases for hypertrophy of the heart.

The prominence of nervous symptoms makes the prognosis grave. Fatty tube-casts, much fatty matter, will indicate a very pronounced form of the disease. The prominence of nervous symptoms is more apt to occur when the disease has passed over into the shrunken form—not into the true cirrhotic form, but into that shrunken condition peculiar to this form of the disease. The danger in this man's case is the increase of the dropsy over which we have so little control. He has twice had dyspnœa, from which he narrowly escaped. You heard in his history that the man has an enlargement of the heart. Some of the most brilliant diagnoses you will ever be able to make will be when you put your finger on a man's pulse and thereby be able to say that man has kidney disease. We find that the left ventricle is hypertrophied. We recognize it by the displacement of the apex beat, by percussion, by the firmness of the pulse, and by the accentuation of the aortic valve sounds. As long as these symptoms are present, there is no particular danger, but after awhile a time comes when the left ventricle begins to flag; the blood accumulates in the left ventricle, in the lungs, in the right ventricle, which flags in turn, and, finally, as the walls of the heart give way, the heart becomes fatty and flabby, and the individual soon succumbs. I give it to you as a sign of the utmost value, that in every case of chronic parenchymatous nephritis, you will find hypertrophy of the heart.

The prognosis in this case is very grave; but the patient has been almost as bad as he now is several times before and partially recovered. I am sure that every one of the older practitioners present have seen cases of Bright's disease quite as bad as this one that got better; but not, as a rule, to the point of a complete recovery.

What is the treatment here? You might naturally think that the proper treatment in such a case would be to push more water through the kidneys to wash out the tubules. So it would be if the tubules were open, but they are closed; they are plugged, and if you attempt to force more water through you will only increase the hyperæmia, stasis, and stagnation which are always present at this stage. In this case there is one diuretic which is indicated, namely, spartein, on account of the weakness of the heart. We shall give this patient one-sixteenth of a grain of the sulphate of a spartein every four hours, not for the disease of the kidney but for the heart.

This is not the true treatment of Bright's disease, however. It is, as a rule, the worst. The true treatment is to substitute the action of the kidneys by the action of the skin. The individual should have a hot bath every evening up to 110° F., remaining in it a long time, half an hour to an hour, then be rolled up in blankets and made to sweat. A patient who will do this right will often get entirely well. The man must have a large bath-tub made. He must have a thermometer in it. The temperature of the water must be kept up by the addition, from time to time, of hot water, beginning with 100° F., and gradually increasing to 110° F. This remedy, which proved to this man of the greatest advantage in the early part of this disease, is now valueless; his heart has become too weak for it. At one time I saw him after a bath, weak and almost pulseless. He was only tided over by hot coffee and brandy. Another most valuable agent in this case is pilocarpine, the active principle of jaborandi. It is given to him in the dose of a quarter grain, administered subcutaneously, increasing it, if it does not produce depression, to a third of a grain, or at times to a half grain. One-third of a grain shows its effect on this patient in fifteen to twenty seconds. He expectorates a half a basin full of saliva in the course of the ensuing half hour, and perspiration stands out in beads and drops, and rolls from his face in streams. He gets such complete relief from its use of the dyspnœa that he pleads for it at times. But pilocarpine is not as curative as the hot bath when it can be sustained. It is a substitute, and, like all substitutes, is not as good as the original. That we keep this patient in bed, and that we allow him no albuminous food need not be said. But with all the relief we may afford him we cannot at this stage sufficiently fortify his heart to prevent the dropsy. We have had subsequent occasion to incise his legs, whereby great quantities of water have found escape, and the persistence of this condition, in spite of all this treatment, shows how extensive is the block in the kidneys. In this operation incision with a bistoury is much to be preferred to punctures with a needle, in that it is less liable to show subsequent inflammation. It is no exaggeration to say that gallons of water have been drained from this patient in this way with corresponding relief of his dyspnœa, which is now his chief distress.

I give you thus the practical points as befits a clinical lecture bearing upon the recognition and treatment of chronic Bright's disease, and with special reference to this individual case. We may not be able to cure the disease in this case—indeed, I believe we will not, for I have come to make my prognosis rest largely upon the tolerance and effects of hot baths, which he cannot now endure. The symptom which now assumes prominence and most seriously threatens life is the dropsy due to the weakened heart. So soon as his stomach will bear it we will give him digitalis—the fresh infusion—in tablespoonful doses every two or three hours. We shall add to its efficiency by adding to it the acetate of potash fifteen grains to each dose. It is well to know, however, that with this addition the preparation does not keep so well, so that four to six ounces should constitute the maximum quantity made at any one time.

ORIGINAL ARTICLES.

FOUR CASES OF POISONING FROM TYROTOXICON, WITH THREE FATAL RESULTS.

INVESTIGATIONS AS TO THE ORIGIN OF THE POISON; RESULTS OF THE AUTOPSY AND CHEMICAL ANALYSES.

BY VICTOR C. VAUGHAN, M.D., PH.D.,
DIRECTOR OF THE HYGIENIC LABORATORY IN THE UNIVERSITY OF MICHIGAN.

SEPTEMBER 23, 1887, I was visited by Dr. A. G. Mesic, of Milan, Michigan, who informed me that he had four members of a family under his charge, all of whom were seriously ill with peculiar symptoms, which he believed to be caused by tyrotoxicon.

Since Dr. Mesic has written out for me the history of these cases, I will insert his report in full, as follows:

"*Saturday, September 17*, while passing the residence of S. H. Evans, a respectable farmer, I was called in to see him. I found him—a man of about fifty years, spare and muscular—vomiting severely, with flushed face, but with a temperature of 96° F. There was marked throbbing of the abdominal aorta; the tongue had a white, heavy coating, and the breathing was very labored. I set to work with the ordinary remedies to allay the vomiting, which had already continued for some hours. The vomited matters were colored with bile. Pupils were dilated, and a rash resembling that of scarlatina, but coarser, covered the chest, forearms, and legs below the knees, while the abdomen and thighs remained unaffected. As the bowels had not been moved since the beginning of the attack, I administered a purgative dose of calomel with a little podophyllin and rhubarb. On Sunday a small stool resulted. During that day and night, and the following day, the retching and vomiting continued. Small doses of carbolic acid seemed to give the most relief. After the movement of the bowels the symptoms were somewhat more promising; but a heavy and unfavorable stupor was observable and persistent.

"On *Sunday* the coating of the tongue remained very thick, and had changed to a dark brown color. At first I thought that his symptoms indicated a depressed condition, which I had known in one instance to precede typhoid fever. However, after a few days, I concluded that I must look for the cause of the condition among the poisons; but I could think of no one poison which would be likely to produce all the symptoms observed. During Monday, Tuesday, and Wednesday there was but little change, and the treatment was continued.

"On *Thursday* morning I found the son Arthur, a lad of eighteen years, strong and vigorous, suffering with the same symptoms, only in a more violent form. After supper on Wednesday evening, he was taken with nausea and vomiting. He had no rash, but the symptoms were otherwise identical with those of the father, except in being more severe. I gave a cathartic, which acted only slightly.

"At my evening visit I found Mrs. Evans, a lady of about forty-five, previously in good health, with the same symptoms. In this case the stupor was more marked from the first. I was unable at any time to obtain any cathartic action in this case. Copious enemata of warm water were used, but succeeded only in washing some hardened lumps from the rectum. By this time I had concluded that the poison was most likely tyrotoxicon.

"On *Friday* morning the only remaining member of the family at home, Miss Alma, sixteen years of age, was affected in the same way as the others. On that day I went to Ann Arbor, and gave a history of the cases so far to Dr. Vaughan, who, from the symptoms, thought that my diagnosis was most probably correct, and he advised with me as to treatment, which I carried out. I gave two grains of sodium salicylate every four hours, and used small doses of the tonics and stimulants, quinine, nux vomica, digitalis, whiskey, and the aromatic spirits of ammonia. On Saturday the symptoms in all remained unimproved, and in the mother and son the stupor and labored breathing grew more marked.

"On Sunday, I again went to Ann Arbor, and brought Dr. Vaughan with me to see the patients. The temperature of the mother on Sunday was as low as 94°, and that of the son 95°. Dr. Vaughan agreed with me as to diagnosis and treatment. Sunday evening the patients were all removed to the house of a neighbor, about forty rods distant (the reasons for this will be given later). Dr. Vaughan and I both expressed the fear that the mother, and possibly the son, would not live through the night. Both of these rapidly grew worse, and the son died at 7.45 A.M., and the mother at 4 P.M., Monday.

"During *Monday* the daughter rapidly grew worse, and at the time of her mother's death could not be aroused, and practically she remained unconscious from that time on. The father was very weak, but retained his consciousness all the time. Convulsive movements of the limbs had been noticed in the son, but not in the mother. These now became more marked in the daughter, who remained in the heavy stupor, with labored breathing, until 5 P.M. Thursday, when she died.

"Mr. Evans has slowly improved, and now, October 18th, is able to walk about the room. The sodium salicylate, even in the small doses used, seemed to cause severe headache; so apparent was this that the drug was discontinued, and drop doses of amyl nitrite, given every hour, seemed to relieve the pain in the head. The father's temperature remained below the normal until Thursday, October 14th, when it reached the normal. After this it was found once as high as 99.5°, then 99°, then again normal, where it remains."

"All complained of a burning constriction in the throat, and difficulty in swallowing, and all, as long as they were conscious, frequently called for ice. In all the pulse was rapid and feeble, and death seemed to result from failure of the heart. Those who died voided urine involuntarily, while Mr. Evans passed small quantities frequently, and for this some buchu and uva ursa were given. During his convalescence some small doses of morphine were given to the father, as he was unable to sleep, and became very restless. He is now taking teaspoonful doses of the elixir of calisaya and iron every four hours."

As stated above by Dr. Mesic, I first saw these patients Sunday, September 25th. On a sofa in the room we found the daughter, Alma. She had been vomiting during the day, and seemed much exhausted. She was not inclined to talk, and seemed to be in a stupor, though when spoken to, she responded rationally. Her pupils were slightly dilated, her tongue coated, her pulse 120 and weak, her face flushed, and a violent throbbing could be felt over the abdomen, which was retracted. Her temperature was 96°.

In another room were the father, mother, and son, two of them dying. The father was rational, and talked with some freedom when I asked as to the kind of food they had been eating, etc. His pupils were normal. His face could not be said to present any peculiar feature. His pulse was rapid, breathing somewhat labored, and the throbbing of the abdominal aorta was plainly felt. The abdomen was retracted, and there was no pain on pressure. He complained of a burning constriction of the throat, swallowed with difficulty, and said that his throat and stomach felt as though they were on fire.

The mother lay perfectly still with eyelids closed, as if in a deep sleep. Her pulse was rapid, her face had a livid flush, her breathing was about 35 per minute, and labored. The skin was cool, but neither abnormally moist nor specially dry and harsh. She could not be aroused. In fact, she was comatose.

The son rolled uneasily from one side of the bed to the other. His breathing, also, was very labored.

His eyelids were closed, and the pupils were markedly dilated—did not respond to light. He could not be aroused. In mother and son, as well as in father and daughter, the abdomen was retracted, and the throbbing of the abdominal aorta was easily felt.

Now, to what were these symptoms due? They were certainly those of some poison. Dr. Mesic had brought me some of the vomited matter, which I tested thoroughly for mineral poisons, with negative results. The symptoms certainly were not those of morphine, strychnine, digitalis, or aconite. They did have some resemblance to those of belladonna, but yet they were not the symptoms of belladonna. The pupils were not as widely dilated as they would be in belladonna poisoning. There was in none of these persons the active delirium of belladonna poisoning. There was no picking at the clothing, no grasping of imaginary objects in the air, no hallucinations of vision. Surely it could not be any vegetable alkaloid with which I was familiar.

On the other hand, we know that nausea, vomiting, headache, dilatation of the pupil, rapid pulse, heavy breathing, constipation, and great prostration, with stupor, do occur in cases of poisoning with certain ptomaines. Therefore, we began to look for conditions which would be favorable for the production of putrefactive alkaloids. These conditions we were not long in finding.

The family, which consisted of the four persons sick, and of a daughter, about twenty years of age, who was away from home at the time when the others were taken ill, and for some months before that time, was evidently a tidy one. This was shown by their personal appearance, and by the clothing and bedding. But the house in which they lived was very old and very much decayed. Mr. Evans had purchased the farm six years ago, and for some three years past, at least, they had been troubled every now and then, one or more of the family, with nausea and vomiting, followed by more or less prostration. But in no instance, up to the present illness, had the symptoms been sufficient to cause them to summon a physician. The family had worked hard in order to pay for the farm, and had determined to make the old house do until they were out of debt. Even before this family had moved to the farm, the house had been known among the neighbors as an unhealthy one, and there had been much sickness and a number of deaths among its former tenants.

The house is a frame one, and one of the neighbors said to me that it was an old house when he came to the neighborhood thirty-seven years ago. It consists of two rooms on the ground-floor, with attic rooms above. The frame rests upon four large logs or sills, which lay directly upon the ground, and are thoroughly rotten. There is no cellar under any part of the house. From the front, at least, the surface slopes toward the house, and the rain water runs under it. In the floor of one room a trap-door had been placed, and directly under this a small excavation had been made for the purpose of collecting the rain water when it accumulated under the house. Although this pit was dry at the time of our examination, its sides and bottom were marked with cray-fish holes, showing that water had stood in it. The floor was laid of unjointed boards, and every time that it was swept much of the filth fell through the cracks, and everytime that the tidy housewife scoured and mopped the floor, the water, carrying with it the filth, ran through the crevices, and thus the conditions most favorable for putrefactive changes were brought into existence, and maintained.

One corner of one of the rooms had been transformed into a small room, or buttery, as it was called, and in this, on shelves, the food was kept. On account of the more frequent scouring demanded by that part of the floor enclosed in this buttery, the boards had rotted away, and a second layer of boards had been placed over the original floor. Between these two floors we found a great mass of moist, decomposing matter, the accumulations of years, which the broom could not reach. When this floor was taken up a peculiar, nauseating odor was observable, and was sufficient to produce nausea and vomiting in one of the persons engaged in the examination. Some of the dirt from beneath the floor, and some of that which had accumulated between the boards in the buttery were taken for further study.

The condition of the house was supposed to be unfavorable to the patients, and for this reason they were moved, as Dr. Mesic has stated, to the house of a neighbor. Of course, thorough examination of the house was not made until the patients had been removed.

Special inquiry was now made concerning the food used by this family. They had been living very simply. They lived upon bread, butter, milk, and potatoes, with coffee and ripe fruit. They had eaten no canned foods for months. They ate but little meat. Occasionally a chicken was killed and served, and rarely, some fresh meat was obtained from the village. During the week in which they were taken ill, all the meat used consisted of slices from a piece of bacon, the only meat which was kept in the house, and a chicken. None of the latter remained, but the bacon was examined. It seemed in perfect condition and contained no trichinæ. Moreover, as has been seen from the history of the cases, all the members of the family were not made sick by any one meal, but the opportunity of obtaining the poison must have been present for some time. Moreover, the fact that previous similar, but less severe attacks had occurred at intervals for the past three years convinced us that the poison must owe its origin to some long existing condition.

The drinking water supply was also investigated. The water was obtained from a shallow well, and some of it was taken for analysis. But several families had for years used water from this well, and had remained healthy.

The milk used by the family was studied. Of course, we could get none of that which had been used before the members of the family were stricken down. As soon as he made the diagnosis of tyro-

toxicon poisoning, Dr. Mesic ordered the discontinuance of the use of milk, not only with the sick, but he forbade the daughter, who had returned, and any of the visitors using it. Mr. Evans owned four milch cows and they were supplied with fair pasturage and abundant water. The greater part of the milk was placed in tin cans which were set in a wooden trough in the yard, and surrounded by cold water. The covers to the cans were arranged so that the air could have free access to the milk, and were left in this position until the milk was thoroughly cooled. Indeed, the cans were furnished by a creamery company, which followed the directions which I have previously given for the care of milk. On his first visit to me, Dr. Mesic brought some of the milk from one of these cans. This I examined, but failed to find tyrotoxicon in it.

However, the family did not drink any of the milk from the cans. That which they did use was kept in the buttery which I have described. Here it stood upon a shelf and some members of the family at least were in the habit of drinking from it between meals. This was especially true, it is said, of the son. He would frequently come from his work in the fields, go into the buttery and drink a glass or more of the milk. Mr. Evans states that he frequently observed that the taste of the milk was not pleasant. On my first visit to the premises, I advised that some milk should be taken from the cans, allowed to stand in the buttery over night and be sent to me the next day. This was done and in this milk we found tyrotoxicon not only by the employment of chemical tests, but by poisoning a kitten with it.

On the death of the mother and son, Dr. Mesic asked for a post-mortem, but the friends objected, and the undertaker used an arsenical embalming fluid, so that, although consent was subsequently obtained, it was decided that the examination would be so vitiated as to be worthless. On the death of the daughter, Dr. O. C. Jenkins, the coroner, summoned a jury and held an inquest. The post-mortem was conducted by Dr. George A. Hendricks, in the presence of the jury and several physicians who had been invited. Dr. Hendricks has kindly furnished me with his report, which I present here in full:

"The autopsy was held fifteen hours after death. The abdominal viscera were first examined. The great omentum was small, in normal position, covering the small intestine. The small intestine was moderately distended with flatus. The jejunum was ashy-green in color; the ileum purplish-green. About eighteen inches from the termination of the ileum was found a diverticulum two inches in length. The small intestine contained very little alimentary matter. The vermiform appendix was free, contained some small fecal lumps, and showed no evidence of any inflammation. The cæcum, ascending, transverse, and descending colon, were empty and their circular fibres were tightly constricted, except at intervals where the intestine was distended with gas. The sigmoid flexure was moderately distended with gas, and the rectum contained small bits of fecal matter. The stomach was somewhat contracted and lay wholly upon the left side of the median line. It contained a few ounces of fluid. Its extremities were ligated and the organ removed. The mucous membrane of the stomach and intestine were not examined until they reached the chemist. The duodenum was distended with flatus. The liver was normal in size and appearance. The gall bladder contained about one ounce of bile. The spleen was normal. One-half ounce of fluid deeply stained with blood was found in Douglas's cul-de-sac. The uterus, Fallopian tubes, and ovaries were deeply congested. The left ovary was enlarged and presented on its posterior surface a hemorrhagic spot, oval, about one-half line in length, and several other less distinct ones. The right ovary was normal in size and showed numerous Graaffian scars. The ureters and bladder were normal; the latter contained a small amount of urine. The peritoneum, pancreas, and kidneys, were perfectly normal.

The thoracic cavity was next opened. The lungs were normal; there was about one-half ounce of free serum in the left pleural cavity; none in the right. Pericardium normal; right auricle in diastole; left auricle and both ventricles in systole.

The dura mater showed venous congestion; the arachnoid normal; the pia-mater congested. On the surface of the centrum ovale, small drops of blood oozed from the divided vessels. The large veins of the velum interpositum were distended. Third and fourth ventricles were slightly distended with serous fluid, but the walls were normal. There seemed to be slight softening of the optic thalami. The sub-arachnoid fluid was about twice the normal quantity.

On examination of the mucous membrane of the stomach and intestine in the presence of the chemist, Prof. A. B. Prescott, nothing abnormal could be found. The membrane was stained with bile, but there was not the slightest redness The solitary glands were distinct, but not at all inflamed. Peyer's patches were normal.

It will be seen that there existed no lesion which would account for the death. The venous congestion observed in the brain would follow from failure of the heart.

Some of the post-mortem appearances bore a striking resemblance to those which I had observed in cats poisoned with tyrotoxicon. This was especially noticeable in the condition of the mucous membrane of the stomach and intestine. Tyrotoxicon produces the symptoms of a gastro-intestinal irritant, but not the lesions. The contraction of the circular fibres of the intestine, which undoubtedly caused the constipation, I had also observed in cats that died from tyrotoxicon poisoning without either vomiting or stool. The action of this poison upon the stomach and intestine must be through the nervous system. Small doses cause both vomiting and purging, while after large doses vomiting may be impossible, and obstinate constipation may exist. Both the vomiting and purging after small doses are undoubtedly due in part to increased activity of the circular fibres of the muscular coats, induced through the nerves; and the inability to vomit, and the constipation, one or both of which may be observed after large doses of the poison, are due to spasm of the same muscles, induced in the same manner.

Prof. A. B. Prescott was requested by Coroner Jenkins to analyze the material for mineral and vegetable poisons. He made analyses of the stomach and part of its contents, and a portion of the liver. His results were wholly negative.

Mr. F. G. Nooy tested a cold-water extract of the

finely divided intestine for ptomaines. The fluid, which was acid in reaction, was filtered, then neutralized with sodium bicarbonate, and shaken with ether. The ether, after separation, was removed, and allowed to evaporate spontaneously. The residue was dissolved in water, and extracted again with ether. This ether residue gave the chemical reactions for tyrotoxicon, and a portion of it was administered to a kitten about two months old. Within half an hour after the administration the kitten began to retch, and soon it vomited. Within the next three hours it was noticed to vomit as many as five times. The breathing became rapid and labored. The animal sat with its head down, and seemed greatly prostrated. The pupils were examined, but could not be said to be dilated. There was no purging. The retching and heavy breathing, with evidences of prostration, continued more or less marked for two days, after which the animal slowly improved.

A quantity of fresh milk was divided into five portions of one quart each, placed in quart bottles which had been thoroughly cleansed, and treated in the following manner:

No. 1 consisted of the milk only, and was employed as a control test.

No. 2 was mixed with a drachm of vomited matter.

No. 3 was treated with a portion of the contents of the stomach.

No. 4 was treated with an aqueous extract of the intestine.

No. 5 was treated with a small portion of the soil, which had been taken from the floor of the buttery, stirred up with water.

These bottles were placed in an air-bath, and kept at a temperature of from 25° to 30° C. for twenty-four hours. Then each was tested for ptomaines. No. 1 yielded no tyrotoxicon, while all of the others contained this poison. The tests were both chemical and physiological. All of the samples yielded a non-poisonous base when treated according to Brieger's method, and the same substance was obtained from perfectly fresh milk. It is most probably formed by the action of the heat and reagents employed in this method. This base was obtained in crystalline form, and several portions of it were administered to kittens without any effect. The further study of this body will be of interest to toxicologists, because it gives many of the general alkaloidal reactions. At first we supposed it to be Brieger's neuridin, and this supposition may still be correct, but, as we obtained it, it gave some reactions which are not given by neuridin. Further investigations will be made on this point.

Tyrotoxicon was obtained from the filtered milk by two methods: (1) The one which we have previously used, and which consists in neutralizing the filtered milk with sodium bicarbonate, and extracting with ether. That portion of the poison employed in the physiological tests was obtained in this way, and in order to be sure that no poison came from the ether, the extract from the milk to which nothing had been added was given to a kitten, and was found to produce no effect. (2) The filtrate from the milk was heated to 70° C. (158° F.) (tyrotoxicon decomposes at 91° C. (195.8° F.)) for some minutes, and filtered. This filtrate, which was perfectly clear, was treated with a small quantity of nitric acid in order to convert the tyrotoxicon into a nitrate, then pure potassium hydrate in the solid form was added until the solution was strongly alkaline. This solution was concentrated so far as it could be, on the water-bath. (The potassium compound of tyrotoxicon is not decomposed below 130° C. (234° F.).) The dark brown residue, after cooling, was examined with the microscope and found to contain the crystalline plates of tyrotoxicon-potassium hydrate, along with the prisms of potassium nitrate. The former was separated from the latter by extraction with absolute alcohol and filtration. The alcohol was evaporated to dryness on the water-bath, and the residue again extracted with absolute alcohol. From this alcoholic solution tyrotoxicon was precipitated with ether. The precipitate was decomposed by adding acetic acid and heating, the tyrotoxicon being broken up into nitrogen and phenol. The phenol was recognized by precipitation with bromine water, and by other well-known tests.

On October 8th, the coroner's inquest, which had been adjourned after the *post-mortem*, in order to await the results of the analysis, was resumed, and after hearing the testimony in accordance with the above stated facts, the jury returned a verdict of death from poisoning with tyrotoxicon.

Ehrhart has recently published the history of some cases of poisoning from cheese, of which the following is an abstract: The family of a workman, consisting of eight persons, ate for supper 600 grammes (about 18 ounces) of Limburger cheese. The rind was covered with a heavy mould, while the interior had become fluid from putrefaction, and was of bitter taste. Three ate only of the mouldy rind, and these remained well. The next morning, the five who had eaten of the inner portion suffered from vertigo, nausea, vomiting, and abdominal pains; no stool. The father had convulsive movements of all the extremities. The pupils were dilated, and did not respond to light; there were double vision, cold sweat, skin cyanotic, abdomen distended, difficulty in swallowing, delirium, mild trismus, and temperature 40° C. (104° F.). The temperature of the mother, on account of the great collapse, was subnormal. She had no convulsive movements, but there was prolonged loss of consciousness. The pulse was small and thready, and threatened paralysis of the heart. Recovery was very slow. The others suffered only from gastro-enteric symptoms. Ehrhart discussed the question as to whether these symptoms were due to tyrotoxicon, or to infection with microorganisms; but as I have not had access to his original paper, I do not know what his conclusions are. (*Schmidt's Jahrbücher*, B. 213, S. 248.) However, there cannot be much doubt that in those cases in which the organism is taken into the alimentary canal, it continues the elaboration of its poisonous products.

There is one other point to which I will only refer at this time. It seems now that small doses of tyrotoxicon, especially when repeated, elevate the

temperature. This is probably due to peripheral irritation, which is a common cause of elevation of temperature. On the other hand, fatal doses cause depression of temperature from collapse.

REPORT OF A CASE OF WLADIMIROFF-MIKULICZ OSTEOPLASTIC RESECTION OF THE FOOT.[1]

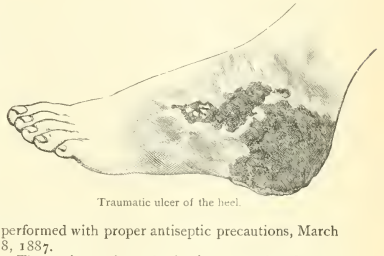
BY WM. BARTON HOPKINS, M.D.,
SURGEON TO THE EPISCOPAL HOSPITAL, PHILADELPHIA.

THE operation which is the subject of this report was originally designed by a Russian, Dr. W. D. Wladimiroff in 1871, but as he published the account of it in his own language, it was not known out of Russia until nine years afterward. In 1880 Dr. John Mikulicz, of Vienna, performed the same operation and published it as his own device, not knowing that it had ever been done before.

Wladimiroff called it the operation for the production of artificial pes equinus; Mikulicz, the osteoplastic resection of the foot. The toe-stump operation would probably still better distinguish it. It consists essentially in removing the entire heel and ankle-joint and applying what remains of the foot to the leg in a position of pes equinus, so that the patient walks on his toes. The conditions for which it has been performed are (1) caries of the larger tarsal bones, and (2) extensive loss of the tissues about the heel, either from disease or injury. For the relief of the former it has been almost exclusively practised, and a number of excellent results have been obtained, though there is, of course, the risk of the disease attacking the remaining bones and causing relapse. To the latter class of cases, though of these there are as yet but few examples, it will probably prove more particularly applicable, as in them the tissues involved preclude the conservative operations of Chopart, Pirogoff, and Syme, and leave no alternative but amputation of the leg. Should further experience confirm the observations so far made, that this operation is followed by decidedly better functional results than amputation, its future scope will probably include many cases of railroad, gunshot, and the like injuries, where the parts destroyed correspond with those which by it are removed.

There have been twenty-one cases recorded within the past seven years. Most of these have been successful and most of them for caries. The case reported this evening is only the second in which the operation has been done for injury of the tissues about the heel. The patient's history is as follows: Wm. D., aged thirty-seven, born in Scotland, a strong, healthy man, was admitted to the Episcopal Hospital November 16, 1886. Two months before his admission he had been run over by a freight car. The wheel had passed over his left foot, tearing away the tissues of the heel down to the bone, laying bare the extensor tendons of the toes and leaving an isthmus of sound integument upon the dorsum of the foot not wider, according to the patient's recollection, than an inch and a half. During his stay in the hospital of nearly four months, the ulcer, for which he was admitted, obstinately refused to heal. Its cicatricial border having advanced to the utmost limit of its tensile strength, would repeatedly break down, so that all efforts to facilitate healing failed. The accompanying cut, taken from a photograph of the foot at the time of the operation, shows accurately the position of the ulcer and cicatrix on the outer side. On the inner side the ulcer did not extend quite so far forward. The operation was

FIG. 1.



Traumatic ulcer of the heel.

performed with proper antiseptic precautions, March 8, 1887.

The patient, after etherization, was placed upon his abdomen; the sound leg was flexed upon the thigh and held out of the way by an assistant. The injured foot having been cleansed, was elevated upon a block placed beneath the rubber cloth and a constant stream of sublimate solution from the irrigator directed upon it during the two hours and three-quarters occupied by the operation.

The first step consisted in dissecting out the posterior tibial nerve. An incision started behind the inner malleolus was carried obliquely downward and forward below it to a point below Chopart's joint. The nerve was found to be so deeply imbedded in newly formed, very dense fibrous tissue, that it was dissected out with some difficulty. It was then divided at the upper and lower angles of the wound, about two inches of its length being removed.

The second step in the operation consisted in forming the flaps. These had to be slightly modified by the form of the ulcer, in order that their edges should consist of moderately healthy skin; in most respects, however, the limits of the ulcer corresponded with rather remarkable accuracy to the prescribed lines of incision. The first incision was carried across the sole of the foot, down to the bone, from the tubercle of the scaphoid on the inside to a point a finger's breadth behind the base of the fifth metatarsal bone on the outside; and the second straight across the back of the ankle half an inch above the os calcis, from the external angle of the sole incision to the upper angle of the tibial nerve incision.

The third step consisted in the resection of the astragalus and os calcis, and the shaving off of the lower ends of the tibia and fibula and posterior sur-

[1] Read before the College of Physicians of Philadelphia, November, 1887.

faces of the scaphoid and cuboid. Disarticulation of the astragalus at the ankle-joint was done from behind forward; of the os calcis at its cuboid joint, and the astragalus at its scaphoid joint from below upward. Due care was taken not to injure the dorsalis pedis during the last-mentioned disarticulation, as the position of the ulcer necessitated the division and ligation of the posterior tibial artery in forming the flaps.

The last step in the operation included the approximation of the bones, divided nerve and tendon ends, and the closure and dressing of the wound.

With the view of obtaining more perfect fixation of the tarsus to the tibia and fibula than has heretofore been found possible, two sterilized bone dowels were placed in holes drilled into the lower extremity of the tibia at points which corresponded as nearly as possible to the centres of the presenting surfaces of the scaphoid and cuboid; the insertion of their projecting points into these bones being deferred until the final adjustment of the parts. A very fine catgut suture was so placed in the divided and retrenched ends of the posterior tibial nerve as to bring these ends into very accurate apposition without undue pressure. The slack, however, was not yet taken up. In like manner sutures of stronger gut were introduced into the divided and retrenched ends of the tendon of the peroneus longus, about three inches of which were excised, and into the divided end of the tendo-Achillis, and the edge of the plantar fascia exposed in the lower flap. These sutures were all allowed to remain slack until the foot should be brought into its new position. Moderate pressure was sufficient to accomplish this and to impale the tarsal bones upon the sharp-pointed dowels. With the foot firmly retained in this position, the extremities of the nerve were brought accurately together and sutured. The tendon of the peroneus longus was likewise sutured and the terminal extremity of the tendo-Achillis stitched to the edge of the plantar fascia. The introduction of drainage catgut and suturing the skin flaps with catgut completed the approximation of the parts. A dressing of gauze, iodoform, and sublimate cotton was applied and the limb was placed upon a straight posterior splint. The latter was in three days substituted by a plaster-of-Paris double dressing, the foot and leg sections being connected by an iron bracket anteriorly in order to leave ample room for washing and dressing the wound. Five weeks later a small ulcer remained, but union of the deeper parts was complete and consolidation of the tarsal and leg bones was found to have begun. The patient at this time complained of tingling in the toes accompanied by occasional shooting pains, and there was partial anæsthesia of the sole of the foot. Sensation gradually returned, and is now restored except over a very limited area.

Three months after the operation, under ether, the toes were extended to a right angle; to accomplish which moderate force only was required. Since then there has been nothing to note. The limb continues to gain in strength and the patient can now, with a cane, walk four miles a day. He has had the braced shoe which he wears but two weeks, and has, therefore, not yet had time to become thoroughly accustomed to it. He walks well without a cane, while with one, when not fatigued, he shows hardly a limp. This cut represents the limb after the operation, and was engraved from a photograph on the block.

FIG. 2.

Artificial pes equinus.

Two modifications of the operation, as practised in this case, deserve mention, namely: the employment of bone pegs or dowels to fix the tarsal bones to the tibia, and the suturing of the divided and retrenched tendons. The dowels provided proved rather too light to make the joint firm and immovable, but they were nevertheless used, as heavier ones were not at hand. Perfect fixation of the tarsus and leg at the outset, by lessening suppuration, by promoting early bony union, and by obviating the necessity of such carefully applied outside support, would seem to be an important factor in the after-treatment of the operation. The dowels should be three-sixteenths of an inch in diameter and three inches in length They may be sunk two inches in the tibia and one inch in the tarsus. Holes need not be drilled for them in the latter, as their sharp points readily penetrate the cancellated structure of these bones. Uniting the severed tendons has, without doubt, added to the function of the foot in this case. Though suggested in THE MEDICAL NEWS editorially, it does not appear to have been attempted before. The plantar fascia was chosen as a strong accessible point to which to attach the tendo-Achillis instead of the tarsal periosteum, as suggested in THE NEWS

Within the narrow limits of motion which now remain, the patient can flex, as well as extend the foot. The motion is partly tarso-metatarsal, and partly tarso-tibial. The latter is diminishing, and the braced boot which he wears may probably be cast aside within one year.

The following table includes, it is believed, all the operations which have been performed, with the exception of five Russian cases reported incidentally by Sklifossowsky. The first nineteen cases are taken from the table of Zesas.[1]

[1] Archiv für klinische Chirurgie, 1886, Bd. 33.

Table of Operations.

No.	Operator.	Year.	Age.	Cause.	Result.	Authority.	Remarks.
1	Wladimiroff,	1871	15	Caries.	Recovery.	Aus den Arbeiten der Gesellschaft der Aerzte der Stadt Kasan, 1872.	Patient walked very well without cane.
2	Mikulicz,	1880	23	Syphilitic ulcer.	Recovery.	Archiv für klin. Chirurgie, Bd. 26.	At the end of four months patient walked with cane and boot, while in eighteen months did hard work, and could walk one hour.
3	Socin,	1881	22	Caries.	Recovery.	Jahresbericht über die chirurgische Abtheilung des Spitales zu Basel, 1881–82.	After two months used cane and worked in the field; no relapse after two years.
4	Mikulicz,	1881	27	Caries.	Recovery.	Centralblatt für Chirurgie, 1884.	Patient, with boot, could walk quite far, but without it had to use a cane; six months afterward died of pulmonary tuberculosis
5	Sklifossowsky,	1882	30	Caries.	Recovery.	Bull. de la Société de Chirurgie de Moskou, 1882.	Patient did well.
6	Haberern,	1882	18	Caries.	Relapse.	Verhandl. der Deutschen Gesellschaft für Chirurgie, 1884.	Amputation of the leg, after five months, from which he recovered.
7	Mikulicz,	1883	16	Caries.	Recovery.	Centralblatt für Chirurgie, 1884.	Patient walked in six months with boot; without it had to use a cane.
8	Lauenstein,	1883	32	Caries.	Recovery.	Ibid.	Patient died in eight months of what appeared to be pulmonary tuberculosis.
9	Lauenstein,	1883	25	Caries.	Recovery.	Ibid.	Patient could walk four hours at a time, and without boot could step firmly upon his foot.
10	Mikulicz,	1883	?	Caries.	Recovery	Verhandl. der Deutschen Gesellschaft für Chirurgie, 1884.	Patient walked well with cane.
11	Roser,	?	?	Caries.	Recovery.	Fischer: Deutsche Zeitschrift für Chirurgie, xxiii. S. 164.	Functional result excellent.
12	Kümmell,	1884	38	Caries.	Relapse.	Centralblatt für Chirurgie, 1885.	After four months resection of the rest of the tarsus, part of the metatarsus, and a portion of the tibia and fibula.
13	Schattauer,	?	10	Caries.	Recovery.	Ibid.	Patient, with boot, could walk many hours without fatigue.
14	Renssen, (Ranke's Clin.)	1884	?	Deformity resulting from fracture.	Recovery.	Ibid.	Seven and a half months after operation patient walked well with boot; 3½ cm. shortening.
15	Schattauer,	1884	9	Caries.	Relapse.	Ibid.	Five weeks after the operation amputation of the leg; recovered.
16	Fischer,	1884	18	Caries.	Relapse.	Deutsche Zeitschrift für Chirurgie, xxiii. 1 u. 2 Heft.	Resection of second and third cuneiform bones and remainder of cuboid; recovered. At the end of a year patient walked well with boot and cane; could go up stairs.
17	Niehans,	?	50	Injury of heel.	Recovery.	....	Very good functional result. Without boot or cane became easily fatigued.
18	Sordina,	1885	20	Caries.	Gangrene.	Centralblatt für Chirurgie, 1886, No. 3.	Amputation at the lower third of the leg.
19	Sordina,	1885	11	Caries.	Recovery.	Ibid.	Very good result.
20	Gutsch,	1886	13	Caries.	Recovery.	Archiv für klin. Chirurgie, Bd. 34, 1886.	Resection included parts of all the cuneiform bones and seven centimetres of the tibia and fibula; function completely restored.
21	Fenger,	1886	20	Caries.	Recovery.	Journal of the Amer. Med. Association, vol. viii., Jan. 1887.	Fifteen months after the operation can walk without boot and cane, and bear the whole weight on the foot; solid ankylosis; lengthening 5 cm.
22	Hopkins,	1887	37	Traumatic ulcer.	Recovery.	....	After eight months can walk four miles with cane and boot; limited motion under voluntary control in flexion as well as extension; about ¾ inch lengthening.

THE APPEARANCE OF A LARYNX NEARLY TWENTY YEARS AFTER THE EXTIRPATION OF AN EPITHELIOMA BY EXTERNAL ACCESS.

BY J. SOLIS COHEN, M.D.,
OF PHILADELPHIA.

ON February 25, 1868, in the presence of the late Professor S. D. Gross; of the patient's physician, the late Dr. John L. Atlee, of Lancaster; the late Dr. Elsberg, of New York; Dr. R. J. Levis, and others, I removed, under chloroform, from the larynx of a gentleman, thirty years of age, a large portion of his left vocal band and the entire lining membrane of the left ventricle, together with masses of morbid growth; portions of which, removed by intralaryngeal procedures, had been pronounced to be epithelioma by the most competent microscopists of the day in Philadelphia and in Washington.

I had been using chemical canterization, had been removing fragments, piecemeal, with forceps, sawing them off with knives and electric cautery; but on finding the bulk of the tumor increasing, despite the removal of masses, which, in the aggregate, exceeded the bulk of the neoplasm when first detected, I determined to cease these efforts. So I performed a precautionary tracheotomy, and, subsequently, split the larynx externally, removed the growths with cutting instruments and forceps, scraped out the lining membrane of the ventricle, and seared all the raw tissues with a solution of acid nitrate of mercury (33⅓ per cent.).

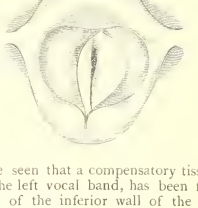
When examined microscopically, the masses removed were pronounced to be epithelioma.

The patient did well, and some months later, there having been no recurrence, I removed the tracheal canula. This case was reported in the *Medical Record*, p. 244, July 15, 1869; and in my treatise on *Diseases of the Throat*, 1872. In the second edition of the treatise (1879) I intimated that as the patient had survived the operation so long without recurrence, I felt that, despite the microscopic evidence, I had been dealing not with an epithelioma but with a benign growth.

Finding that the patient was free from laryngitis only when in a warm and equable inland climate, I advised him to fix his residence permanently in a locality which I selected. This advice was taken. Its wisdom has been emphasized by the fact that every summer visit to Pennsylvania has excited hoarseness and some amount of inflammation of the mucous membrane, from both of which conditions perfect immunity has been experienced while the patient remains in his home of expatriation.

A few weeks ago the patient called upon me hoarse with a laryngitis, and somewhat worried by recent newspaper gossip. Upon relief from the laryngitis his voice became excellent, better than I had ever heard it, and not sufficiently harsh to attract attention. His voice, at home, he has told me at previous visits, "could be heard a mile along the railroad track," so it must be perfectly satisfactory.

Believing that a picture of the larynx at so late a date would be interesting, I requested my colleague, Prof. Watson, of the Polyclinic, to use his skill in preparing it.



It will be seen that a compensatory tissue doing service as the left vocal band, has been formed at the expense of the inferior wall of the ventricle, which has been in great measure obliterated by the eversion.

As acknowledged in my report of the case (*loc. cit.*, p. 245), I feel indebted for much of the success to a whispered suggestion from Prof. Gross, after removal of the tumor and staunching of the hemorrhage, that I should take the sharp edge of the heel tip attached to the handle of my bistoury and scrape out the entire ventricle; and thus, in his forcible language, remove "the very atmosphere of the disease."

AN OBSCURE CASE OF UNCONTROLLABLE EMESIS; LAPAROTOMY; DEATH.

BY WILLIAM T. SMITH, M.D.,
PROFESSOR OF PHYSIOLOGY IN DARTMOUTH MEDICAL COLLEGE, N. H.

ON the 12th of August, Maggie M., a domestic, eighteen years of age, consulted me at my office for a disordered stomach, with vomiting. I gave a simple remedy and did not see her again for a week, when she came, saying that the vomiting had not ceased and she was no better. Two days later I was called to see her at her house, and then I learned the following history of the case.

About a year ago she had a short sickness, with bloody discharges from her bowels. From that time she was subject to frequent attacks of headache and vomiting. The headaches, after a time, ceased, but the attacks of vomiting persisted. They came as often as once in ten days, the longest period of immunity being one period of three weeks. The bowels, which had been regular in their action, became from the time of the first attack very costive. She would go a week without a movement. Her menstruation became somewhat irregular. Except that she was constipated, she was perfectly well between the attacks of vomiting, and worked steadily. These, when they came on, lasted a day or part of a day, and then she would be entirely relieved.

At the time when I was called to her house, she had been vomiting two weeks. She had no fever, a pulse of about 80, no pain, no local soreness, no tympanites. I could find no tumor of any description in the abdomen. Her bowels had moved slightly within a few days. I examined the uterus thoroughly and the adjacent tissues, but found nothing abnormal. The urine was normal. There were

no symptoms of disturbance of nerve centres. I gave enemata, but got only slight liquid discharges for three days. I then gave three compound cathartic pills. For the next twelve hours her vomiting was copious and distinctly fecal. After the effect of the pills had ceased, the fecal character was less marked, but it continued in a greater or less degree to the end. Professors E. S. Dunster, C. P. Frost, and Charles B. Nancrede, saw and examined the patient. She was fed by the rectum, and various methods were assiduously tried to check the vomiting, but in vain. Laparotomy was discussed, but postponed from day to day on account of the lack of definite local symptoms, and because there was repeatedly a discharge of liquid fecal matter per rectum, proving that no complete obstruction existed.

Obturator hernia was excluded by the absence of signs on examination. After ten days had elapsed since I was called to her bedside, and more than three weeks since the vomiting began, it was decided that laparotomy, as the last resort, offered the only chance, and that a slight one, of recovery. Dr. Nancrede performed the operation, assisted by Dr. Dunster. The strictest antiseptic precautions were observed. An incision four inches long permitted the introduction of the hand, and careful search was made for obstruction. None was found, though there was a suspicious narrowing of the gut in a portion of its course. The incision was closed. The patient recovered promptly from the ether, and there were no symptoms of shock. She rallied well from the operation and lived through the night, but died the next morning.

At the post-mortem, a portion of the ileum about one inch long, five feet from the ileo-cœcal valve, was found to be narrowed, apparently by cicatricial contraction, to half its normal calibre. The valvulæ conniventes were obliterated, and the surface of the thickened membrane suggested distinctly a healed ulcer.

It is a well known fact that to excite reflex vomiting it is not necessary that the whole calibre of an intestine be cut off—a partial constriction is sufficient. We were compelled to accept this as the solution of this sad and perplexing case.

SUB-BENZOATE OF BISMUTH, AN ESCHAROTIC.

By ALLEN J. SMITH, M.D.,

ASSISTANT DEMONSTRATOR OF PATHOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

In the treatment of a phagedenic tendency in several cases of chancroids in the venereal wards of the Philadelphia Hospital the writer, then on duty as a resident physician, became satisfied of the faulty character of the local measures, in that the escharotics usually employed were too severe for use, except with anæsthetics, and had to be applied too rapidly because of their excessive action. Recalling certain characteristics of several benzoates, a combination of that acid with bismuth suggested itself as of possible service; and acting upon this idea, Mr. Joseph W. England, Chief Druggist of the Hospital, kindly prepared a quantity of the oxy- or sub-benzoate for trial.

Bismuth subnitrate was treated with nitric acid, heated and dissolved. To this, hot water in small quantities at a time was added until a marked opalescence was obtained; and the solution thus prepared added slowly and with constant stirring to a solution of sodium benzoate in water.

The white precipitate was collected, and washed with alcohol to separate any free benzoic acid or sodium benzoate, and then dried. The chemical reactions upon which these steps are based are in Mr. England's opinion probably as follows:

$$BiONO_3 + 2HNO_3 = Bi_3NO_2 + H_2O.$$

$$Bi_3NO_2 + NaC_7H_5O_2.H_2O = BiOC_7H_5O_2 + NaNO_3 + 2HNO_3.$$

In the second equation the bismuth salt is precipitated and the nitrate of sodium and nitric acid separated in the filtrate, in which is present also a quantity of free benzoic acid. After drying, a smooth white powder, of a relatively light specific gravity, was obtained. This was employed in dressing the chancroids, just as iodoform or other antiseptic powders are used; the sore being carefully cleansed, a little of the powder was dusted over the surface and the dressing completed with some simple bland ointment. For a short time no sensation whatever was experienced, then a warmth of the part, and in about ten minutes a burning and tingling sensation manifested itself and continued for several hours—not severe enough in character to render the patient positively uncomfortable, except from excitations of the part, which were afterward controlled by camphor or bromide of potash administered internally, or by adding a little morphia to the bismuth salt in dressing the sore.

The dressing was renewed once or twice daily, and the bismuth powder employed until the type of the sore had changed – within seventy-two hours in the three cases under the writer's care, the unhealthy purulent surface becoming clean and red with active granulation. After this point had been reached iodoform was substituted for the sub-benzoate and the sores allowed to heal, which they did thoroughly and quickly.

This material is undoubtedly a mild escharotic when thus applied, with a slow and continued action; and erodes the unhealthy tissues gradually and comparatively painlessly, thus avoiding the inconveniences of such powerful caustics as nitric acid and bromine.

It was used as an occasional dressing for indolent leg ulcers with marked benefit, stimulating the sores into granulating surfaces, and cleaning them of the peculiar glazed coating such ulcers often present, just as an occasional application of nitrate of silver would do.

223 South Seventeenth Street, Philadelphia.

HOSPITAL NOTES.

THE TREATMENT OF TYPHOID FEVER.

Good Samaritan Hospital, Cincinnati.

Dr. Whittaker's treatment for the mild cases is purely expectant. Most of them require nothing more than rest in bed and milk diet. In all cases, when the

temperature reaches 103°, antifebrin, three to five grains, is administered. Few cases have required more than three grains to effect a reduction of two degrees within an hour. Five grains produce, for the most part, excessive diaphoresis and chills. When this accident has occurred after three grains, antipyrin is substituted, in doses of ten grains. In one protracted (six weeks) case under the writer's observation antifebrin, in three to five grain doses, was given every two to four hours, for three weeks, with invariably good effects upon the temperature and general condition. In protracted cases expressed beef-juice with calves'-foot jelly, is added to or substituted for milk. In all cases whiskey is administered as soon as the pulse flags, and in cases of distinct enfeeblement of the heart the sulphate of spartein is given in one-sixteenth of a grain doses, every four hours, in lieu of digitalis, whereby the stomach is not disturbed.

Of fifteen cases under observation at one time, two showed sharp complications on the part of the lungs. Slight bronchial catarrh was present in nearly all the cases. Rusty and bloody sputum, with crepitus and dulness, occurred in two cases, one of which, the case of a victim of chronic alcoholism, was additionally complicated with profuse hemorrhage from the bowels. Two of the fifteen cases were affected with profuse hemorrhage. One died—the only fatal case thus far; the other, the case referred to, probably will die.

Upon the supervention of hemorrhage all food is interdicted; thirst is allayed with ice. Ice-bladders are placed on the abdomen, small quantities of opium are administered, and subcutaneous injections are made of sclerotinic acid, which keeps better and irritates less than ergotin. In desperate cases salt water is transfused subcutaneously, as recommended by Ziemssen. This treatment proved entirely futile in one case, as stated. The autopsy revealed extensive ecchymotic patches, stretching over a distance of nearly two feet of the ileum. This entire section of the ileum showed intense hyperæmia throughout. The ulcers were clean, with distinct, sharp edges, and were apparently not the sources of the hemorrhage, which issued per diapedesin. In this case each occurrence of hemorrhage was attended with a reduction of temperature to a subnormal degree, and a complete relief of all nervous symptoms. In the case still living the loss of a large amount of blood, while reducing the temperature in the same way, does not, in the least, clear the intellect. In all severe cases the temperature is taken in the rectum, a difference of two degrees having been frequently observed between the temperature of the rectum and mouth. In no case is any reliance placed upon observations made in the axilla.

PRESBYTERIAN HOSPITAL, CHICAGO.

The usual course pursued in DR. HENRY M. LYMAN'S Ward, at the outset of the disease, is to secure a thorough cleansing of the patient. For this purpose he is treated with a full bath externally, and with two or three cathartic, doses of calomel internally. If there is much diarrhœa, mercury and chalk are substituted for calomel. When the stools indicate the action of the cathartic, mercurials are suspended, and medication is directed chiefly toward the skin and the kidneys. In cases of doubtful character, where the possibility of malarial fever is admitted, full doses of quinine are prescribed for a few days; but they are omitted as soon as the uncomplicated typhoid character of the fever is apparent.

During the course of the fever, when no complications arise to require special attention, the patient is frequently sponged with tepid water. The kidneys are stimulated with a solution of potassium chlorate—one drachm to the pint of water, the whole to be drank during twenty-four hours. If patients prefer an acid draught, they are allowed lemonade, tamarind water, or dilute phosphoric acid and water, so long as diarrhœa does not forbid. Sleep at night is procured for restless patients by the administration of whiskey and milk, or urethan in half-drachm doses, or chloral hydrate with potassium bromide. Opiates are rarely found necessary in uncomplicated cases. Alcoholic stimulants are not used unless the heart shows signs of weakness. A diet of milk and animal broths is carefully administered. Gruel *ad libitum* is given, unless flatulence indicates indigestion of starchy substances.

Diarrhœa is not specially treated, unless it threatens to become excessive. Ordinary cases get nitrate of silver and opium every six or eight hours. If the tongue becomes red and glazed, especially if the heart is at the same time enfeebled, turpentine emulsion gives good results. Unusual flatulence is greatly relieved by disinfection of the bowels with naphthaline, in five grain doses every three or four hours. Antipyrin is reserved for cases with high temperature, restlessness, and insomnia. It is not used continuously.

During convalescence, the principal reliance is placed upon a careful dietary and general hygiene, with such medicines as assist digestion and nutrition. Abundant nursing and the least possible medicine are the objects at which we aim in the treatment of uncomplicated typhoid fever.

COOK COUNTY HOSPITAL, CHICAGO.

DR. NORMAN BRIDGE, in cases seen early and when there is any doubt of the diagnosis, gives quinine in a few large doses, to the extent of producing positive cinchonism. He frequently afterward gives it in small or tonic doses, for many days continuously. If there is not positive proof that the bowels have been thoroughly evacuated already, this end is accomplished by a laxative of calomel. Calomel is given occasionally in the course of the sickness in some cases when a laxative is required, this drug having been found more mild and harmless than any other. The most common method of evacuating the bowels, however, when any assistance is required, is by an enema of warm water. No patient is allowed to pass more than forty-eight hours without evacuation of the colon, and in constipated patients an enema is often given each day.

Patients with diarrhœa receive rather full doses of salicylate or subnitrate of bismuth, the former by preference, and small doses of deodorized tincture of opium, but rarely any preparation of turpentine. For severe headache or backache early in the sickness, small doses of opiates are often given, but when headache alone is complained of, and there is much fever, moderate doses of antipyrin are found most useful, since they relieve more or less both conditions.

Alcohol is used only in conditions of serious prostra-

tion with weak heart and rapid pulse, when it is given freely, and with as much regularity as to times and doses as any other remedy. It is unusual for a patient to receive more than eight ounces of whiskey in twenty-four hours, the more common quantity being two to four ounces. Nux vomica and strychnia are given often in the same conditions.

High temperatures are combated with sponge baths and partial or complete packs with tepid water, and with antipyrin or antifebrin. Quinine is not used as an antipyretic. A pack is often continued for several hours, the patient having little or no clothing but the wet sheet. It is not regarded as necessary to resort to any of the water measures till the temperature has reached 103° F., and rarely then unless they are grateful to the patient; and they are discontinued as soon as the temperature falls to 101° F. During the bathing and packing, as well as at all other times, the extremities of the patient are kept warm by clothing and hot applications, regardless of the temperature of the trunk of the body. A bath in a tub has not been used.

Antipyrin is given in ten to twenty grain doses at intervals of one to two hours when the temperature is high, and the pulse not specially weak. More than three such doses are rarely received by a patient in a day, or a night. Patients who have, with their high temperatures, fulness and pain in the head, experience most relief from this remedy and to such it is given by preference.

Antifebrin has been used comparatively little, but in a few cases it has been employed in the same conditions and in the same cases as antipyrin, and with effects nearly identical. Thallin has been used a little, but was discarded on account of its suspected tendency to depress the heart.

A high temperature for a few hours each day is not regarded as, *per se*, a very grave condition; and the disposition on the part of *internes* to use antipyretics of all sorts, is repressed rather than encouraged.

The stools are directed to be received into utensils containing some sufficiently powerful disinfectant.

The diet is in the main fluid, milk being the staple. One or two quarts of milk daily are taken by each patient, who takes nothing else. Egg-nog, beef tea, and other fluid meat preparations are allowed. A little stale bread, or cracker, is often allowed to mild cases throughout, and always forms a part of the diet early in convalescence. In bad cases of diarrhœa milkman's cream is sometimes added to the milk, a smaller quantity being taken, and a corresponding reduction in the amount of the casein being secured.

The presence of tympanites does not lead to any change in the treatment, beyond the application of turpentine stupes to the abdomen.

Hemorrhage from the bowels is regarded as an indication for the use of opiates, warmth to the extremities, for a reduction in the foods that can produce fecal matter, and for stimulants to a moderate degree.

Care is exercised during convalescence to prevent patients from eating improper articles, or too much, and from taking too much exercise; from being chilled generally, and from having cold extremities in particular. It has been found, it is believed, that neglect of these points has led to many true relapses of typhoid fever.

MEDICAL PROGRESS.

Antiseptic Rules for Monthly Nurses and Physicians.—Dr. Playfair, in a paper read at the late meeting of the British Medical Association, gave the following rules for antisepticism in the lying-in chamber:

1. Two bottles are supplied to each patient; one contains a solution of perchloride of mercury, of the strength of one part to one thousand of water, tinted with litmus (called the 1 in 1000 solution), the other carbolized oil (1 in 8).

2. A small basin containing the 1 in 1000 solution must always stand by the bedside of the patient, and the nurse must thoroughly rinse her hands in it every time she touches the patient in the neighborhood of the genital organs, for washing or any other purpose whatsoever, before or during labor, or for a week after delivery.

3. All sponges, vaginal and rectal pipes, catheters, etc., must be dipped in the 1 in 1000 solution before being used. The surfaces of slippers, bed-pans, etc., should also be sponged with it.

4. Vaginal pipes, enema tubes, catheters, etc., should be smeared with the carbolized oil before use.

5. Unless express directions are given to the contrary, the vagina should be syringed twice daily after delivery with warm water, with a sufficient quantity of Condy's fluid dropped into it to give it a pale pink color.

6. All soiled linen, diapers, etc., should be immediately removed from the bedroom.

N.B.—These rules are for the purpose of protecting the patient from the risk arising from accidental contamination of the hands, sponges, etc. It is, therefore, hoped that they will be faithfully and minutely adhered to.

There are, in addition, a few precautions to be used during the labor to which the practitioner should himself see.

1. Before making any examination, or using the antiseptic lotion, he should thoroughly cleanse his hands with soap and water, being specially careful as to his nails, about and under which septic matter may easily lurk.

2. At an early stage of the labor the vagina should once be thoroughly syringed with the antiseptic lotion, and vulva sponged with it.

3. When the head is distending the perineum the external genitals should again be sponged with the lotion.

4. Cold cream, lard, etc., should not be used for lubricating the fingers, and carbolized oil or vaseline should be employed.

5. When possible, sanitary towels should be used to receive the lochial discharges in preference to diapers, as they may be burned when soiled. All risk from imperfectly cleansed diapers is thus avoided.

I do not think that these suggestions impose on the practitioner a burden grievous to be borne, or call upon him to do anything which, having the interest of the patient at heart, he should for a moment hesitate about. —*British Medical Journal*, November 12, 1887.

Hydrate of Chloral a Preventive of Rabies.—At a recent meeting of the French Academy of Sciences,

Brown-Séquard reported a series of experiments upon rabbits and birds, in which by injecting oil of tansy he had produced a species of rabies, which was controlled by the vapor and subcutaneous injections of hydrate of chloral. Arguing by analogy, Brown-Séquard considers chloral a preventive of true rabies, and refers to his previous writings on the subject, and to cases in the human subject, in which he had been able to exemplify his theory.—*L'Union Médicale*, November 5, 1887.

FOR CHRONIC GOUT.—VIGIER has used to advantage

R.—Lithii carbonat.	. . .	℥ 2½.
Sodii iodid.	. . .	℥ 2½.
Ext. gentian.	. . .	gr. 23.

Pulv. gummi arab.	. . .	gr. 23.
Ext. gentian.	. . .	gr. 70.—M.

Ft. pil. 100 in num.
Sig.—One with each meal.—*Revue de Thérapeutique* November 1, 1887.

POISONING BY ANTISEPTIC SOLUTIONS OF BICHLORIDE OF MERCURY.—MR. A. J. PEPPER calls attention (*Lancet*, November 5, 1887) to the source of danger to life from the use of bichloride of mercury in the form of very weak solutions—*e. g.*, 1 in 1500 or 2000. I understand, he says, that in midwifery practice it is not at all uncommon to employ injections of the strength just mentioned for cleansing purposes, not only as a corrective against septic discharges, but also as a prophylactic. Where the patient is free from organic disease of the kidneys one has little need to fear untoward consequences from the treatment under consideration. I am aware of two cases of death from acute inflammation of the bowels following closely on the injection of very weak mercurial solutions into the vagina shortly after parturition. As in each instance no other cause of the fatal complication could be discovered, there is little doubt that the acute irritative lesions in the intestines were due to the bichloride in the course of its elimination. The action of the salt was concentrated, so to speak, in this particular region by reason of grave renal affection. In one of the two cases I made a very exhaustive post-mortem examination. The whole of the small and large intestine was acutely inflamed. There were thousands of hemorrhagic patches, punctate and irregular in shape. There were a few minute recent ulcers. The catarrhal congestion was extreme. Lymph was effused into the substance and upon the surface of the mucous membrane. Slight general peritonitis seemed to have started at the middle of the colon, where the intestinal lesion was more marked than elsewhere. The stomach was not affected. The kidneys were in an advanced state of fatty degeneration. No aperients had been administered to the patient, but a solution of bichloride of mercury (1 in 2000) had been injected into the vagina to prevent decomposition of the lochia. Profuse diarrhœa ensued, and continued until death. The body temperature was never raised, and latterly it was subnormal. I was at a loss to account for the ultimate cause of the diarrhœa and its fatal consequences until the circumstances were explained to me by an obstetric physician who was present at the necropsy, and who had witnessed a precisely similar case in his own practice. The lesson to be learnt from the foregoing narrative is—that even a very attenuated solution of a mercurial salt should not be employed as a vaginal injection without first ascertaining the state of the kidneys by an examination of the urine.

PYLORECTOMY FOR CANCER.—DR. BERNAYS reports, in the *Medical Brief*, No. 8, 1887, a case of cancer of the pylorus, which he found extended into the duodenum, and was adherent to the head of the pancreas. He removed the tumor, and sutured the resected gut, carefully isolating the orifices of the bile-ducts. A drainage tube was left in the abdomen, and antiseptic dressings applied. Bichloride of mercury, 1 to 4000, was the antiseptic employed. The patient died of shock, nineteen hours after operation.

Dr. Bernays' conclusions, from his study of the subject, are as follows:

1. The operation of pylorectomy, for the cure of a cancerous stricture can be successfully performed in only a limited number of cases. It will always be impossible to determine the feasibility of the operation before making an explorative laparotomy.

2. The operation of pylorectomy, in cicatricial stricture following round ulcer, is clearly indicated, and will be feasible in the majority of all the cases.

3. Uncontrollable hemorrhage from a round ulcer of the stomach, which threatens the life of a patient is a clear indication for gastrotomy—not necessarily for pylorectomy. The operation necessary to check the hemorrhage will become apparent after inspection of the location and source of the hemorrhage.

4. Perforation of an ulcer of the stomach into the abdominal cavity is an imperative and vital indication for laparotomy and consequent gastrotomy and gastrorrhaphy.

5. In cases of inoperable carcinoma of the stomach the operation of gastrostomy is indicated with a view to local treatment of the tumor by means of chemicals or the curette from within this organ.

A valuable bibliography is appended to the paper.

THE ALKALINITY OF THE BLOOD IN CERTAIN DISEASES.—VON JAKSCH, of Graz, in an extended article in the *Zeitschrift für klinische Medicin*, Band 13, Heft 3 and 4, concludes that

1. Fever lessens, in greater or less degree, the alkalinity of the blood.

2. This lessened alkalinity is a constant symptom in uræmia.

3. Diseases of the liver, in which destruction of the parenchyma occurs, produce this condition.

4. Leukæmia, pernicious anæmia, and chlorosis lessen the alkalinity of the blood.

5. Poisoning with carbon dioxide produces this result also.

Excision of the Larynx for Malignant Disease.—The operative treatment of malignant disease of the larynx is an essentially modern development of surgical art, and in spite of one or two brilliant but exceptional triumphs, it has till quite recently been marked more by boldness of conception and execution than by solid success. That, however, is no more than could at some time have been truly said of many other provinces of surgery in which the knife, which at first was little better than a lethal weapon, is now an instrument of real and lasting good. The larynx was first completely excised little more than twenty years ago by Dr. Patrick Heron Watson, of Edinburgh, in a case of syphilitic stenosis which directly threatened the patient's life; and in 1873 total extirpation was successfully performed by Billroth for cancer. Since then the operation has been done by many surgeons, but the results have, on the whole, been extremely discouraging.

From Mr. Butlin's recent analysis in his *Operative Surgery of Malignant Diseases*, of Hahn's valuable statistics (Volkmann's *Vorträge*, No. 260, 1885), we learn that 74 cases of excision of the entire larynx for new growths have been recorded: in 3 the disease was respectively tuberculosis, papilloma, and polypi. Of the 71 malignant cases, 25 died within the first fortnight, and 5 within six or seven weeks after the operation; death was due, in a large majority of instances to pneumonia, or purulent bronchitis, and could in no case be attributed to recurrence of the disease. Thus, there appears to be a mortality of about 40 per cent. directly due to the operation itself. Not one of the cases in which the disease was sarcoma and not carcinoma died. Of the 65 cases in which the larynx was completely excised for carcinoma, 30 died from the immediate, or almost immediate, results of the operation; as in the case of abdominal sections, the death-rate has slightly diminished recently, through improvements in operating and after-treatment. A few of the cancer cases died of collapse or hemorrhage; the remainder succumbed to the pulmonary complications above mentioned. The direct entrance of air into the trachea endangers the lungs, as after tracheotomy; but the severe type of inflammation generally observed after excision of the larynx is distinctly septic, and is due to the escape of discharges from the wound into the trachea; the patient, moreover, is always in a more or less enfeebled state of health.

Resection of the larynx or removal of a portion of the organ was first performed for epithelioma by Billroth in 1878; the patient survived the operation six months, when he died of recurrence of the disease. In another case, in which the left half of the organ was excised by Reyher, of St. Petersburg, in 1880, the patient was alive and free from recurrence fourteen months after the operation. At the International Medical Congress of London in 1881, however, the late Dr. Foulis, of Glasgow, who read a paper embodying the whole experience of the profession on the subject up to that date, argued strongly in favor of complete, as against partial, excision, on the ground that whilst little, if at all, more dangerous in itself, the risk of perichondritis is avoided, and the disease is more thoroughly eradicated. Subsequent experience has not borne out this view. Owing to the great and apparently irreducible fatality attending it, complete excision of the larynx has been looked upon with growing disfavor by surgeons, whilst the removal of a portion of the organ in suitable cases has, during the last few years, been shown to be not only much less dangerous in its immediate consequences, but also more effectual in restoring the patient to comparative health and comfort. The progress that has been made in this direction is largely due to Dr. Eugene Hahn, of Berlin; and one or two of our own countrymen have also operated with success so far as can be judged in the meantime.

The following are the results of partial excision up to the present time: In 12 cases, where half the larynx was removed—in 10 cases for carcinoma, in 2 for sarcoma—only 1 patient died from the direct effects of the operation. The wound is far easier to dress and the patient's condition less desperate than when the entire larynx is excised. In 6 cases the larynx has been completely, and in 2 partially, removed for sarcoma. The after-history of 1 of the complete operations is lost; of the remaining 6, it appears that 1 was quite well and free from recurrence six years after operation; 1 was well two years after; 1 died of phthisis a year and a half after excision of the larynx, without a sign of recurrence of the local disease; 1 died of recurrence of the sarcoma seven months after operation; and 1 fifteen months after. In the 2 recorded cases of partial excision for sarcoma, 1 was free from recurrence "some time after the operation;" 1 died ten months after from pulmonary complication, without recurrence of the new growth. Of the 35 cases of excision for carcinoma which recovered from the operation (excision, as above noted, proved directly fatal to 30 patients), 20 died within a few months from recurrence. Of the remaining 15, the history of 1 case is lost; 2 died of pneumonia at the end of three and four months respectively; 7 cases were yet alive when these statistics were prepared, and free from recurrence at periods ranging from fourteen months to four years. Thus only 1 patient could be considered cured. Out of 7 partial excisions of the larynx for cancer, 1 died of the operation; 3 died of recurrence within seventeen months, and in the 3 which remain there was no recurrence, but only fourteen months had elapsed in one of these, eleven in another, and an unrecorded space of time in the third. It must be observed that many of the above cases appear to have been badly selected, the patient being in an unsatisfactory state of health, or the disease much advanced. Unfortunately, the survivors, not very numerous at the best, too often find but little comfort in life after the operation. Solis-Cohen remarked at the International Medical Congress in London, in 1881, that recovery and mere survival after the operation are two different things; and Sir Morell Mackenzie observed that a patient after extirpation of the larynx was usually in a condition "of great misery." Professor Lefferts, of New York, stated that the "main reason for the patient's subsequent discomfort, not unusual, however, in like cases, was the impossibility of closing the large defect in the neck, by any form of artificial apparatus, so as to permit of perfect deglutition." Since 1881, cases have been noted where the patient's condition was not in any instance altogether unsatisfactory. Still the frequency of fatal lung complications above recorded is suspicious. The loss of voice can be remedied, more or less, by the use of an artificial larynx. After partial

operations the patient can often swallow easily within a few days; but after complete excision, with extensive removal of the surrounding parts, deglutition may be impossible without assistance, and the patient may need to be fed by means of a funnel and tube. Altogether, excision of the larynx is a gloomy subject to contemplate. For sarcoma, partial or even complete removal is not very unsatisfactory, provided that the disease has not advanced too far. Partial excision for carcinoma is also no desperate operation, but it has not been performed with sufficient frequency to allow of a very decided verdict. As to complete excision for carcinoma, it is highly unsatisfactory. As a rule, it appears to mean death; as an exception, it signifies a short but harassed lease of life, with constant fear of recurrence and of lung complications. Truly a patient under such conditions may say of his life, like the Duke in *Measure for Measure*, "If I do lose thee, I do lose a thing that none but fools would keep."—*British Medical Journal*, Nov. 19, 1887.

THE ANTISEPTIC TREATMENT OF DIPHTHERIA.—LE GENDRE, of Paris, in the *Archives de Laryngologie*, No. 1, 1887, gives the following formulæ for antiseptic mixtures to be used in diphtheria:

Bichloride of mercury may be given in

Aquæ destillat. . . .	ʒ 3¾
Tinct. aconit. . . .	♏ 15 to 30.
Sodii chlorid.	
Pepsinæ	aa gr. ¾.
Hydrarg. bichlorid. . .	gr. 1/6 to 2¼.—M.

Sig.—A teaspoonful every hour.

Cyanide of mercury has been employed in the following solution:

Aquæ destillat. . . .	ʒ 15.
Tinct. aconit. . . .	♏ 15.
Hydrarg. cyanid. . . .	gr. 1/6.—M.

Of which a teaspoonful may be given hourly.

Iodoform may be locally applied in the following:

Ether	ʒ 6¼.
Balsam tolu. . . .	♏ 75.
Iodoform	gr. 38.

In powder it may be mixed with sugar, 1 to 3.

Bromine and the bromides may be given in

Bromin. (pur.)	
Potass. bromid. . . .	aa gr. 8 to gr. 15.
Aquæ destillat. . . .	ʒ 30.

with which the pharynx may be penciled every two or three hours; it may also be used by inhalation.

Sulphur and sulphides may be prepared for use as follows:

Ol. amygdal. dulc. . .	ʒ 5⅝.
Sulphur. sublimat. . .	gr. 38.

This may be used as a gargle.

The following, in pill form, has given good results:

Calcii sulphid. . . .	gr. ¾.
Digitalin.	
Quiniæ arsen. . . .	aa gr. 1/60.

For infants the dose should be but one-half.

Salicylic acid may be used in

Aquæ destillat. . .	ʒ 25.
Glycerin. . . .	ʒ 2½.
Aquæ lauro-cerasi . .	♏ 15.
Acid. salicylic. . . .	gr. 4½.

which may be applied upon cotton to the fauces.

Benzoate of sodium has been frequently tested, and is used by Litzerich in the following:

Aquæ destillat.	
Aquæ menth. piper. . .	aa ʒ 10.
Syrup aurant. cortic. . .	ʒ 2½.
Sodii benzoat. . . .	gr. 75.

From half a teaspoonful to a dessertspoonful hourly.

Lactic acid is given by Bricheteau and d'Adrian, by inhalations of spray, in solution 1 to 100, as a gargle:

Aquæ	ʒ 25.
Syrup aurant. . . .	ʒ 7½.
Acid. lactic. . . .	gr. 75.

may be employed.

Diphtheritic ulcers may be touched with

Glycerin	ʒ 15.
Acid. lactic. . . .	gr. 45.

Oxalic acid, given internally, may be used after the prescription of Cornillon:

Infusion of green tea . .	ʒ 32½.
Syrup aurant. cortic. . .	ʒ 7½.
Acid. oxalic. . . .	gr. 23.

Dose, a teaspoonful to a dessertspoonful every three hours. With this treatment is generally combined the use of a tea made by infusing laurel leaves. The local use of oxalic acid is best in solution, 1 to 20, or in glycerine, 1 to 100.

The writer personally prefers the following treatment: Three or four times daily touching the diseased surfaces with corrosive sublimate, 1 to 100 in alcohol; he dips a small sponge or pledget of cotton in this, carefully presses out superabundant fluid, and touches the false membrane. Every four hours he orders thorough spraying or douching of the nares and fauces with *warm* boric acid solution, 4 to 100. Internally, benzoate of sodium, gr. 45 to ʒ 3 per diem, in a mixture given in teaspoonful doses hourly. Bordeaux, Spanish, and Champagne wines and coffee are to be freely used. In a succeeding number of THE MEDICAL NEWS will be given additional formulæ for the treatment of diphtheria, as collected by LE GENDRE.

THE CARE OF SCHOOL CHILDREN'S EYES.—At the Vienna Congress of Hygiene COHN, of Breslau, in an extended study of the eyes of school children concluded that of all lights the electric is the best. Definite provisions regarding desks, books, paper, types used, and the arrangements of curtains and blinds are advised, and especial caution in avoiding overwork is enjoined. Regarding glasses, no child is allowed to wear glasses whose myopia is less than two dioptres. If the myopia ranges between two and six dioptres, a concave glass, whose distal focus is about twenty inches, is given, and precautions are taken to prevent the child from injuring the chest by constant stooping. If the myopia is more than six dioptres, it is generally found that a complica-

tion of eye disorders is present, and glasses are often harmful. The attention of the profession, and of the State is urged for the careful supervision of schools and scholars.—*Deutsche medicinische Wochenschrift*, November 3, 1887.

Pregnancy (Rachitic Pelvis); Induction of Labor; Cæsarean Section; Recovery.—Breisky, of Vienna, reported at a meeting of the College of Physicians of Vienna, October 28, 1887, the case of a rachitic woman, who in addition to the usual effects of rachitis suffered from atrophic coxitis. As no absolute hindrance to delivery existed premature labor, at the beginning of the ninth month, was induced. The head, however, failed to descend into the pelvis; the temperature rose, and labor made no progress. Sänger-Cæsarean section was performed. A five per cent. carbolic acid solution was used to disinfect the decidua, and iodoform was freely used. The stitches were removed on the tenth day; perfect recovery followed. Breisky warns against undertaking Cæsarean section for insufficient reasons, because (1) We cannot measure the conjugata vera with exactness; (2) we cannot determine the size of the head exactly before birth; (3) we cannot estimate the power which the uterus will exert, nor the success of the uterine contractions. In view of these facts, no merely theoretical grounds should lead to the performance of Cæsarean section.—*Wiener medizinische Presse*, October 30, 1887.

An Efficient Vesicant.—Soules has obtained excellent results from

Acid. carbolic.	gr. 30.
Alcohol	gtt. 5.
Camphor. pulver.	gr. 75.

To be pulverized together; and

Ol. olivæ.	℥ 4½.

to be added.

This may be used as a vesicant, as the conditions indicate, with proper caution. Dressings should be renewed at least daily.—*Revue de Thérapeutique*, Nov. 1, 1887.

Carcinoma of the Descending Colon; Three Operations for the Relief of Occlusion; Recovery.—At a meeting of the Vienna College of Physicians, on November 4, 1887, Von Hacker exhibited a patient on whom an operation for artificial anus was performed in January, 1887, for carcinoma of the colon, with occlusion of the bowel. In May, the patient returned, asking that the fistula be closed, as feces were passing naturally. This was done, but at the end of June last it was necessary to remove the tumor, to relieve the original symptoms which had returned. The patient recovered from the intestinal resection in four weeks, and was entirely relieved. The constricted bowel was so nearly occluded that a match could be inserted into the stricture with the greatest difficulty. The tumor was a carcinoma, of the cylindrical epithelial type. Billroth remarked that in these cases when left to nature, the necrosis of the exuberant elements of the cancer resulted in their discharge and in the temporary relief of the stricture; the cicatrization which followed, however, made the occlusion still more pronounced.—*Wiener medizinische Presse*, Nov. 6, 1887.

Iodophenol in Pertussis.—Rothe prescribes

R.—Acid. carbolic.	gr. ¾.
Alcohol	♏ 1.
Tinct. iodin.	gtt. 5.
Aquæ menth. piper. . . .	℥12½.
Tinct. belladonn. . . .	♏ 15.
Syrup. papaveris . . .	℥2½.

(*Syrup papaveris* is but little used in America; its opium strength is half a grain of opium to one thousand grains of syrup, and more definite preparations of opium may be better employed.) Of this a small teaspoonful to a dessertspoonful may be given every two hours.

Rothe found that this combination of remedies reduced very distinctly the number and frequency of the paroxysms.—*Journal de Médecine de Paris*, October 30, 1887.

Pseudo-asthmatic Dyspnœa in Cancer of the Pharynx.—Legueu reports, in the *Gazette Médicale de Paris* of November 5, 1887, the case of a woman, aged fifty-two, admitted to the Hospital Cochin, complaining of pharyngeal pain and paroxysmal dyspnœa. Examination could find nothing to account for the dyspnœa, except mechanical obstruction to breathing, and in a paroxysm, threatening life, tracheotomy was performed. Temporary relief followed, but paroxysms of dyspnœa recurred, which finally proved fatal. Under the temporary relief afforded by tracheotomy, the respiratory tract was carefully explored. Phonation was unimpaired, the larynx was normal; visual examination of the pharynx revealed no lesion to account for the dyspnœa, but, on introducing the index finger into the pharynx, an induration was found above the lower border of the velum palati and upon the left lateral wall of the pharynx, whose extent it was impossible to determine. The canula remained entirely free, and death evidently resulted from a lesion beyond the larynx. Post-mortem examination revealed cancer of the left lateral wall of the pharynx, a little above the lower border of the velum palati, and extending downward on the posterior pharyngeal wall. At one point the pharyngeal wall had been perforated, and the prevertebral tissue had become involved, and a cavity containing about a drachm of fetid pus was present. So extensive had been the involvement of the pharyngeal wall that both the pneumogastric and superior laryngeal nerves of the left side had been implicated; they were adherent to the tumor by indurated cellular tissue. The trachea and larynx were absolutely free. There was no involvement of the tracheal and bronchial glands. Death was caused by the implication of the nervous supply of respiration.

Primary Actinomycosis of the Brain.—Bollinger, of Munich, reports the case of a woman, aged twenty-six, who suffered from symptoms of a cerebral tumor, without convulsions. Death resulted, in coma. Post-mortem examination showed cysto-myxoma of the third ventricle, with œdema and cerebral anæmia. The mass of the tumor was composed of actinomycoses. The invasion of the parasite was probably by the blood, and then the formation of cerebral emboli containing actinomycoses.—*Wiener medizinische Presse*, Nov. 6, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to illustrate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance. . . . . $5.00.

Single Copies. . . . . 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in registered letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, DECEMBER 3, 1887.

THYMOL IN DIABETES MELLITUS.

Isolated cases of disease are valuable on account of their rarity or because they have been thoroughly studied; doubly so when they unite both of these qualities. Diabetes mellitus can scarcely be called a rare disease. Its diagnosis is readily made and the details of its dietetic management are, with minor exceptions, generally agreed upon. In its medicinal treatment, however, the number of drugs that may be employed is suspiciously large, a fact doubtless owing to inaccurate observations. The proper study of a case of diabetes may be compared to an elaborate physiological experiment. In fact, it is nothing else. Not only does it demand that the quantity of urine and its percentage of sugar be estimated, but also that careful records be kept of the body weight and the amount and quality of the ingesta, and this work is merely preliminary to the study of the effect of any of the so-called remedies for this disease.

To appreciate properly the effect of a drug in this affection, it should be administered, not only while the patient is on an exclusively proteid diet, but also while he is partaking of carbohydrates, for, in the former case, the improvement, or cure, may be ascribed to the drug when it is due, in whole or in part, to the diet.

In the recently established therapeutic clinic of the University of Siena, Prof. Bufalini has thoroughly studied the action of thymol in two cases of diabetes, the object of his investigation being twofold. He first endeavored to ascertain the effect of thymol upon the excretion of sugar, and, secondly, whether its well-known power as an intestinal disinfectant would exert a favorable influence upon the condition known as acetonæmia.

To determine the former question, the patients were first placed upon a mixed diet of soup, meat, eggs, bread, coffee, milk and wine, the amount of each being given by weight. The quantity of feces and urine, the density of the latter and its percentage of sugar were also ascertained, as well as the bodily weight in one case, the other being too feeble to be moved. After from a week to ten days of such observations, thymol was given in doses of 30 to 45 grains per diem and continued long enough (to the two cases 12¾ drachms were given in eighteen days) to demonstrate that, while the patient is on a mixed diet, this substance exerts no appreciable effect upon the quantity of urine, its specific gravity, or its percentage of sugar.

When the patient is on an exclusively proteid diet, the case is different and requires some explanation. It is a common observation that as soon as a diabetic is placed upon an albuminoid diet, the sugar in his urine will diminish, perhaps entirely disappear. A persistence in this regimen is, however, apt to be followed by digestive disturbances, with abnormal intestinal putrefaction, and a speedy reappearance of the absent, or increase of the diminished sugar. This occurred in one of Bufalini's cases. Under a proteid diet continued for one month, the sugar had entirely disappeared. Continuing the same diet, gastro-intestinal disturbances (anorexia, vomiting, borborygmi, diarrhœa) set in and were soon followed by a reappearance and steady increase of the sugar. At this juncture it occurred to Bufalini to administer thymol, he believing with his colleague, Martini, and with the writer of this article, that it is the best known intestinal antiseptic. The result was immediately favorable and the conclusion with reference to the drug is that it is not only useful but necessary in cases of diabetes placed upon an exclusively proteid diet. No deleterious effects from the use of thymol were observed by Bufalini and none need be apprehended, although, in the writer's experience, smaller doses (from ʒss to ʒj) are quite efficient in abnormal conditions of intestinal putrefaction.

The second object of Bufalini's research was to test the effect of thymol upon the condition known as acetonæmia. Both of these patients presented all the symptoms of this condition. They were somnolent, greatly prostrated, and they exhaled the odor, and their urine gave the reactions of this substance. Under the use of thymol, the characteristic odor of the breath diminished and the reactions of acetone in the urine became faint, while the general condition improved. Bufalini holds that these results of the thymol treatment establish the fact that acetone is formed in the intestine by abnormal fer-

mentation of the sugar excreted by this channel, and that the ferment is an altered gastro-intestinal mucus.

LAPAROTOMY FOR GUNSHOT WOUNDS OF THE ABDOMEN.

One of the most remarkable revolutions of modern surgery has been that which has occurred in the treatment of penetrating gunshot wounds of the abdomen. Until very recently, a surgeon would have been considered foolhardy had he opened the abdomen for the purpose of searching for and repairing intestinal lesions. Now one who fails to perform laparotomy when there is a probability that the viscera have been injured or bloodvessels torn, by a shot or other penetrating wound, is considered reprehensible; and, without doubt, in the near future, the surgeon who fails to offer his patient the chances afforded by an operation, will be held criminally responsible in the event of an unfavorable issue of the case. The statistics of the late Civil War, as compiled by Otis, which demonstrated how almost uniformly fatal these injuries were, when treated expectantly; the vigorous writings of Marion Sims, and the experimental work upon animals, performed first by the elder Gross, and more recently by Parkes, of Chicago, have been potent factors in effecting this radical change in the treatment of these injuries. It only required the successful cases of Kocher and Bull, to prove convincingly that what was true as regards animals, also held good in the case of human beings.

At the opening session of the Surgical Section of the Ninth International Medical Congress, Dr. Charles T. Parkes, of Chicago, introduced this subject in an instructive paper. Up to the present time somewhat more than forty operations for gunshot wounds have been performed, with a success of about thirty per cent., which rate will undoubtedly increase as operators become more skilled, and acquire more confidence in the procedure. In our issue of November 12th, Dr. J. M. Fox, of Philadelphia, reports another recovery after abdominal section, and suturing of the intestinal lesions, which is believed to be the first successful operation of this nature which has been performed in this city. At the Congress in Washington, there was a considerable diversity of opinion in regard to certain points, but it was generally conceded that laparotomy was proper when there was a well-founded suspicion that the bullet had penetrated the peritoneal cavity. It can scarcely be doubted, however, that the number of successful cases treated expectantly has been underestimated, but we cannot recommend this method of treatment except under exceptional circumstances.

There are some questions connected with this subject which have not received sufficient elucidation. Is it necessary to perform laparotomy in every case of penetrating abdominal wound? It is our opinion that all wounds of the abdominal parietes should be explored with a disinfected finger or probe, and if penetration has been effected, the wound should be enlarged, in order to determine whether lesions of any kind have been made. In stab-wounds the lesion must be limited to the region of the wound, hence it is not necessary to perform median section, and make an extensive examination of the bowels; but in gunshot wounds, unless the bullet is of very small size, median section had best be performed.

Should laparotomy be performed for posterior and side wounds? The same rule applies as for wounds of the anterior abdominal wall; the wound should be explored with finger, probe, or by incision, and if it leads into the peritoneal cavity, section in the linea alba should be made. Fortunately, wounds in the back and side, even when they do penetrate the solid or hollow viscera, are very much less fatal than those which enter from the front, owing doubtless to the better drainage, and to the fact that the peritoneum is absent from the posterior surfaces of some of the viscera.

We think that whilst there may be some difference of opinion in regard to the propriety of an operation in individual cases, there can be no dispute upon the propriety of operating in general when there is a probability of perforation of the intestines, or any of the other abdominal viscera. The fact appears to be well established that all penetrating wounds of the abdomen are less fatal when treated by operation than when left to the processes of nature.

ALTERNATING PYREXIA IN HODGKIN'S DISEASE.

In the *Berliner klinische Wochenschrift* of August 1st and November 7th, Eistein describes a remarkable case of lymphadenoma of the internal glands with an alternating pyrexia of most peculiar type. The patient, a man, aged nineteen years, had ten attacks of fever between the 13th of November, 1886, and the 6th of July, 1887. The pyrexial period continued thirteen or fourteen days, and the fever reached as high as 104°–105.8° F. In the intervals, which lasted, on an average, ten or eleven days, the temperature was usually subnormal. There was moderate enlargement of the spleen, no increase in the size of the external lymph glands, and, with the exception of the fever, the patient presented no special symptoms. The blood was examined, with negative result. After the 7th of July the fever became almost continuous, and death occurred with œdema and coma on the 14th of August. The autopsy revealed the lesion of lymphadenoma of the bronchial, mediastinal, and retroperitoneal groups,

with growths in the lungs, pleura, and liver. The case, then, was one of Hodgkin's disease, or pseudo-leukæmia, with an unusual type of pyrexia, which had, however, been previously described by Murchison, Gowers, and Pel, though in none of the instances on record was the alternating pyrexia of so striking a character.

What interests us particularly is the fact that Professor Ebstein regards his case as an illustration of a new disease, and writes under the caption of "Chronic Relapsing Fever, a New Infectious Disease." As the affection has nothing whatever to do with true relapsing fever, the febris recurrens, we must consider the name most inappropriate, in spite of the recurrent type of pyrexia; but we object still more seriously to any such multiplication of diseases by giving undue prominence to some one feature or symptom. The truth is, that in Hodgkin's disease the fever is very variable; some cases are afebrile throughout, more commonly there is for periods a continued fever, or the type is remittent. We have seen one case in which the fever was distinctly intermittent with paroxysms of chill, hot and sweating stages, and then we have the alternating pyrexia noted by the writers referred to above, the most remarkable illustration of which is afforded by the case under discussion. Manifestly, it would be just as reasonable, should we meet in further cases with a well-marked type of pyrexia, to describe them under the title of "chronic malaria, a new infectious disease," as it is for Professor Ebstein to make a chronic relapsing fever out of a case of Hodgkin's disease with alternating pyrexia. Nor do we think that any satisfactory classification of the cases of the disease can be made in a factor so variable and uncertain as the fever. The type of alternating pyrexia appears to be more common in cases in which the deeper glands are involved, and a knowledge of its occurrence may be a help in diagnosis, and in calling attention to this Ebstein's contribution will be of great service. We cannot, however, but regard it as a curious error in judgment that he should have described the case as a new infectious disease, and under such a misleading title as chronic relapsing fever.

Typhoid fever is, at present, epidemic in Cincinnati. The visitation is chiefly attributable to the state of the Ohio River, which has never been so low since 1881, when this disease was unusually prevalent. The death reports for the week average about six per day; the number of cases is variously estimated at 600 to 1000. The various hospitals of the city contain about 150 cases. The disease prevails in all parts of the city, in the most remote suburbs, as well as the city proper. Upon the advice of physicians most families take the precaution of boiling all the drinking water and milk. It is a common sight to see children on their way to school with bottles of boiled water slung across their backs with their satchels. There is general testimony at the medical societies that the disease is mild, though the mortality report is much larger than at any time in the history of the city. One prominent physician informs us that he has seen in private practice more cases of severe hemorrhage than in any previous experience with the disease.

Drs. Rushford and Cameron, of the Bacteriological Laboratory of the Medical College of Ohio, have succeeded, by Brouardel's method, in discovering by culture experiments, and demonstrating before the Cincinnati Academy of Medicine the bacillus of typhoid fever in the waters of the Ohio River.

No more striking illustration could be given of the progress which the Japanese have made in modern medical methods than in the *Journal of the College of Medicine of the Imperial University, Tokio*, No. 1 of which has just reached us. It is in small quarto form, and in typographical detail is not equalled by any of our exchanges. The execution of the colored lithographs, made, we notice, by native artists, is on a par with the choicest German work of the kind. The subject-matter is worthy of the setting. The principal article contains in full the research on the contagion of syphilis, by Disse and Taguchi, the preliminary account of which has already been noticed in The News. They claim to have isolated, cultivated, and successfully inoculated a microbe in this disease. A second long article is on chyluria, by Murata, assistant at the medical clinic of Prof. Bätz. A third shorter one, on the situation of the inner ear, completes the number. The *Journal* will be warmly welcomed the world over, and will take a prominent position among the scientific publications of the day.

Dr. Charles B. Nancrede has been elected Surgeon to the Jefferson College Hospital in the place of Dr. R. J. Levis, resigned.

The fact that more than 1200 practitioners of medicine have taken courses at the New York Polyclinic since its opening in November, 1882, is proof that in this country, at least, post-graduate schools meet a want.

Dr. Theodore R. Varick died November 23, 1887, at his home in Jersey City, at the age of sixty-one years. In his death northern New Jersey loses her most eminent surgeon. He was a native of New York, coming from Revolutionary stock—Col. Varick, one of his ancestors, having been on the staff of General Washington. He attended Rutger's College, and, at the age of twenty years, took his medical degree from the New York University. He

soon after took up his residence in Jersey City, and there remained during the rest of his life. He was a large man physically and intellectually, and went into the front rank in every medical and sanitary department in which he interested himself. He became remarkably skilful as a surgeon. He was for seventeen years Surgeon-General of the State, and, at the time of his death, President of the Hudson County Health Board, and Surgeon to the St. Francis and Jersey City hospitals. The cause of his death, which was unexpected, was consequent upon an accident, about a week before, whereby he sustained a fracture of both bones of the leg. He was properly treated, and was feeling so well that he undertook to receive the visits of some of his patients in his office. Suddenly he was taken with symptoms of heart-clot, and the tide of life rapidly ebbed. He left a family of six children, the eldest of whom is a physician who had been associated with him for ten years.

We understand that Professor Da Costa will deliver the next Middleton Goldsmith lecture under the direction of the New York Pathological Society some time in the coming spring.

REVIEWS.

A System of Gynecology by American Authors. Edited by Matthew D. Mann, A.M., M.D., Professor of Obstetrics and Gynecology in the Medical Department of the University of Buffalo, N. Y. Volume I. 8vo. pp. 789. Philadelphia: Lea Brothers & Co., 1887.

In his preface the editor declares that his purpose has been to secure not only full and complete articles, but also those thoroughly practical; and in this he has been markedly successful. The impression made by the book is that of one written by practitioners of gynecology for the general practitioner who includes diseases of women in his practice. The tone of the book is not didactic, but is rather that of the concise statement of facts, with the coloring which the writer's experience has caused them to assume in his own mind. Abundant illustrations, three of them in colors, and full references to the literature of the subject add to the interest of the reader.

The Historical Sketch, by Dr. Jenks, affords an interesting exposition of the development of gynecology in the United States; among the events justly considered historical are included several of minor importance, hardly worthy of a place in such a retrospect. It is not the discovery of a novelty, but the demonstration of its value which is of sufficient merit to cause it to be remembered. Dr. Garrigues writes upon The Development of the Female Genitals and their Malformations, in a lucid and interesting manner, showing a thorough review of the literature of the subject. Dr. Coe's article on The Anatomy of the Female Pelvic Organs abounds in practical applications, and is highly valuable and interesting. Gynecological Diagnosis, Surgery, and Therapeutics are treated with satisfactory conciseness by Drs. Grandin, Dudley, and Skene; and Electricity as a medical agent is fully discussed by Dr. Rockwell. Dr. Wylie expresses his beliefs regarding Menstruation and its Disorders in terse and forcible language which commands consideration, if not acquiescence. The well worn field of Sterility is traversed by Dr. Jackson, while the editor contributes a well written article on Diseases of the Vulva. Dr. Palmer writes upon the Inflammatory Affections of the Uterus, and Dr. Reamy on Subinvolution of the Vagina and Uterus, both articles being upon subjects of the highest importance, and treated with corresponding ability. Dr. Maury and Dr. Van de Warker, in Peritoneal Inflammation and Pelvic Hæmatocele and Hæmatoma, complete the volume with articles sustaining the excellence of those which preceded.

The editor's arrangement of the present volume is excellent, and Mann's System of Gynecology, as a guide and aid for the practitioner, will prove not only valuable but highly interesting and convenient.

Anatomy, Descriptive and Surgical. By Henry Gray, F.R.S. Drawings by H. V. Carter, M.D. Edited by T. Pickering Pick. New American from the Eleventh English Edition. Revised and re-edited with additions. By William W. Keen, M.D., Professor of Surgery in the Woman's Medical College of Pennsylvania, etc. Royal 8vo. pp. 1100. Philadelphia: Lea Brothers & Co., 1887.

Much as we have abridged the title-page, what we have copied from it indicates the high estimation in which this book is held by students of anatomy, an estimate which has remained for more than twenty years. Always attractive to students from the ease with which its plates can be used as a preparation for the quiz-room, this book is now presented to the profession in America, not only with the additions made to it by the English editor, but with very numerous ones made by Dr. Keen. These last are too varied for mention here. It is enough to say that the American editor has added one hundred and thirteen engravings, many of which are original. Among them we note as particularly valuable those of sections through different parts of the body and the series illustrating cerebral localization and topography. Those giving the points for the application of electricity to the muscles will also be found of much assistance to the general practitioner. Holden's *Landmarks* has also been added to the volume after revision by Dr. Keen.

The coloring of the arteries, veins, and nerves is a new feature in the book, but the American student is able to choose between an edition possessing this novelty and one in simple black and white. Well entitled as the older editions of "Gray" are to praise, it is only right to add that its value has been much enhanced by the labors of its well-known American editor, reaching as they do, not only to the illustrations but to a careful and thorough revision of the text. Indispensable as this Anatomy has been found by the vast army of physicians who have used it, and relied upon it in the past, he lacks a most important help whose shelves do not carry this new and handsome edition.

SOCIETY PROCEEDINGS.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, November 11, 1887.

THE VICE-PRESIDENT, WILLIAM GARDNER, M.D., IN THE CHAIR.

TREATMENT OF ULCERS BY THIERSCH'S METHOD OF SKIN TRANSPLANTATION.

DR. BELL read a paper on the above subject and exhibited a number of cases which had been treated by Thiersch's method. One case of large ulcer of the leg in an old man was healed completely in three weeks with one dressing. The ulcer had never been healed for thirteen years. Three other large chronic ulcers of many years standing had been completely healed and covered with good sound skin in less than a month. Dr. Bell said that the advantages of this method are, that ulcers which cannot be induced to heal by the usual modes of treatment could be healed in from three to four weeks without preparatory treatment and usually with a simple dressing. The method consists in the removal of the granulations and all unhealthy tissue, and the transplantation of large pieces of epithelial layer of the skin under the strictest antiseptic precautions. The important gain obtained by this method was reproduction or rather perpetuation of good sound healthy skin, which was much less likely to break down than the scar left after the usual mode of healing. The reader claimed that the operation was suitable for all kinds of non-specific ulcers of any magnitude.

DR. F. W. CAMPBELL congratulated Dr. Bell on his successful treatment, but said that while new methods might be of advantage, it was not well to discard the old ones. He himself had had phenomenal success in treating old chronic ulcers of the leg by blistering and Boynton's strapping. He had often healed ulcers in this way in three weeks, the patient going about the whole time.

DR. RODDICK exhibited a number of

CYSTINE CALCULI

passed per urethram. The patient was a delicate man æt. fifty-seven. He had a history of several attacks of renal colic. The first attack was some three years ago, and was followed by the passage of some fifty calculi, varying in size from a pin's head to a large pea. Latterly the attacks had been less severe and had not been followed by the passage of calculi.

Formerly the pain was equally severe over both kidneys, but latterly only the left was painful. There was no hereditary history of stone. Dr. Roddick remarked that the cystine calculus was exceedingly rare, less than one per cent. in European collections; Gross never met with a case. It is common in dogs. Nearly all cases reported show a history of heredity. This variety of calculus always forms in the kidney and is usually multiple. The calculus has the appearance of beeswax and is easily compressed. The specimens exhibited show a faceted appearance due to lying in contact either in the kidney, pelvis, or prostatic urethra. The majority of stones passed in this case were coated with uric acid.

DR. RUTTAN remarked that this was the only calculus that contained sulphur. He described the chemical characters of cystine and showed the tests by which it might be recognized.

DR. RODDICK also exhibited a large

PERIOSTEAL SARCOMA OF THE LOWER END OF THE FEMUR

which he had some days before removed from a man æt. twenty-four. The patient, a civil engineer by profession, was thin and very anæmic. Family history of tubercle, but none of malignant disease or tumor of any kind. No history of syphilis. Was in good health until last July, when he sustained a slight injury of the left knee, this was aggravated later on by kneeling in a canoe for several days paddling. At first the case looked like a simple or rheumatic synovitis and was treated as such by rest and blistering. When he came under Dr. Roddick's observation there was a great deal of distention of the knee-joint with very severe pain. The skin was thickened and slightly œdematous, but had not the characters of strumous synovitis. Aspiration showed thin bloody serum containing blood clots and broken-down tissue. Sarcoma was now suspected, and the patient having been etherized an exploratory incision was made into the joint, when the true state of affairs was revealed (viz., a sarcoma of the lower end of the femur), and the thigh was amputated in its upper third. Dr. Roddick said that had the patient's condition warranted it he should have preferred amputation at the hip-joint. He believed periosteal sarcoma was never liable to recur if the bone was amputated in its continuity. If the case was one of myeloid or central sarcoma he should not hesitate to amputate through a healthy part of the affected bone. The patient was doing remarkably well, and the wound had healed by first intention.

DR. HINGSTON said he, in similar cases, always removed the whole bone, when he amputated in the continuity of a bone he had always regretted it, for recurrence was generally the rule, but when he removed the whole bone recurrence was the exception.

DR. BELL thought that the chances in persistent sarcoma were quite as good if the affected bone was cut through at a sufficient distance from the tumor, as if the whole bone was removed, and in his experience the recurrence usually took place in some internal organ and not in the remaining portion of the amputated limb.

GANGRENE OF THE INTESTINE FROM STRANGULATION; RESECTION OF THE AFFECTED PORTION.

DR. BELL showed ten inches of gangrenous ileum which he had excised from a patient suffering from strangulated hernia. The history of the case is as follows:

B. D., æt. seventeen years, plumber, was admitted into the Montreal General Hospital on the evening of the 8th of November, suffering from a strangulated inguinal hernia on the right side. On Sunday, November 6th, suffered severely from pain in the upper zone of the abdomen and noticed a swelling in the right side of the scrotum. He took a dose of black draught, which caused one small motion. Vomiting set in the following morning and continued until his admission into the hospital. The patient having been placed under ether, moderate taxis was employed, and failing to reduce the

hernia, operation was determined on. On opening the sac about ten inches of small intestine were found in the canal. The constriction was incised and the bowel drawn out and examined. It was dark in color but glistening, and was distended with gas. Thinking the bowel to be in fair condition it was returned within the abdomen. The obstructive symptoms, however, remained unrelieved, and tympanitic distention of the abdomen gradually developed. The pulse and temperature as well as the general symptoms indicated peritonitis. Thirty-six hours after the herniotomy he decided to open the abdomen and endeavor to relieve the obstruction.

An incision was made in the middle line and the cavity opened. General peritonitis was present and all the small intestine enormously distended. The obstruction was found to be due to the collapsed condition of the portion of gut which had been found in the hernial sac; this was seen to be the lower part of the ileum and it was quite gangrenous, the lines of demarcation being at the points where it had been strangulated at the internal ring. The gangrenous portion was excised as well as a triangular portion of the mesentery, the operator cutting through the healthy bowel half an inch beyond the line of demarcation at either end, the lower section being about three inches from the ileo-cœcal valve. The cut ends of the intestine held in a towel by an assistant, were carefully united with sutures, the first six or eight being carried through the whole thickness of the wall of the bowel at opposite points to secure accurate coaptation, and then a continuous Lembert suture was employed. The intestines, which, on account of their distended condition, had been allowed to escape from the abdomen, could not be returned, so they were punctured with the needle of an aspirator which allowed the escape of gas and so enabled the bowels to be replaced. The abdomen was washed out with warm water, a drainage tube introduced, and the abdominal wound closed. The operation occupied one and a half hours. The patient, who was much collapsed, died two hours after the completion of the operation.

Dr. Armstrong said that he had twice returned gut in strangulated hernia, which had afterward became gangrenous. In both cases the gut had the glistening appearance of health. He, himself, was inclined to doubt the value of this sign, and in future, would not rely on it.

TUBERCULOUS DISEASE OF THE BLADDER.

Dr. Johnston exhibited the kidneys and bladder taken from a patient who had died of general tuberculosis.

The man, whose age was about thirty-five, entered the Montreal General Hospital November, 1886, suffering from symptoms of stone in the bladder, viz., frequent and painful micturition, and pain increased on movement, occasional hemorrhage at the end of micturition, etc. On examination, no stone was found. The urine was examined for bacilli of tubercle, but none found, After remaining in hospital some time, Dr. Bell performed a median cystotomy, and explored the bladder, but found nothing; patient went out with the perineal wound unhealed, and with no improvement in his symptoms. He returned about a month ago with the wound still unhealed, and in an emaciated condition. The granulations of the wound and urine were again examined, without result, for bacilli. Soon after he developed symptoms of meningitis, and died. At the autopsy, there was found a condition of general tuberculosis, tubercular peritonitis, meningitis, and pleuritis; also, tubercular cystitis. There was tuberculosis of the prostate, trigone, and wound. In the right ureter there were tubercular deposits, and in the pelvis of the right kidney. There was amyloid disease of the kidneys and liver. Dr. Johnston stated that he had no doubt at all that the first deposit of tubercle occurred in the prostate.

Dr. Shepherd said that it was a curious fact that in these cases tubercle did not appear in the lung till a late stage, if at all. In the first stages, the diagnosis of tuberculous disease of the bladder is obscure, the onset being often insidious. The three prominent symptoms were frequent and painful micturition and bloody urine. The treatment is not satisfactory. Guyon, of Paris advises cystotomy and the avoidance of catheterization. This authority regards the bleeding in these cases as analogous to hæmoptysis in cases of lung tuberculosis. Dr. Shepherd also remarked that frequent and painful micturition was often the first symptom of tuberculous disease of the kidneys, and said, that in every case where the diagnosis was obscure, the bacillus of tubercle should be searched for.

Dr. Bell said that last summer, whilst in Paris, he had seen Guyon, in suspected cases of tuberculous bladder, perform suprapubic cystotomy, illuminate the bladder, and search for the affected portion. In one case he saw him carefully scrape out the ulcer with a sharp spoon, and afterward cauterize it. He could not say what was the result of this mode of treatment.

CORRESPONDENCE.

USE OF BRAIDED SILK SUTURES IN LACERATED CERVIX AND PERINEUM.

To the Editor of The Medical News,

Sir: For several years past silver-wire sutures have been used almost universally in operations for restoration of lacerated cervix and perineum. Although nearly every authority in gynecology teaches that silver-wire sutures are the best in operations for lacerated perineum and cervix, I am convinced that the right kind of silk, properly prepared and properly used for sutures, *will accomplish as good results* as silver-wire sutures, and that there are advantages in the use of silk sutures over silver-wire sutures.

I have used silk sutures in thirteen cases with exceedingly good results, and Prof. Dunster has used it exclusively for two and a half years with most excellent results.

I claim for silk sutures:

(1) They are as easily introduced as silver-wire sutures.

(2) Easier to tie silk and adjust the parts than to twist silver-wire sutures.

(3) Much less irritation to the patient (especially in the perineum) while the sutures are *in situ*, which is important.

(4) Removal of silk sutures is very much less painful.

(5) Silk sutures give as good results as silver-wire sutures.

The *hard braided* silk should be used for the sutures (about No. 10 for the perineum, and a size or two smaller for the cervix), and should be rendered thoroughly antiseptic before and after waxing in bichloride of mercury solution (1 to 800 or 1 to 1000), or carbolic acid solution.

In tying braided silk one important precaution is necessary; it is best to make the knot with a triple tie, and the last tie to be drawn down tightly or it may become untied.

NEWS ITEMS.

THE CASE OF THE CROWN PRINCE.—SIR MORELL MACKENZIE has written the following report of the case of the Crown Prince, from the time of his visit to England till his arrival at San Remo, from notes supplied by Dr. Norris Wolfenden and Mr. Mark Hovell, and the report is now published by the wish of the Crown Prince.

"After the removal of the growth last summer, and the subsequent application of electro-cautery, no recurrence of the growth took place. Some general congestion of the larynx remained, and whilst his Imperial Highness was in the Isle of Wight, a slight thickening of the mucous membrane on the posterior surface of the arytenoid cartilages near their base was observed by Dr. Norris Wolfenden, at that time in daily attendance on the Crown Prince. At one of my weekly visits I verified Dr. Wolfenden's report, and perceived that the thickening presented the form of a ridge raised to the extent of about a millimetre, of yellowish color, and extending horizontally from the outer border of one cartilage to that of the other. The action of the left vocal cord, which had been noticed in Berlin to be slightly impaired, continued in the same state. It should perhaps be here mentioned that soon after his Imperial Highness arrived in England, a marked disposition to catarrhal inflammation of the larynx and trachea, or fugitive congestion, was observed. A rather sharp attack occurred in the Isle of Wight, and this was followed by general relaxation of the mucous membrane of both the pharynx and larynx.

"The congestion disappeared while the Crown Prince was in the Highlands; and during this period the thickening at the base of the arytenoid cartilages, already described, was absorbed. On the return of his Imperial Highness to London, the condition of the larynx was on the whole satisfactory; the movement of the left vocal cord was much more free, and the voice strong, though not quite clear, owing to a slight increase in the congestion having taken place on leaving Braemar. The Crown Prince's general health was excellent.

"On September 9th a slight thickening was noticed on the posterior extremity of the left vocal cord, which increased for a few days, and then gradually disappeared, being on the 18th no longer visible. For a few days previous to the development of this thickening, the larynx generally had again been more congested. On September 13, Dr. Evans, of Paris, extracted the Crown Prince's left lower second molar tooth, which was much decayed, the fangs showing the result of a considerable amount of periostitis.

"On September 14th, an oblong thickening of the mucous membrane, about five millimetres in length and three in width, was observed by Mr. Mark Hovell nearly half an inch below the middle of the left vocal cord, and parallel with its free border. Mr. Hovell states that this swelling gradually increased in size, and when seen by me on September 22d it was nearly round, and measured rather more than half a centimetre in diameter. Two days later the Crown Prince took cold, and on the following day complained of a sense of fatigue, disinclination to take food, and great sleepiness in the daytime. On examining his throat, the left aryepiglottic fold was found to be œdematous. His temperature was 101° F. In twenty-four hours the œdema had entirely disappeared, and the temperature had become normal. Although the œdema was apparently due to cold, the possibility of its being caused by limited perichondritis was discussed at the time. The acute swelling had no apparent effect on the little thickening below the left vocal cord, which gradually became smaller, but did not entirely disappear.

"The Crown Prince continued to enjoy good health after his arrival at Baveno, and when I left Italy everything appeared satisfactory, though slight general congestion remained, as well as the thickening referred to previously. On the evening of October 17th, Mr. Mark Hovell noticed a marked increase in the congestion of the larynx, both vocal cords being of a bright red color. During the next few days the congestion decreased; but on the 21st the hyperæmia again increased in intensity and was more diffuse. On the 27th an increase was noticed in the size of the thickened surface beneath the left vocal cord, and at the same time slight general tumefaction of the left side of the larynx appeared. During the next few days the thickened surface slightly increased, and on the 31st the surface was seen to be irregular, and in one place there was a distinct spur or projection. The next day superficial ulceration of the new formation was noticed, and the left vocal cord was seen to be slightly swollen along its free edge. On the 28th the voice of His Imperial Highness was quite clear; and, indeed, in the opinion of the Crown Princess, was perfectly natural, but since this date the Crown Prince has been much more hoarse. On October 30th a slight reddish projection was noticed beneath the *right* vocal cord; this remained stationary for two or three days, then disappeared, and formed again on November 5th. On November 1st a slight enlargement of the left submaxillary gland was noticed, and this subsequently increased in size.

"On November 3d the new formation had further enlarged, and was now rather more than a centimetre in diameter, and raised to the extent of about four millimetres. The extension of the growth since it was first seen had always been upward. On the morning of the 4th a very slight œdema was noticed at the base of the left arytenoid cartilage, which disappeared in the evening, and was again present on the morning of the 5th.

"On the following day I arrived, and found the state

of the larynx such as Mr. Hovell had described to me. On the afternoon of the 8th, intense œdema of the mucous membrane covering the left arytenoid cartilage was noticed, and in the evening the œdema involved the entire fold, which was tense and red. On November 9th the patient was examined by Professor Schrötter and Dr. Krause, but, owing to the œdema, it was impossible to obtain a complete view of the new formation at the lower part of the larynx. On November 10th the patient was again examined by the same physicians, and also by Mr. Moritz Schmidt; the œdema was already much diminished, and a good view could be obtained of the whole of the larynx.

"In my opinion, the œdema is due to limited perichondritis, which in its turn has probably been set up by the growths which have been formed from time to time in the larynx. Although the nature of the growth which has lately appeared has not been determined by microscopic examination, it presents every appearance of cancer."

The *British Medical Journal* of November 19th, calls special attention to the following points in this report:

1st. The occurrence on the posterior surface of the arytenoid cartilages of a deposit, which was after a time absorbed; 2d. A swelling taking place at the site of the old growth and then disappearing altogether; 3d. A swelling forming under the left vocal cord, which first increased, then receded, and subsequently formed the base of the new growth; 4th. A swelling, or growth, under the right vocal cord.

The formation of these growths, and the total absorption of some of them, with the retrogression and subsequent development of others, points to the probability of the fact that chronic inflammation has played a considerable part in the development of the disease. It is no doubt this feature which has masked its malignant nature. It is noteworthy that the deep-seated cervical glands are not affected in this case (the superficial glands seldom are involved in malignant disease of the larynx). There is now slight swelling of the submaxillary gland, but this has only recently been observed, and is of little significance in the absence of any secondary enlargement of the lymphatic glands. That a case of cancer of the larynx should run ten months without any ulceration, except such as was produced artificially by electric cautery and operation with the laryngeal forceps is also remarkable; indeed, the healing of the wounds thus caused would seem to indicate that the affection in its early stages was not of a cancerous nature.

The Prevention of Puerperal Fever.—The health authorities of Vienna have instituted a strict supervision of midwives, in which they call upon all practitioners for aid. This is intended to cover reports and inspection of each woman to determine whether she has recently attended puerperal fever, and whether her appliances and instruments are clean.

The Effects of Melinite.—At a meeting of the Paris Academy of Surgery, on October 26, 1887, a number of cases of wounds by melinite were reported, caused by a recent explosion at Belfort. The wounds were peculiarly penetrating. The skin was very little injured, and the shock produced was out of proportion to the extent of the lesions. The wounded presented marked evidences of severe nervous shock. Death had resulted from cerebral injuries and from sepsis, leading to a suspicion that poisonous gases were generated by the explosion.—*L' Union Médicale*, Nov. 3, 1887.

The Dangers of Football.—The *Boston Medical and Surgical Journal* reports that at the Harvard-Princeton football match at Cambridge, on November 11th, which was very warmly contested, Holden, the captain of the Harvard (victorious) team, who was playing half-back, sustained a fracture of the sternum, with depression of a portion of the bone.

The Medical Investigator is the title of a journal shortly to appear, which will be devoted to the cause of temperance, from the standpoint of medicine. It is announced to be published at Louisville, Kentucky.

Dirty Floors in Living Rooms the Breeding Grounds of Bacteria.—Emmerich, of Leipzig, is quoted by the *Sanitary News* of November 12, 1887, in a series of extensive investigations he has made regarding the contamination of dwellings by accumulated filth:

He made a large number of analyses of the damping material used for filling up the space between the ceiling of one flat, and the floor of the flat above. He found an almost incredible pollution of this material. His analyses show that, to use his own words, "there exists nowhere in nature, not even in the neighborhood of human dwellings, a soil so highly contaminated with nitrogenous organic substances and their decomposition products as the damping material under the floor of dwelling rooms." The amount of chloride of sodium found in this material was on an average seven times greater than that found in the ground under leaky cesspools, and twelve times greater than that in the soil round a dung-hill, although this soil was visibly soaked with filth. When the coarse pieces of stone were separated from this material, it was found that the finer dust and sand that was left, contained even more nitrogenous matter than human excrement. "In the damping material of a single room, there was usually more excremental matter present than in a large cesspool." That all this filth is alive with microörganisms, is shown by the amounts of products of decomposition which result from their activity. Thus under the floor of one single room, Emmerich found that there were more than 6 cwt. of nitric acid in the form of nitrates. He also showed that the carbonic acid in the air of rooms left shut up and empty increased, although all other known sources of carbonic acid, such as subsoil air, etc., were excluded. The chief cause of this contamination was undoubtedly the soaking of fluids and shaking of dust through the fissures and spaces between the boards in the floor. Often, however, the rubbish which was used as damping material was contaminated from the beginning, having been taken from old houses, or rubbish heaps, such apparently as many houses in this country are built upon.

Emmerich followed up this research by another no less interesting one in connection with the same subject.

In a prison at Amberg, there had persistently occurred for years epidemics of croupous pneumonia. The last of these had attacked every seventh, and killed every twentieth prisoner. As is well known, the late Dr. Friedländer, of Berlin, discovered the presence in cases of croupous pneumonia of a species of bacterium, cultivations of which, when inhaled by, or inoculated into certain animals, produces a similar disease in them. There can thus be little doubt as to the causal connection between this organism and the disease, or at any rate certain forms of it. Emmerich examined the damping material from the infected rooms in the Amberg prison. He not only found this material full of organic matter as usual, but actually discovered Friedländer's bacterium in enormous numbers.

POISONING FROM ARSENICAL WALL PAPER.—DR. EVERETT SMITH, of Boston, reports in the *Boston Medical and Surgical Journal* of November 17, 1887, the case of a lady who, upon returning to her town house for the winter, was seized with symptoms of irritant poisoning. Although some of the wall-paper had been found to contain arsenic in considerable quantities, it had seemed at first improbable not only to myself, but to Drs. Wood and Whittier, whom I consulted in the case, that the wall-paper already found to contain arsenic could be the sole cause of all this arsenical poisoning. The paper was upon the walls of a small room on the entrance floor of the house where the patient had been very little, the parlors were on the floor above, and her chamber on the floor above the parlors. In hopes, therefore, of finding some other source of arsenic, dress goods and window draperies were analyzed, but with negative results so far as finding arsenic were concerned. Chromium was, however, found in large amounts in one pattern of dark green dress goods. I had early seen to it that all cretonnes and turkey-red material were removed from the chamber, since they are well known to be highly charged with arsenic.

The almost conclusive proof, however, that the sole cause of my patient's sickness existed in this room is as follows: The dangerous wall paper was removed while the patient was convalescent. She insisted that she was not yet strong enough to venture from home and so remained in the house, confined strictly to her room, while the work went on. After the walls had been scraped and washed, and the room thoroughly cleaned preparatory to the laying of the new paper, she ventured to look into the room but remained there scarcely ten minutes. She very soon had a return of nausea and vomiting, which lasted nearly twenty-four hours. I thereupon insisted that she go into the country and that in her absence the entire house be thoroughly cleaned and dusted. This was done, and since her return she has presented no further symptoms of arsenic poisoning.

Another member of the family was affected by the removal of the paper, his symptoms taking the form of a sharp diarrhœa. The other two members did not at any time present marked symptoms of arsenical poisoning, except a noticeably sallow complexion and a pretty constant feeling of lassitude all winter. They had, however, had more exercise in the open air than my patient.

THE CONSULTANTS AT SAN REMO. — The *British Medical Journal* describes the specialists called to meet in the case of the Crown Prince as follows:

The German specialists who have been called in to advise with Sir Morell Mackenzie as to the treatment of the Crown Prince of Germany in the critical phase on which his illness seems now to be entering are all well known to laryngologists throughout the world, though their names may not be familiar in this country. Dr. L. von Schrötter, who is Professor Extraordinary of Laryngology and Internal Medicine in the University of Vienna, is the leading teacher of throat diseases in that great school, and his reputation throughout Germany is of the highest. He was one of the pioneers of laryngology, and his name would certainly be always one of the first mentioned when the question of calling in further advice arose. Dr. Hermann Krause, though comparatively a young man as age is counted in professional life, is a distinguished teacher in the University of Berlin, and stands high in his special line. Dr. M. Schmidt, of Frankfort-on-the-Main, though not perhaps quite so well known as his two colleagues, is a sound and experienced specialist, and has, moreover, the great recommendation in the present case of having already seen and treated the illustrious patient.

SOME RESPIRATORY NEUROSES.

A Clinical Lecture Delivered at the Jefferson Medical College Hospital, Philadelphia, Session 1887–1888.

BY PROFESSOR ROBERTS BARTHOLOW, M.D., LL.D.

GENTLEMEN: We have for consideration to-day a most interesting example of a respiratory neurosis. Really a typical example of a comparatively rare affection, it appeals to us, not because it is uncommon, but for the larger reason that it requires a mode of treatment different from that we would otherwise find more effective. The patient is a young man, not yet thirty years old, of a well-marked neurotic constitution. His general health seems good, and the one disability for which he seeks our aid, is an apparent, or *pseudo-angina pectoris*. He has not had rheumatism, syphilis, or diphtheria, and his heart, in the intervals of the seizures, presents no evidence of disease.

The paroxysms, which began four or five years ago, then, as now, consisted in sudden pain in or about the præcordial region, and shooting thence through the chest in all directions, but especially in the left neck and shoulder; sometimes downward into the left arm. Respiration becomes gasping and shallow, cyanosis appears quickly, the countenance assumes an agonized expression, the eyes protrude somewhat, the skin grows cold, and is covered with a clammy sweat; an inhibition of the heart's movements first occurs, but presently the tension of the vessels falls, the action becomes rapid and feeble, and irregular in rhythm; a deadly faintness comes on, and lately consciousness is lost for an instant of time. Although, when the paroxysms began, the symptoms were, in a high degree, suggestive, their true significance could not be appreciated. At first simple in form and localized to the præcordial region and chest, as the case went on they increased in complexity and in meaning. New elements entered into the problem. Some twitchings of the facial muscles were observed, and, in course of time, it was seen that the faintness extended into complete unconsciousness. The question of loss of consciousness, arisen of late, has deep import. Is the unconsciousness a mere fainting, because of cerebral anæmia due to inhibition of the heart, or mere weakness of the organ? In the absence of certain symptoms which now appear outside of the chest, it would seem to be the latter. Of late, however, muscular twitchings have occurred, and the seizures are preceded by certain uneasy sensations, which, as the patient has learned to know, announce a paroxysm, but the attack itself comes on with a sudden rush and tumult.

The paroxysms, which have been occurring during the past year more frequently, have also been widening in the complex of the symptoms, of which the nerve-elements have just been mentioned, but here note, also, that pronounced disorders of digestion have appeared. Acidity, heaviness, gas eructations, constipation, etc., are complained of. Just before a paroxysm, a sensation of weight and præcordial oppression, with anxiety and foreboding, copious gas eructations, and nausea, take place, and then very quickly the angina comes.

Now that we have come to look over the case, to analyze its symptoms, and construct our theory of its nature, we see that we have the usual morbid complexus of a pseudo angina pectoris, but other phenomena obtrude themselves and demand recognition. We observe warning symptoms coming from the organs connected through the solar plexus. Shall we call it an aura? When unconsciousness occurs some twitchings of facial muscles are observed. Here then are phenomena which ally the case to epilepsy, and, indeed, more and more has it assumed the characteristics of epilepsy with the progress of time. Trousseau, in one of his admirable clinical lectures, has described such cases under the term, "masked epilepsy." I do not know of any author who has so well characterized these cases, which, beginning with an angina pectoris terminate in a well-developed epilepsy. When I read this lecture some years ago, my attention was drawn to the subject, but I have seen few examples of the malady. One of the most nearly typical examples that has fallen under my observation was that of a physician who had attacks of what was supposed to be *angina pectoris*, and they were not understood until the paroxysms became epileptic in the most pronounced manner.

It is important in respect to treatment to recognize the true nature of these attacks. The best results are had from a combination of remedies addressed to both the true seat of the malady, and to the organs suffering the most severe functional disturbances.

As the bromide of sodium is far less hurtful than the corresponding potash salt, I will direct thirty grains three times a day. As during the paroxysms it is evident that the tension of the vascular system is abnormally high, I will give the one per cent. solution of nitro-glycerine, increasing the dose from one minim until its characteristic action is manifest, at which point it should be kept for the present.

As it is very obvious that errors of diet often precipitate the seizures, and always add to their violence, a careful regulation of the food becomes essential. Indeed of all the measures we have to propose, this is the most important. The allowance of meat should be restricted to one meal, it should be fresh meat, and small in quantity; one egg may be given at breakfast; one vegetable at dinner, such as spinach, celery, lettuce, or similar non-fermentable articles; some fresh fruit at supper. The only drink should be a moderate cup of warm skimmed milk.

It is difficult to regulate the diet of these subjects;

they have fierce appetites, and a fiercer way of indulging them; but every consideration should be brought to bear that may be effective in support of their own resolution.

Very often we have here as this morning, examples of difficult respiration, arising from reflex influences at a distance from the apparent seat of morbid action. Thus, asthmatic trouble from renal disease, renal asthma. Difficult breathing, of which the first intimation comes by hoarseness, may be the initial symptom of Bright's disease. But these and others we reserve for further consideration.

ORIGINAL ARTICLES.

ON THE ELIMINATION OF SULPHURETTED HYDROGEN ARTIFICIALLY INTRODUCED INTO THE BODY.

By AUSTIN FLINT, M.D., LL.D.,
PROFESSOR OF PHYSIOLOGY IN THE BELLEVUE HOSPITAL MEDICAL COLLEGE, PHYSICIAN TO BELLEVUE HOSPITAL;
AND

ON THE ACTION OF SULPHURETTED HYDROGEN ON CERTAIN MICROORGANISMS.

By FRANK GRAUER, M.D.,
INSTRUCTOR IN THE CARNEGIE LABORATORY OF THE BELLEVUE HOSPITAL MEDICAL COLLEGE

THE observations which form the basis of this article were begun early last spring, shortly after the publication of the so-called Bergeon treatment of pulmonary phthisis by gaseous enemata; but delay in obtaining absolutely pure cultures of the bacillus tuberculosis has deferred the completion of the experiments until now, when the interest in the subject has to a great extent subsided. Many able articles indeed, which have appeared in periodical medical literature within the last few months, have nearly covered the ground which we intended to go over, and we shall therefore consider the questions involved very briefly.

If it could be shown that a substance, innocuous as far as the human organism is concerned, could be introduced into the body and be eliminated by certain avenues, destroying in its passage morbific germs, the ideal treatment of many diseases would be to a great extent realized. If such a method were applicable to one class of diseases dependent upon the existence or multiplication of microörganisms, it might logically be assumed that other diseases could be treated in the same way; and the possibilities of such measures of treatment could hardly be exaggerated. Inasmuch as many organisms which act as morbific agents must penetrate through the lungs, it would be natural to look for some germicide which would attack microörgauisms in this situation; and the most effective way of reaching the materies morbi would be to introduce a germicide into the system by the alimentary canal or the subcutaneous tissue, provided it could be exhaled into the air-cells, and provided, always, that this could be done with safety. It was this idea, which logically followed the assertions of Bergeon, that led me to ask the assistance of Dr. Grauer in some experiments with sulphuretted hydrogen.

I proposed to leave out of the question, for the present, the apparent benefit derived by tuberculous patients from the treatment by gaseous enemata. The history of various so-called specifics for pulmonary phthisis shows with how much caution accounts of improvement in patients must be received. Much time must elapse and great numbers of cases, carefully observed under various conditions, must be recorded and analyzed before any positive conclusions can be reached as regards the results of any new method of treatment, particularly in this disease. Leaving, then, this consideration out of the question, I proposed to study the following problems:

1. Is sulphuretted hydrogen, introduced into the lower bowel, eliminated by the lungs?

2. Is sulphuretted hydrogen, injected in solution in water under the skin, eliminated by the lungs, and can it be safely introduced in this way?

3. What influence has sulphuretted hydrogen on certain microörganisms, particularly the bacillus tuberculosis?

In various communications that have recently been published on the gaseous enemata, it has been stated that sulphuretted hydrogen, mixed with carbonic acid gas and introduced in quantity into the large intestine, is eliminated by the lungs. Its detection in the expired air is very easy. A piece of white filtering paper, moistened with a solution of lead acetate and held before the mouth, will instantly reveal the presence of sulphuretted hydrogen in the breath, being discolored by the formation of lead sulphide. Gaseous enemata, after the method proposed by Bergeon, have repeatedly been employed in Bellevue Hospital. In many instances the breath has been tested during and after the enemata, and the characteristic reaction of sulphuretted hydrogen has never been observed. I made on May 2, 1887, a careful observation of this kind:

A man, thirty-two years of age, affected with pulmonary phthisis in the second stage, with considerable cough and expectoration, was the subject of this observation. He had been treated for some weeks with gaseous enemata, and thought he had received some benefit. The enemata were employed in the usual way. A bag was filled with about a gallon of carbonic acid gas freshly made and passed through a pint bottle of Sharon Springs sulphur-water, the emanations from which reacted promptly with lead acetate. Without giving in detail all the steps of the observation, I may simply state that during twenty minutes, while the injection was continued, there was no elimination of sulphuretted hydrogen by the lungs. I then substituted for the natural spring water a bottle of a saturated solution of sulphuretted hydrogen in distilled water. During fifteen minutes of this injection, there was no pulmonary elimination of sulphuretted hydrogen. The injection was then discontinued and the breath was tested at short intervals for an hour, always with negative results.

On May 5, 1887, I injected about half a fluid ounce of a saturated solution of sulphuretted hydrogen in water into the rectum of a dog, weighing 19 pounds. The breath was tested continuously during the ten minutes immediately following the injection, and then at intervals after the injection, as follows:

17, 25, 45, 60 and 90 minutes. There was no reaction of sulphuretted hydrogen.

On November 7, 1887, one fluid ounce of a saturated solution of sulphuretted hydrogen in water was injected into the rectum of a dog of medium size, and the breath was tested continuously for a number of minutes immediately following the operation. In three minutes and twenty-three seconds, the elimination of sulphuretted hydrogen began. This elimination continued for two minutes and fifty-three seconds, when it ceased. The reaction was distinct, but by no means so marked as when sulphuretted hydrogen is injected into a vein.

On April 25, 1887, I injected about one fluid drachm of a saturated solution of sulphuretted hydrogen into the stomach of a dog weighing 27 pounds, through a gastric fistula. This was not followed by the elimination of sulphuretted hydrogen by the lungs. Twenty-two minutes after the injection, the dog urinated, and part of the urine was obtained. This urine did not contain sulphuretted hydrogen.

In a number of experiments on dogs, I injected about three fluid drachms of a saturated solution of sulphuretted hydrogen under the skin of the flank, and careful and frequent tests of the breath, repeated from the time of the injection up to one or two hours after, at short intervals, failed to show the exhalation of sulphuretted hydrogen.

I have repeatedly injected sulphuretted hydrogen into the veins in dogs and have always noted a prompt elimination by the lungs; but this continues for a few seconds only, after the injection is discontinued. In an experiment made May 5, 1887, one fluid drachm of a saturated solution was injected into the external jugular vein of a dog weighing 22 pounds. The sulphuretted hydrogen appeared in the breath in three seconds after the injection was begun, and disappeared almost instantly after the injection was discontinued. The animal suffered no inconvenience from the operation. This is a repetition of an experiment by Bernard, well known to physiologists. Bernard also injected sulphuretted hydrogen, about a fluid ounce of a saturated solution, into the rectum of a dog. Elimination, in one experiment, began sixty-five seconds after the injection, but had ceased in five minutes.[1]

The following experiments were made by Dr. Frank Gruner, and are given in his own words.

EXPERIMENT I.—Small clippings of linen rags were thoroughly sterilized by being boiled in water for thirty minutes. In small watch glasses that were thoroughly sterilized by means of a dry heat of 250° C. (482° F.), there was placed liquid gelatine containing different microörganisms; namely, Finkler and Prior's comma bacillus of cholera nostras, typhoid bacillus, Koch's comma-bacillus of Asiatic cholera, and Friedländer's pneumococcus. The small clippings of rags which had been sterilized, were allowed to soak in the gelatine for ten minutes and were then carefully removed by means of a sterilized forceps and placed in sterilized tubes 4 inches long and $\frac{7}{8}$ of an inch in diameter, with both extremities open so as to allow a current of gas to pass directly through them. These tubes were then placed in a larger tube 14 inches long and 2 inches in diameter, and exposed to a strong current of sulphuretted hydrogen gas for twenty-five minutes. The gas was obtained by pouring sulphuric acid over ferrous sulphide, and then passing the gas evolved through a wash-bottle filled with distilled water. After the rags had been exposed to the gas, they were carefully removed and placed in test tubes one quarter full of liquid gelatine which became solid in a few moments. The object of liquefying the gelatine was to have the rags firmly embedded, so as to give the microörganisms all possible chances for growth. At the end of thirty-six hours, the growth of the different microorganisms was perceptible. Microscopical examination of each growth was made in order to exclude the following: First, the possibility of the growth of some other microörganism that might have lodged on the rags while passing from one tube to the other; second, the rags contain a certain quantity of sulphuretted hydrogen, which, coming in contact with the gelatine, produces a slight precipitation that to one unaccustomed to bacteriological investigations might be thought to be a growth due to microörganisms.

In contrast-experiments, the same steps and precautions were taken, with the exception that the rags were not exposed to sulphuretted hydrogen. Growth of microörganisms was perceptible in thirty-six hours.

The gelatine used in all these experiments was inoculated in the watch-glasses, by means of the platinum needle, with virus from pure cultures.

EXPERIMENT II.—Linen clippings, sterilized as in Experiment I., were soaked for two minutes in gelatine that had been inoculated twice with virus from pure cultures of Finkler and Prior's comma-bacillus and the pneumococcus. They were then exposed to a current of sulphuretted hydrogen gas for half an hour on three successive days, the object being to note the effect of repeated exposures. After the third exposure, the rags were embedded in gelatine in tubes as in Experiment I. Growth of microörganisms was observed in forty-eight hours.

In contrast-experiments, without exposure to sulphuretted hydrogen, growth of microörganisms occurred within twenty-four hours.

The delay, I think, in the growth in the rags exposed was not due to the sulphuretted hydrogen, but to retarded activity attributable to less favorable conditions of nutrition, etc.; for in sub-sequent experiments, in which rags had been kept for three days in a sterilized test-tube and were afterward put in gelatine, the growth was retarded by between twelve and twenty-four hours.

EXPERIMENT III.—Rags, sterilized and soaked for two minutes in gelatine that had been inoculated once with virus from cultures of typhoid bacillus, pneumococcus, and the comma-bacillus of Asiatic cholera, were exposed to a steady current of sulphuretted hydrogen gas and then embedded in gelatine in test-tubes. No growth was perceptible in twenty-two hours.

In contrast-experiments there was no growth.

The failure of growth in both instances was due, in my opinion, to the extreme dilution of the virus.

EXPERIMENT IV.—Rags sterilized and soaked with

[1] Bernard: Leçons sur les effets des substances toxiques et médicamenteuses. Paris, 1857, p. 59.

a gelatine that had been inoculated twice with anthrax bacillus and Koch's comma-bacillus were exposed to a current of sulphuretted hydrogen gas for an hour and were then embedded in gelatine in test-tubes. Growth of microörganisms was perceptible in thirty-six hours.

Growth of microörganisms was also observed in contrast-experiments.

EXPERIMENT V.—Rags sterilized and soaked in gelatine that had been inoculated twice with virus from pure cultures of anthrax and comma bacillus were exposed for three hours to a steady current of sulphuretted hydrogen gas and then placed in gelatine in test-tubes. Growth of microörganisms was perceptible in thirty-six hours.

Contrast-experiments also showed growth of microörganisms in thirty six hours.

EXPERIMENT VI.—Six test-tubes of liquid gelatine while cooling were exposed to sulphuretted hydrogen under pressure for two minutes and were then inoculated from pure cultures of pneumococcus, anthrax, and Asiatic cholera. Growth of microörganisms was perceptibly twenty-four hours after inoculation.

EXPERIMENT VII.—A large test-tube of distilled water was thoroughly sterilized by boiling for four hours and then exposed to a steady current of sulphuretted hydrogen gas for three hours. Ten drops of this water were added to each one of six test-tubes one-quarter filled with liquid gelatine. After the gelatine had solidified, the tubes were inoculated with typhoid, anthrax, and comma bacilli. At the end of twenty-four hours, growth of microörganisms was seen to take place along the lines of inoculation.

EXPERIMENT VIII.—Ordinary Croton water, such as is used in New York, was exposed to sulphuretted hydrogen for twelve hours under good pressure. Fifteen drops of this water were added to each one of three test-tubes of liquid gelatine, which were set aside to await results. Forty-eight hours after, I examined specimens from the tubes with the microscope, and found them filled with various kinds of microörganisms; showing that twelve hours of exposure to sulphuretted hydrogen did not affect the germs in ordinary drinking water.

EXPERIMENT IX.—Two test-tubes containing sterilized blood-serum were inoculated by the platinum wire with virus from a pure culture of tubercle bacillus and then exposed for two hours to a current of sulphuretted hydrogen gas. They were then kept at the temperature of the body in the brood-oven. At the end of two weeks, growth of microörganisms was noted over the entire surface of the blood-serum. At the same time, an old culture of tubercle bacillus was exposed to the gas for about three hours and was afterward used to inoculate two test-tubes of blood-serum. From these inoculations, beautiful growths developed in two weeks.

As far as my experiments and those of Dr. Grauer bear upon the questions proposed at the beginning of this article, the following answers may be given.

1. Is sulphuretted hydrogen, introduced into the lower bowel, eliminated by the lungs?

In the single experiment on the human subject which I have recited, and according to quite an extensive experience in Bellevue Hospital, sulphuretted hydrogen gas mixed with carbonic acid gas and injected according to Bergeon's method is not eliminated by the lungs. That it may be eliminated in small quantity under certain conditions, is possible; but the quantity of gas thus thrown off must be very small. How far the carbonic acid acts as a vehicle carrying the sulphuretted hydrogen to the lungs, I cannot say, as I have not found the sulphuretted hydrogen in the expired air.

In one experiment on a dog, there was no pulmonary exhalation of sulphuretted hydrogen after the injection of half an ounce of a saturated solution in water into the rectum. There was a slight but distinct elimination following the injection of an ounce of a saturated solution into the rectum of a dog, the elimination lasting a little less than three minutes.

It would appear from these observations, that a certain quantity of sulphuretted hydrogen introduced, even in saturated aqueous solution, may be destroyed in some way in the system without being eliminated as sulphuretted hydrogen.

2. Is sulphuretted hydrogen, injected in solution in water under the skin, eliminated by the lungs, and can it be safely introduced in this way?

My experiments show that such injections may be safely made, and that the sulphuretted hydrogen, thus introduced, is not eliminated by the lungs. I have no theory to offer as to the mode of its decomposition in the system.

3. What influence has sulphuretted hydrogen on certain microörganisms, particularly the bacillus tuberculosis?

The experiments of Dr. Grauer—which were devised and executed by himself, I having merely suggested the questions to be answered—are very definite in their results, although these results are entirely negative. These experiments fail to show any marked influence upon the organisms of typhoid fever, pneumonic fever, anthrax, cholera nostras, Asiatic cholera or the bacillus tuberculosis. They also fail to show any influence upon various microörganisms found in ordinary drinking water.

Whether the Bergeon treatment of pulmonary phthisis be or be not useful, either as a palliative or as a curative measure, extensive clinical experience must decide; but the theories by which a supposed palliative or curative influence is explained have thus far no foundation in fact. Sulphuretted hydrogen, injected according to the method proposed by Bergeon, seldom appears in the expired air. When introduced in such quantity and in such a way that it is eliminated by the lungs, the time of elimination is very brief, lasting from a few seconds to about three minutes. It is hardly reasonable to suppose that this brief and imperfect exhalation of sulphuretted hydrogen could have any beneficial effects. If the assumed benefit be due to sulphuretted hydrogen, this agent must act in some way not connected with its elimination by the lungs. It is possible that carbonic acid may aid in the elimination of matters of a character unknown, or that this gas itself may affect certain microörganisms; but our experiments do not bear upon this question. It is certain that

sulphuretted hydrogen has no sensible effect upon the growth of the bacillus tuberculosis in proper nutritive media, and that it is equally inert as regards the organisms of typhoid fever, pneumonic fever, anthrax, cholera nostras, and Asiatic cholera.

Finally, according to the *Medical Record*, the treatment of certain diseases by gaseous enemata is by no means new. "The rectal injection of 'fixed air' was recommended long ago by Priestley as of great utility in 'putrid diseases,' and Percival in 1768, and McBride in 1776, reported marvellous results from this method in pulmonary phthisis."[1]

LAPAROTOMY FOR INTRA-PERITONEAL RUPTURE OF THE BLADDER.

By JOSEPH M. FOX, M.D.,
OUT-PATIENT SURGEON TO THE PENNSYLVANIA, UNIVERSITY, AND CHILDREN'S HOSPITALS, PHILADELPHIA.

The following case came under my care during the summer of 1886 while substituting for Dr. T. G. Morton at the Pennsylvania Hospital.

Case. *Intra-peritoneal rupture of the bladder; abdominal section; death.*—Edward M., aged forty-five years, laborer, was admitted into the hospital, August 16, 1886. He had been intoxicated the previous evening and went to sleep on a lounge in the house of a friend; about one o'clock in the morning, while walking in his sleep, he fell out of an open window to the pavement ten feet below. He passed his water four hours before the accident, but had been unable to pass any since, although he had a constant desire to urinate.

Upon admission the patient, a healthy-looking man of medium size, was found to have a fracture through the neck of the right femur, and as he complained of pain in the lower part of his abdomen with the desire but inability to urinate, the resident surgeon passed a soft catheter and drew off three ounces of bloody urine. When I saw him a metallic catheter was passed and a pint of bloody urine drawn off; the urine was drawn with difficulty, the catheter, as was afterward evident, having passed through the tear in the bladder into the abdominal cavity.

The condition of the patient just previous to the operation was as follows: He was very restless and had an anxious expression, his abdomen was distended and tender to the touch, he complained of pain in the abdomen and lower part of the rectum, and he had vomited twice; the respirations were frequent, his pulse 100, and his temperature 99½°.

Dr. John B. Roberts, at the time substituting for Dr. Levis, saw the case with me in consultation, and agreed in the diagnosis of probable intra peritoneal rupture of the bladder, and to the advisability of performing laparotomy as giving the man his only chance for recovering, and he also assisted me in the operation.

Operation at 8.30 P. M., nearly twenty hours after the accident. After etherization the abdomen was opened under strict antiseptic precautions, the spray only being omitted, by a small incision in the median line just above the pubes, the finger was inserted into the abdominal cavity and the tear in the bladder felt, the incision was then increased to four inches extending from the pubes upward.

About a pint and a half of bloody urine with a few small blood-clots were removed from the abdominal cavity; the intestines were found deeply injected; the bladder was contracted, with its superior surface torn completely across from side to side, the tear being, in the contracted state of the organ, about two and a half inches in length. The bladder was held forward while the stitches were being introduced by drawing upon two pieces of catgut passed through the bladder on either side of the tear, fifteen Lembert catgut sutures being required to sew it up, the bladder was then tested and found to hold three or four ounces of warm water without leaking.

The abdominal cavity was cleansed by pouring in several quarts of a warm solution of bichloride of mercury (1 to 6000), and dried with sponges. The abdominal incision was brought together with interrupted catgut sutures, a drainage tube being first inserted a short distance into the abdominal cavity, and an iodoform and bichloride gauze dressing applied. A soft catheter was passed through the urethra and left in the bladder. The time occupied by the operation was about one hour and a quarter. The pulse at the end of the operation was 120, and his general condition quite good.

On the following morning his pulse was 140 and was much weaker, the respirations were more frequent and his temperature 101°; his abdomen was tympanitic and tender to the touch, and there had been a considerable discharge of blood-stained serum through the drainage tube; several ounces of urine had passed through the catheter.

As he complained of abdominal pain and was somewhat restless he was ordered opium, and was also given small quantities of whiskey, milk, and ice.

In the evening he was worse, having vomited several times through the day.

Aug. 18th, the signs of peritonitis had become more marked, the respirations were very frequent and shallow, pulse was 160 and very weak, and his temperature was 101°; he continued to fail and died about noon, thirty-nine hours after the operation.

Autopsy.—The abdomen was much distended; the abdominal incision looked well. There was found about a half ounce of bloody serum in the abdominal cavity; the intestines were deeply injected and showed signs of peritonitis, being slightly coated in places with lymph, and two or three coils were bound together with recent adhesions. The bladder was contracted and found perfectly empty, and the stitches had all held; it was tested and held three ounces of water without leaking.

Remarks.—Death was due in this case to urinary intoxication and peritonitis, caused by the length of time the peritoneum was exposed to the urine after the injury, before the operation was performed (twenty hours).

I regret very much not having washed out the abdominal cavity more thoroughly; it was simply washed by pouring in the bichloride solution, which, of course, reached only the viscera in the lower portion of the abdomen; if the latter had been

[1] Medical Record, August 13, 1887, p. 192.

thoroughly washed out the peritonitis might have been checked.

Very little difficulty was experienced in introducing the sutures into the bladder, as the latter was drawn well forward by pulling upon the two pieces of catgut passed through on either side of the tear; the intestines were kept out of the way with sponges and gave very little trouble.

The incision, four inches in length, was found longer than necessary, as the abdominal walls contained very little fat—a three inch incision would have been long enough.

The diagnosis was made from the abdominal symptoms, the inability to urinate, and the bloody urine drawn off by the catheter; had the metallic catheter been felt for through the abdominal walls when it passed through the tear in the bladder, its tip could have been felt just beneath the belly wall, and this, with its extreme freedom of motion, would have been a positive sign of rupture of the bladder.

Intra-peritoneal rupture of the bladder is a comparatively rare injury, and has nearly always proved fatal. Of the few cases that have recovered, five were treated by abdominal section; Rivington,[1] in 1882, collected one hundred and twenty nine cases of this injury with eight reported recoveries; of these recoveries one was Walter's case of abdominal section, and another was Morris's case,[2] which recovered without any operative treatment; in the other six cases the correctness of the diagnosis has been doubted by such high authorities, Rivington himself among the number, that any estimate of the percentage of recoveries in different methods of treatment other than by laparotomy, is valueless. Moreover, in the light of modern abdominal surgery, the treatment by laparotomy is the only one that offers any reasonable prospect of success.

In Sir William MacCormac's table of cases of abdominal section for rupture of the bladder he gives sixteen cases in which this operation had been performed up to that time; in two of these the rupture was extra-peritoneal, and in one other there seems to be doubt of its having been intra-peritoneal; therefore, leaving out these three cases, and adding the one since reported by Mr. Holmes[4] (successful), we have fourteen cases in which laparotomy has been performed up to the present time for the relief of this injury, with five recoveries, namely, the two cases of MacCormac's, and one each by Walters, Walsham, and Holmes. Out of the fourteen cases three have been operated upon in this country, with one recovery, that of Walters. Of the five recoveries, in one the rent in the bladder was not sutured, but abdominal drainage, and a catheter tied in the bladder were relied upon; in the other four cases the tear was sewed up with the Lembert suture, five silk being used in three of them, in the other one the material used is not stated.

Of the nine fatal cases, in three some of the bladder sutures were found at the *post mortem* to have given way, and in two of these at least catgut had been used for the sutures; one of the other cases died from peritonitis, the bladder wound not having been sutured; one died from exhaustion following a secondary hemorrhage from a perineal wound, perineal cystotomy having been performed, and one from suppression of urine; of the other three cases two died from shock, one of them having the bladder injury complicated with a fracture of the pelvis, and the remaining case (my own) from urinary intoxication and peritonitis.

From the study of these few cases I think we are justified in drawing the following conclusions: Silk is the best material for the bladder sutures, catgut not being safe; the Lembert suture should be used, and the muscular, as well as the peritoneal coat, included in the stitches. If difficulty is experienced in getting at the tear in the bladder to introduce the stitches, as quite often seems to be the case, an air tampon can be passed into the rectum and distended, as was done by McGill, to raise the bladder out of the pelvis; or the peritoneum can be divided at the sides of the bladder, as was done by MacCormac in both of his cases; or the bladder can be drawn forward by the method which succeeded perfectly in my case, care being taken not to include the mucous coat in the material used for the traction.

Holmes thinks it unnecessary to test the bladder wound after it has been sutured, by injecting fluid into the bladder through the urethra, but it can do no harm, and in two cases at least, in which it was so tested, leaks were found and remedied by additional sutures. The abdominal cavity should be thoroughly washed out before closing, either with warm water or a weak antiseptic fluid.

Cystotomy should not be performed unless the rupture is extra peritoneal also. MacCormac advises, instead of leaving a catheter in the bladder, to draw off the water every three or four hours with a soft catheter; this certainly would be an advantage if it is safe, as it would seem to be, for it was done in two of the successful cases, and in one of the others it was unnecessary, as he passed his water voluntarily from the first; but if any doubt is felt, the catheter can be left in for a few hours until some union has taken place between the peritoneal surfaces.

Although abdominal section for this injury is hardly alluded to in medical works, yet from the recent great advances made in abdominal surgery I think no surgeon of the present day would hesitate to perform laparotomy for the treatment of intra-peritoneal rupture of the bladder. The future of this operation, I think, is very bright, and I believe it will show more successful results than abdominal section for any other form of intra-peritoneal injury, saving the large majority of cases from what was considered, but a very short time ago, a necessarily fatal injury.

A HEAT CENTRE IN THE CORTEX CEREBRI. A PRELIMINARY NOTE.

By ISAAC OTT, M.D.,
OF EASTON, PA.

FROM a series of researches upon the lower animals, I am enabled to state that a centre exists about the juncture of the supersylvian and postsylvian fissures,

which, when mechanically destroyed, causes a rise of temperature, persisting for several days. The increase of temperature is from three to four degrees, and is caused by an increased production of heat. This augmentation of heat-production continues at the end of twenty-four hours after the date of lesion of the brain, as measured by the calorimeter of d'Arsonval, although the weight of the animal is falling.

It is well known that at the anterior part of the cortex, just posterior to the cruciate sulcus, Eulenberg and Landois have also discovered a centre which causes a rise of temperature, especially in the extremities of the side opposite the lesion, but not in the trunk. The centre in the postero-lateral part of the cortex causes an increase of temperature in all parts of the body. Details will be published hereafter.

CASE OF CEREBRAL ABSCESS; OPERATION; RECOVERY.

By L. D. WILSON, M.D.,
OF WHEELING, W. VA.

THE cavity of the abdomen having at length been pretty thoroughly ransacked, it is evident from the recent tendency of enterprising surgery, that the cranial cavity will shortly have to undergo a similar experience. As a contribution to the results already attained in this direction, the following case is reported. It is proper to state that the history, up to a little more than a week prior to the operation, was obtained from the patient's mother, who until that time had resided in a distant city, and it is somewhat unsatisfactory on certain points, owing to the fact that a severe domestic affliction overtook her during the progress of the case, which distracted her attention in another direction for a considerable time. It is reasonably certain, however, that the account there given is correct in every material particular.

CASE.—J. J., a well developed boy, eleven and a half years old, while snow-balling, in the latter part of January, 1887, fell, striking his head on a railroad coupling-pin. He was for a short time unconscious, but had recovered consciousness when brought home about two hours afterward. It was found that he had sustained a scalp-wound about a third of an inch in length, penetrating to the bone, its situation being on the right side of the head, two and a quarter inches above the outer orbital angle, one and three-quarters inches to the right of the median line, and one and three-quarters inches anterior to the coronal suture. It had bled freely, to restrain which cold water and snow had been liberally applied before he was taken home. No signs of injury of the skull were observed. Recovery seemed to take place promptly, and the boy continued to go to school.

About ten days afterward his appetite began to fail, and on the fifteenth day after the accident, he complained of severe pain in the head and shivering. This was followed during the day by vomiting. For a considerable time after this, the stomach continued to be extremely irritable, so much so that, to use the words of his mother, "nothing would lie on it for five or six weeks." Then the vomiting rather suddenly ceased and did not return. In a week after the vomiting began, the pulse-rate had fallen to 40, and a week later it rose again to 70–80, at which it remained. The pain in the head, which during all this time had been severe and continuous, now began to be intermittent, but at the same time very excruciating. It was always complained of as being especially severe in the *teeth*, and a part of the time there was also pain in the *right* hip. About four weeks after pain and vomiting began, convulsions set in, at first five or six a day, gradually diminishing in number to two or three a week, until about July 1st, when they began again to be more frequent and severe. The convulsions were early followed by paralysis of the *right* arm and loss of power in *both* legs, but these symptoms disappeared about the 1st of June, up to which time the boy had been confined to bed. After this date he was able to walk about, but would fall suddenly when convulsive attacks came on, and his gait was awkward at all times. As soon as the vomiting ceased he began to eat voraciously, and a great increase in flesh followed; the abdomen became enlarged and the face lost expression.

About the 1st of July, he was brought to this city and placed under the care of Dr. George Baird. At this time, in addition to the symptoms first detailed, he presented the following. The face was slightly drawn to the *left; right* eye totally blind, and very great impairment of vision in the *left;* both pupils dilated; a slight convergent squint; noises and impaired hearing in right ear; complete loss of sense of smell; tongue partially paralyzed, but sense of taste not affected; urine scanty; sleep disturbed; speech slow; some mental dulness, but no impairment of memory. The symptoms being clearly referable to the preceding injury, it was speedily determined that an operation offered the best chance of relief, and accordingly, on July 9th, at the instance of Dr. Baird, and with the assistance of himself and his son Dr. R. M. Baird, the skull was trephined at the site of the original injury. The cicatrix was found to be somewhat depressed and very tender on pressure. On reflecting the soft parts, the external table presented no evidences of injury except a small perforation sufficient to admit a small probe, which extended through the entire thickness of the bone. On removing the disk of bone no change in its internal surface was observed except the small perforation mentioned. The dura mater, which bulged moderately into the opening, was then incised with a narrow bistoury, and immediately a jet of pus spurted out a distance of three or four feet, and so continued for several seconds until the opening was enlarged with scissors. It then flowed out freely, and at a moderate estimate the quantity discharged was fully three ounces. When the flow ceased, a drainage tube was inserted and the scalp-flap replaced and sutured.

The wound discharged freely for several days, when the tube was removed and the wound healed promptly, except at one point where a small fistulous opening remained for a time, occasionally discharging small quantities of serous fluid. It permanently closed in about a month.

As a result of the operation, the pain and convulsions at once ceased, the boy began to sleep well, the appetite became natural, the superabundant flesh gradually disappeared, the natural expression of countenance returned, vision in the left eye improved, and returned in the right eye to a limited degree, hearing in the affected ear became much better, there has been a slight return of the sense of smell, and the functions of all the paralyzed muscles have been restored. The boy seems to have entirely recovered his usual health. His pupils are still moderately dilated and there remains also a slight squint.

Through the kindness of Dr. W. S. Hutchins, of this city, I am able to present the following report of an examination of the eyes made by him at my request.

"*October 15, 1887.* Pupils considerably enlarged. Examination with test-types shows R. $\frac{1}{200}+2.25$ D. $=\frac{8}{200}$. L. $\frac{2}{200}+2.25$ D. $=\frac{8}{200}$. Dilated pupils with duboisia, which did not alter above result with test-types. Ophthalmoscopic appearance as follows: Right eye: cornea, iris, and media normal; papilla white, much swollen; central vessels appear to emerge from apex of a cone, the base of which spreads far beyond and obscures the disk entirely. Vessels diminished in size and tortuous, can be clearly seen over swollen papilla, but much less so over retina, which is infiltrated and has decided lack of transparency. There are dense opacities seen along the line of ascending vessels, in upper nasal quadrant—glistening patches with striated edges. In upper outer quadrant, quite a collection of these brilliant spots or opacities near the equator. In the lower hemisphere, these spots are scattered here and there over the retina, between the vessels mostly, but occasionally being over and hiding a portion of the vessel from view. Left eye: cornea, iris, and media normal; papilla very nearly normal; outline of disk clear; vessels, however, are smaller and tortuous; retina infiltrated, but less so than that of right eye: few small white shining patches scattered over surface of retina with an occasional spot along course of vessel; one small collection lies near the equator on the nasal side of the disk."

I have had opportunity during the past three or four years to examine two cases of cerebral abscess, post-mortem, both the result of external violence. Both of these were associated with slight fracture, one involving the external table only, the other including both, with a small, depressed, pointed fragment pressing upon the dura mater. In the first of these, a small abscess containing about a drachm of pus was found in the brain beneath the seat of fracture, and three others of similar size, and not communicating with the first, or with each other, were found at varying depths in the same hemisphere. Operative measures here would no doubt have been disappointing, as neither the presence nor site of other abscesses than the one primarily sought for would likely have been suspected in time to permit successful interference. In the latter case, a single large abscess was found in the cerebrum beneath the external wound, and in addition there was a considerable extravasation of pus between the brain and dura mater, causing marked flattening of the convolutions. An early operation in this case would have afforded as fair a chance of success as in the one here reported.

NOVEMBER 7, 1887.

DIABETES MELLITUS IN AN INFANT.

BY J. Y. DALE, M.D.,
OF LEMONT, PA.

THE rarity of diabetes mellitus during infancy is probably a sufficient excuse for reporting the following case:

The patient, a female child, aged twenty-one months, when first brought to me for treatment, on February 13, 1887, did not seem very ill, and the symptoms, as related by her mother, indicated slight gastro-intestinal derangement. Ten days subsequently the child, having grown worse, was once more prescribed for, but was not again visited until March 1st, by which time the disease had developed to such an extent as to cause its true nature to be easily recognized.

The child had been weaned at the age of nineteen months, and the mother now recalls that thereafter it drank water freely, but the thirst and frequent micturition became prominent only during the latter part of February.

At this time (March 1st) the following symptoms were present: she had constant thirst during the daytime, passing a large amount of urine, which her mother said was "sticky," and had a sweet odor. During the night the thirst was not so urgent, and she slept well; appetite and digestion good; bowels moved naturally; abdomen prominent; was losing flesh and strength rapidly; sometimes was bright and playful, but generally inclined to lie in the cradle during the greater portion of the day.

For obvious reasons it was difficult to estimate the quantity of urine passed, or to procure any for examination; but, on the third of March, a sample was furnished, which was of a pale straw color, acid, with a specific gravity of 1038. Heat and nitric acid produced a slight flocculent deposit, and Trommer's test showed a large percentage of sugar.

On March 4th the patient grew worse rapidly; on the 5th there was great dyspnœa, with short, quick respirations, followed by drowsiness and deep coma—death occurring on the 6th.

In endeavoring to find a possible cause for the disease, it was ascertained that the child had several hard falls on the back of her head during the summer of 1886, from which she suffered severely.

HOSPITAL NOTES.

TREATMENT OF TYPHOID FEVER IN THE PHILADELPHIA HOSPITALS.

PENNSYLVANIA HOSPITAL.

DR. DA COSTA does not adopt any specific plan of treatment, although he generally administers the mineral acids; of these he most often prescribes nitro-muriatic acid, twenty drops of the dilute acid every fourth hour. He does not interfere with the action of the bowels, unless the discharges exceed three, when

he is most apt to order opium, in the shape of suppository.

He insists upon the patient being fed with liquid food every two hours during the day-time, but not quite so often at night. He generally begins with stimulus in the second week of the disease, taking as his guide the state of the first sound of the heart. Rarely, however, does he give more than from eight to ten ounces of whiskey in twenty-four hours.

The patient is sponged with cool water twice daily, oftener if the temperature exceed 103°. Under these circumstances, too, an occasional decided dose of quinine, or antipyrine is resorted to, particularly if the high temperature be in the morning or show signs of persistency. He is an advocate of being very watchful for complications, and for their early treatment. Late in the fever and during convalescence he generally directs quinine.

Philadelphia Hospital.

Dr. Tyson's treatment of typhoid fever is mainly a symptomatic one. Placing the patient upon a milk diet from the outset, and continuing it until convalescence is established, symptoms are treated as they arise. Diarrhœa is preferably controlled by nitrate of silver and the extract of opium, one-quarter grain of each three or four times a day. In more obstinate cases of diarrhœa where this treatment fails, although seldom necessary, the more powerful astringent acetate of lead, and more rarely tannin, is substituted for the nitrate of silver. Abdominal pain and tenderness are treated with poultices in addition to opium.

High temperature (104° to 105°) is combated by sponging the body. Persistent temperature above 105° is treated by wrapping the trunk with cloths wrung out in iced water, which are renewed every hour or half hour, and even oftener if necessary, the temperature under these circumstances being taken hourly. Quinine is given in almost every case, not as an antipyretic, but as a tonic and stimulant in doses of from six to sixteen grains daily. The stage of dry tongue is treated with turpentine in doses of ten drops every three hours.

Alcoholic stimulants are used in almost every case as required: moderately in mild cases, and in full doses in severe cases, frequently half an ounce every two hours. Sometimes larger doses are given. *Very high temperatures are regarded as demanding the fullest stimulation.* Dr. Tyson has used largely the modern antipyretics, thallin, antipyrin, and antifebrin, but considers them inferior to the iced cloths. Of these antipyretics, however, he prefers antifebrin as less alarming in its effects, and equally efficient with the others in reducing temperature.

Dr. E. T. Bruen conducts his treatment without reference to the administration of specifics. During the first few days, especially in the fall of the year, when malarial influences prevail, it is customary to give for one or two days full doses of quinine for diagnostic purposes. If the continued nature of the fever is demonstrated an expectant plan of treatment is inaugurated, which in mild cases is continued throughout the course of the disease till its termination.

If the temperature exceeds 104°, sponging with cool or cold water is the means usually adopted. The sponging must be repeated every few hours. Sometimes cold water in rubber bags is applied to the back of the head and abdomen. The cold bath is reserved for those exceptional cases in which the high temperature seems to be influencing the nervous centres. The cold water bath he believes can be employed in the early stages of the fever with more safety than later on, since the vasomotor centres are much more responsive and dangerous congestions of the viscera are avoided. The administration of antipyretics, such as antipyrin or antifebrin, so useful in the zymotic fevers of childhood or in the hectic of consumption, is to be avoided in typhoid fever for fear of disturbing the activity of the stomach. When the typhoid state is marked, associated with high temperature, the occasional use of antifebrin, in five grain doses, is desirable and preferable to the cold bath. But persistent systematic sponging of the surface of the body in the usual order is the safest and best means in his hands of reducing temperature in typhoid fever. Quinine is employed in tonic doses, but not as an antipyretic.

Great stress is laid upon the administration of nourishment. From four to six ounces of milk should be given every two hours for eighteen hours out of the twenty-four. An interval of five hours once in the twenty-four should be secured to foster the digestive powers. Care should be taken to prevent the coagulation of the casein by dilution with Apollinaris or lime-water; one or two raw eggs may be administered every other day. This method of diet is relied upon till convalescence is inaugurated, when the beef broths, prepared with some cereal, are allowed. The importance of delaying the use of meats until the temperature has been quite normal for more than a week, cannot be overestimated, and the first solid diet permitted to convalescents is farinaceous in character.

When diarrhœa manifests itself, nitrate of silver in $\frac{1}{8}$th grain doses with $\frac{1}{24}$th of ext. opium is given every four hours, with opium suppositories, if necessary, in addition. In the majority of cases this is sufficient; but acetate of lead is resorted to in case of failure. Turpentine in emulsion (with muriatic acid in cases in which silver is not used) is always employed as soon as the typhoid state begins. The general stimulative properties of turpentine, aside from its local effects, render it invaluable in a majority of cases. Constipation of the bowels must be avoided, and every other day at least the bowels should be moved. Enemata, carefully given, seem to him the best mode of securing the desired end.

Internal congestions are antagonized by changing the position of the patient, by turpentine stupes, and by cupping the chest when the lungs are the organs involved. A cotton jacket neatly made and applied, is very useful under these circumstances. Hemorrhages from the bowels are treated with opium and acetate of lead. In order to stimulate the circulation whiskey is given early in the history of those cases in which high temperature marks the reception of a full supply of the typhoid poison, and the advent of the initial symptoms of the typhoid state are carefully looked for even in those patients in whom the mild character of the symptoms does not seem to call for stimulation. Those patients who have been habitual free consumers of alcohol require the largest amounts of this drug during typhoid fever. It is important, whenever practicable,

to suspend the medicine, as well as the food, for one five-hour interval in the twenty-four in order to avoid overtasking the stomach.

EPISCOPAL HOSPITAL.

DR. FREDERICK P. HENRY, in treating the cases in his wards, seeks to control diarrhœa and allay its attendant peristalsis; to subdue nervous excitement, and to keep the temperature within moderate bounds. To accomplish these ends, the nutrition, stimulation, and medication of the patient receive the most careful attention. While the fever lasts, the diet is altogether liquid and consists of milk with lime water, and animal broths. In giving these substances he endeavors to proportion their amount to the patient's digestive powers, for, to quote the language of Collie, without fully accepting it "pints of milk and eggs in the stomach or bowels undigested are about as useful there as a cannon ball."

When convalescence begins and farinaceous foods are first administered, a slight rise of temperature is the rule. This does not contraindicate their continued employment, but may be regarded as physiological.

Stimulants are not given as a matter of routine, but only *pro re nata*. It is seldom that more than six ounces of whiskey are given *per diem*, and a certain number of mild cases receive no alcohol whatever. When diarrhœa is obstinate, port wine is substituted for whiskey.

Heroic measures have never been in vogue at this hospital, and, therefore, an attitude of "masterly inactivity" was preserved during the period of the cold bath craze. A more gradual, and, therefore, a more physiological effect, certainly one more soothing to the nervous system, is obtained by repeated sponging with tepid water. The latter method may be compared to a hint; the former to a denial, and in dealing with men's bodies as with their minds, suggestion, so to speak, is better than contradiction.

Some ten years ago, quinine was given in large amount—gr. xv to xx in the course of an hour—for its antipyretic effect, but this method was soon abandoned, and for several years the doses of this drug have not exceeded gr. xij *per diem*. To this extent it has been, until quite recently, administered as a matter of routine. Antipyrin and antifebrin have been thoroughly tested, and the opinion with reference to them is that they should be used with caution and reserved for emergencies of hyperpyrexia. The rapid descent of temperature produced by these remarkable agents has been, in rare instances, attended with a somewhat alarming condition of collapse. Fifteen grains of antipyrin given in three doses in the course of a half hour are, as a rule, sufficient to produce a decided effect, and Dr. Henry possesses a temperature chart, which shows that, on several occasions, five grains of antifebrin have caused a defervescence of from 4.5° to 5 F. In another chart a fall of nearly 6 (from 103.6 to 98) was effected by the same dose. A decided impression upon the temperature has often been made by doses of 2.5 grains.

The benefits to be derived from turpentine are problematical, which is not to be wondered at, when it is recalled that the gastric mucosa is always in a hyperæmic or catarrhal condition, and has been more than once observed to be the seat of the specific typhoid deposit and ulceration. Accordingly, this drug is but little used. Opium suppositories are mainly relied on to check excessive diarrhœa and allay peristalsis, and, when they prove insufficient, astringents, such as acetate of lead and gallic acid, are given *per os;* a moderate diarrhœa is never interfered with. By moderate, as here employed, is understood from three to six gruel- or mush-like evacuations in the twenty-four hours. The same drugs that are used to control diarrhœa are, with the addition of ergot, administered in case of intestinal hemorrhage. When tympany is great, powdered charcoal and enemata of tepid water have been found of decided benefit.

The treatment outlined above may be described as symptomatic and expectant. It is, in no sense of the word, specific. The latter adjective may be applied, with propriety, to measures which have as their object, the shortening of the course of the disease, or the mitigation of its severity, and which are addressed to the specific intestinal lesions. Such measures have not been neglected in the Episcopal Hospital. Nitrate of silver, carbolic acid and iodine, and Labarraque's solution have been systematically tested, but Dr. Henry believes them to be, one and all, inferior to thymol. He has given his experience with this drug in a recent contribution to THE MEDICAL NEWS (Sept. 3, 1887), to which the reader is referred, and, since that time, he has received confirmation of his statements from several sources. "The favorable effect of the drug was evinced by a steady descent of the temperature, by a gradual diminution in the daily number of stools, by the absence of mental excitement, and, most conspicuously, by the clean, moist tongue presented in every instance. . . . I have always prescribed the thymol in pill, of which the best excipient is medicinal soap, and, so far, have not given more than thirty grains in twenty-four hours, two $2\frac{1}{2}$ grain pills every four hours. This is a small dose, but I have seen no reason to increase it. This may be done, however, with perfect safety, and, perhaps, with still better results."

Quite as good results have been claimed for naphthalin, but, so far as he knows, it has not been used in the Episcopal Hospital, and, other things being equal, the comparative innocuousness of thymol should entitle it to the preference.

HOSPITAL OF THE UNIVERSITY OF PENNSYLVANIA.

DR. PEPPER holds that there is no disease more influenced than this in its later course and result by the management of its initial period. Whenever there is the least suspicion that typhoid fever is beginning the patient should have the benefit of the doubt, and from that moment should be treated with strict thoroughness. Sometimes this will induce abortion of the case, for it is one of the diseases which is, so to speak, self-perpetuating, owing to the continual development of the materies morbi in the intestinal canal so long as the contents afford a suitable culture medium.

This condition is much affected by the diet, and by agents which influence the lesions of the intestinal glands. It is well to repeat that from the earliest moment we must insist on absolute rest. Much harm is done by postponing for two or three days the necessary

confinement to bed. So should an absolute restriction of diet be imposed at once. It seems to Dr. Pepper that the intestinal canal is kept in the best condition when from the earliest hour the diet has consisted exclusively of milk, light gruels or broths, and pure water. Milk may seem to disagree, but it will then usually be found that it has been given in too large amounts or at too short intervals or that to enable it to be digested it must be diluted or peptonized. For patients with typhoid fever must be fed, not on theory, but according to the observed effects of the food given. Tympany and diarrhœa are often the result of excessive or improper feeding, although more commonly they may be caused by the enfeebled state of the muscles of the intestinal and abdominal walls, and by the lesions of the mucous membrane. Under the influence of the unqualified dictum that fevers should be fed, a dictum much more universally applicable to typhus than to typhoid fever, many cases of the latter are injured by injudicious feeding. Not only may tympany and diarrhœa be promoted thereby, but the accumulation of imperfectly digested organic matter in the bowels may favor the multiplication of the specific materies morbi, and also the development of ptomaines. This question of feeding is, therefore, the fundamental one in typhoid fever, and should be treated with caution and minute attention in each case.

Next in importance seems the administration of some remedy directed to the invariably present lesion of the intestinal glands. Drugs which exert a sedative astringent effect, which do not hurt the stomach, and which are antiseptic either directly or by their action on albuminoids, would seem to be indicated; and Dr. Pepper thinks that some such remedy should form a part of our treatment of every case of typhoid fever, from the earliest hour when we suspect the nature of the case. Creasote, carbolic acid, iodoform, mineral acids, especially muriatic and sulphurous, and nitrate of silver, suggest themselves. In the great majority of cases he much prefers nitrate of silver, and since he revived the use of the remedy in typhoid fever it has been employed so extensively and with such admirable results as to have established its value. It is given from the outset, in doses of gr. $\frac{1}{6}$ to gr. $\frac{1}{3}$ thrice daily, combined with small amounts of opium, or belladonna, or nux vomica, according to special indications. He has come to believe that the appearance of dangerous symptoms is rendered less frequent, and the entire course of the disease rendered more favorable by the early use of this remedy in conjunction with an early insistance on absolute rest and carefully adjusted feeding.

When the typhoid symptoms become pronounced, especially the dry, brown, tremulous tongue with weak heart, and paretic tympany, he substitutes, or adds, turpentine. When the tongue remains moist but is flabby and white coated, the bowels torpid, and the secretions scanty, the mineral acids with strychnia in solution seem indicated. Space forbids mention of the obvious indications in certain cases for other remedies of this group. Alcohol is required sooner or later in most cases of typhoid fever, yet he never prescribes it except when definite indications call for it. These indications are sought in the character of the cardiac action, of the nervous symptoms, of the digestion, and of the pyrexia. By withholding it until called for, and then giving it in small doses, and by cautiously increasing the dose and strength of the preparation used, we secure all possible benefit, and avoid the harm which follows here, as elsewhere, its excessive or untimely use.

Nearly always also there arises in the course of typhoid fever the necessity of controlling the pyrexia. But this necessity will be less frequent in proportion as the elements of treatment already insisted on are early and thoroughly attended to. So long as the temperature remains reasonably low, 102½° to 103°, and no nervous or cardiac symptoms appear attributable to the mere pyrexia, we need pay no special attention to it. But at any time, even during the earliest days, the fever may reach a point requiring interference. If quinine has been given in moderate doses, as is often the case, one or two full doses are now used, but recent experience had led to a preference for antipyrin when only an occasional antipyretic effect is required, or to the external use of cold water by sponging or affusion when the tendency to hyperpyrexia shows more obstinacy.

Dr. Osler believes a plan of armed expectancy to be, in the present state of our knowledge, the most rational. The majority of the cases require little or no medicinal treatment. The routine of a restricted diet under the watchful care of an intelligent nurse, meets the *indicatio morbi*.

No initial purge is given, as the cases are never brought to hospital very early, and constipation is not dreaded. An acid mixture is sometimes ordered, or dilute hydrochloric acid is added to the water, which is given freely. As it is possible that the defective elimination of the products of regressive tissue changes may be, in part at least, the cause of the so-called typhoid symptoms, every effort is made to keep active the skin and kidneys. Repeated spongings and an abundance of fresh cool water to drink, answer the purpose.

A milk diet is ordered—about three pints in the twenty-four hours. Very exceptionally it has to be artificially prepared. An examination of the stools will often indicate if too much milk is taken, or if it is not digested. Warm milk is less apt to produce flatulence. Broths and beaten-up eggs are allowed in mild cases.

When the fever reaches 103°–104°, the spongings are more frequently used. If it rises higher—104°–105°—the wet pack is ordered, or a dose of antipyrin or antifebrin, either of which acts promptly. The cold-water treatment is specially indicated in those cases with profoundly ataxic symptoms, though all the features in this state are not due to the pyrexia.

For diarrhœa, when excessive, aromatic sulphuric acid, bismuth, or naphthalin is ordered. For tympanites, turpentine stupes, turpentine internally, creasote, or naphthalin. Constipation is disregarded unless it persists longer than seven or eight days, when a saline purge or an enema is ordered. The severe headache of the early stage may demand leeches. Bromide or chloral will usually overcome the troublesome insomnia of certain cases.

When there are indications of heart failure, alcohol is given, and, if necessary, in large doses. Camphor, strychnine, and ergot supplement, but cannot replace, alcohol in this condition.

Should hemorrhage occur, opium is given and an ice-bag placed on the abdomen.

A return to ordinary diet is permitted ten or twelve days after convalescence is established.

JEFFERSON MEDICAL COLLEGE HOSPITAL.

DR. J. C. WILSON treats his cases of enteric fever by the systematic use of laxative doses of calomel during the first ten days, and by carbolized iodine, as originally suggested by Professor Bartholow, throughout the course of the disease. The most careful attention is given to the details of nursing, dietetics, and hygiene, and symptoms are treated as they become prominent.

Due regard being had to the peculiarities of individual cases, the general plan is as follows:

Upon the evening of admission the patient receives seven and a half to ten grains of calomel in combination with ten grains of sodium bicarbonate, at a single dose. If the case be still in the first week, which is not usual with hospital patients, this dose is repeated every second night until its third administration; if already in the second week, a single dose only is given. After the tenth day it is given cautiously or omitted altogether. If there be constipation, the first dose of calomel is followed by two or three large stools mostly of the consistency of mush, the later doses by stools decidedly liquid. Diarrhœa is not regarded as a contra-indication. On the contrary, it almost always becomes less troublesome after the action of the mercurial. During the subsequent course of the disease, constipation is not allowed to continue at any time beyond the third day; but is relieved, as a rule, by an eight ounce enema of warm, thin gruel, slowly injected, or exceptionally by a five, or seven and a half, grain dose of calomel; the choice being influenced by the character and prominence of abdominal symptoms. Under this plan of treatment diarrhœa is not commonly excessive. When necessary, it is treated by one grain suppositories of the aqueous extract of opium.

From the beginning the patient receives at intervals of two hours during the day, and three hours during the night, and immediately after the administration of nourishment, two or three drops of a mixture of two parts tincture of iodine and one part pure liquid carbolic acid. This dose is administered in an ounce of iced water.

Unless the temperature exceeds 104° F., the fever calls for no special treatment, beyond cold sponging, which is practised in every case at least twice in the twenty-four hours. A higher temperature receives prompt attention.

After trial of the list of new antipyretics, the choice is antipyrin. It is used in single doses of ten to fifteen grains, and repeated when the temperature again rises beyond 104° F. If this remedy fails of its effect, large compresses of several thicknesses extending across the chest and abdomen from the neck to the pubes, and freely wet with iced water, are used. The gradually cooled bath is held in reserve.

Alcohol has no necessary part in the routine treatment of enteric fever. Many cases do not require it; some are unquestionably benefited by it; while to a considerable proportion it is an absolute necessity. Dr. Wilson believes that the employment of alcohol in the treatment of fevers should be regarded not as a dietetic but invariably as a medicinal measure.

Space does not permit the discussion of the treatment of complications, nor of the management of convalescence. If perforation occurs during or after the period of defervescence, namely, in the fourth week or later, laparotomy should be performed.

MEDICAL PROGRESS.

CANCER OF THE LARYNX.—The Paris correspondent of the *Lancet* of November 26, 1887, writes that M. TILLAUX showed a patient at the Academy of Medicine upon whom he had performed tracheotomy five months ago for the relief of suffocation due to cancer of the larynx. Since then there has been, as is generally the case soon after an operation of the kind, a partial retrogression of the tumor, and the patient has resumed his occupation, having recovered his appetite, strength, and spirits, and gained seven pounds in weight. M. Tillaux said he made this communication because the question as to the best line of conduct in such cases is still open, as is shown by M. Schwartz in his thesis on the subject. Should a radical cure be attempted by extirpation of the larynx, or should the palliative operation of tracheotomy be adopted? M. Tillaux said that he thought the history of his case showed that tracheotomy was useful in some cases, and for his part he was not disinclined to prefer it, as a rule, to extirpation.

Professor Verneuil considered that the superiority of tracheotomy over extirpation was incontestable. With the latter operation, when the patient does not die from the immediate consequences, he speedily succumbs to a relapse. In one case of epithelioma, tracheotomized by M. Verneuil a year ago, the tumor was so considerable that it was difficult to understand how it was possible to breathe at all. After tracheotomy, or rather Krishaber's operation of laryngo-crico-tracheotomy, the patient resumed his ordinary business, and is even able to speak pretty distinctly when the opening of the canula is occluded.

M. Richet mentioned a similar case.

M. Labbé did not agree with his colleagues. He said that he had, like them, performed tracheotomy for the relief of laryngeal cancer, and should no doubt do so again. But he could not admit this to be the only operation possible, and that there are not cases in which we ought to practise extirpation of the larynx. As a rule, extirpation is done too late, upon subjects already tracheotomized, and for the relief of aggravated symptoms. It is reasonable to suppose that better results would be obtained if the operation were performed as soon as the cancerous nature of the growth is recognized, and before there is any secondary infection of the neighboring glands. The gravity of the operation is not so considerable as is generally supposed. In four cases of the kind M. Labbé had had three absolute operative successes, the patients living for different lengths of time without relapse. In the fourth case death was due to the accidental negligence of the nurse, who omitted to change the canula, as had been directed; in consequence the patient was nearly asphyxiated by the accumulated secretions, and died a fortnight later of septic pneumonia.

The thesis of M. Schwartz (*Thèse d'Agrégation*, 1886), the most impartial monograph upon extirpation of the larynx in the French language, necessarily serves as a

groundwork for all general reviews of this question, and the current number of the *Bulletin Médical* contains a good *résumé* of it by M. Maurice Hache, who brings the statistics of M. Schwartz up to date by the addition of recent cases. In 105 observations quoted of total extirpation of the larynx, death took place fifteen times within the first week from hemorrhage, collapse, embolism or septicæmia, or other causes; twenty times during the second week from pneumonia or bronchopneumonia. To these are added one case of death from pulmonary gangrene on the twenty-fifth day, five of late pneumonia, and two of exhaustion, making forty-three deaths in all from the operation itself, a mortality of forty per cent. Twenty-eight of the remaining relapsed, two before the expiration of three months, six others before six months, eight before a year, two between the first and second years, and two before two years and a half. Thirty-four patients are recorded as cured—fifteen after six months' observation, eight more after less than a year. One was published fifteen months; one, sixteen months; two, from two to three years; three, from three to four years; two, five years; and one, ten years after operation. Counting those as cured who have lived two years, there have been eight certain successes in 105 cases. Of twenty-seven published cases of partial extirpation, in one there had been no relapse after eighteen months, in another the cure was definite after seven years. Seven other operations had been successful, but the time elapsed at the date of publication was under a year and a half. From a functional point of view the condition of those who have been operated on is less unsatisfactory than might be supposed. Deglutition is restored sometimes within a week, nearly always after a couple of months; and by means of Gussenbauer's artificial larynx there is a very fair restoration of the voice.

Iodoform in Variola.—Colleville has had excellent results in preventing severe scarring and lessening pain in variola by the local use of

Iodoform	1 part.
Vaseline	20 parts.

Although used freely in cases of confluent variola, no ill effects were observed.—*Revue de Thérapeutique*, November 15, 1887.

The Technique of Antipyrine Hypodermatically.—Hirsch, of Hanover, has used a fifty per cent. solution of antipyrine by hypodermatic injection for pain with excellent results. He finds that the needle frequently clogs with crystals of antipyrine. He finds that five per cent. carbolic acid solution is the best dissolvent for these crystals. The carbolic solution should be drawn through the needle until it remains clear in the barrel, when no antipyrine is present. If antipyrine is present, a cloudiness will result from the union of carbolic acid and antipyrine.—*Berliner klinische Wochenschrift*, November 14, 1887.

Chlorosis and Retention of Feces among Girls.—Sir Andrew Clark, in the *Lancet* of November 19, 1887, contends that the anæmia or chlorosis of girls arising in nervous constitutions with imperfectly developed sexual organs is caused for the most part, and in the first instance, by feculent retention and its consequences, and that the right as well as speedily successful treatment lies in the enforcement of a sound hygiene, the administration of ferruginous cathartics, and in the provision after cure for a daily and, as far as possible, a natural relief to the bowels.

His treatment of an ordinary case is as follows: On first waking in the morning, sip a quarter of a pint of cold water. On rising, take a tepid sponge bath; dry quickly, and follow with a brisk towelling. Clothe warmly and loosely; see that there is no constriction of the body or of the limbs. Have four simple but liberal meals daily, arranged after this fashion: Breakfast, eight to nine—whole-meal bread and butter, with one or two eggs, or some broiled fresh fish, or the wing of a cold chicken or pheasant, and toward the close of the meal half a pint of equal parts of milk and tea, not infused longer than five minutes. Lunch or dinner, one to two—fresh, tenderly dressed meat, bread, potato, well-boiled green vegetable, and any sort of simple farinaceous pudding or of cooked fruit, preferably apple; drink one glass of Burgundy alone or in half a tumblerful of water. Tea from four to five—whole-meal bread and butter, with a cup of equal parts of tea and milk. Dinner or supper, from seven to eight—this should resemble the mid-day meal, but should be less in quantity. Nothing is to be taken after this meal, nothing between meals, and nothing but what is here set down. Walk at least half an hour twice daily, and as much more as strength and convenience will permit. Retire to bed about ten, and repeat the sponging and towelling. See that your bedroom is cool and well ventilated. Lead a simple, regular, active, occupied, purposive life; and do not notice or distrust yourself.

With such instructions modified according to individual peculiarities, I prescribe an old-fashioned ferruginous cathartic, to be taken twice a day, about eleven and six. Usually it is an acid mixture, designed somewhat as follows:

R.—Ferri sulphatis	gr. xxiv.
Magnes. sulph.	℥vj.
Acid. sulph. arom. . . .	℥j.
Tinct. zingiberis	℥ij.
Infus. gent. co. vel quassiæ .	℥viij.

Fiat mist.

Sig. One-sixth part twice daily, about eleven and six.

Occasionally this acid mixture produces sickness, dries the skin, and is otherwise ill borne. In such cases I prescribe an alkaline cathartic mixture.

R.—Ferri. sulphat.	gr. xxiv.
Sodii bicarbonat.	℥ij.
Sodii sulphat.	℥vj.
Tinct. zingiberis	℥ij.
Spts. chlorofor.	℥j.
Inf. quassiæ	℥viij.

Fiat. mist.

Sig. One-sixth part twice daily, about eleven and six.

Sometimes neither mixture agrees, and then I prescribe sulphate of iron in pills with meals, and a saline aperient on first waking in the morning.

Upon the plan of treatment here described nine out of ten cases of this anæmia of girls recover their health in from one to three months; and if, when health is

quite restored, one prescribes once or twice a week an aloes, myrrh, and iron pill, in doses just sufficient to bring about a moderate natural action of the bowels, the recovery will prove in all probability permanent. But upon this statement some of my auditors will remark, "It is the iron which cures; it is not the aperient." That iron has much to do with the cure of the malady I admit, but I doubt if it plays the chief part; and I know that in numerous cases the use of iron, arsenic, and manganese unaccompanied by aperients has failed to cure. Furthermore, I have seen many patients who, having been treated in this manner unsuccessfully for months, speedily recovered their health under the influence of a ferruginous cathartic mixture and a regulated diet. And so clear and strong is the teaching of my experience upon the point under consideration that if in the treatment of this malady I were perforce limited to the employment of one sort of drug, the drug which I should choose for use would be an aperient.

ICHTHYOL IN RHEUMATISM.—DOUBELIR reports that in the military hospitals of Moscow ichthyol has been given in 8 cases of articular rheumatism, 6 of which were acute and 2 were chronic. The result was diminished pain, but continued swelling. The remedy may be given in pills or capsules containing one and a half to three grains each. Of these from six to twelve of the first and from three to six of the second may be given in twenty-four hours.—*L'Union Médicale*, November 5, 1887.

TO PREPARE SATURATED SOLUTIONS OF BORIC ACID.—CABANÈS has found the following formula useful in securing the solution of boric acid:

Acid. boric.	12 parts.
Magnesiæ calcin.	1 "
Aquæ destillat.	75 "

—*Journal de Médecine*, November 13, 1887.

A POST-MORTEM EXAMINATION OF A MORPHO-MANIAC.—At a recent meeting of the Paris Academy of Medicine, BALL reported an interesting case of morphomania, with fatal termination, from failure of respiration.

Post-mortem examination revealed the heart muscle pale, fatty; the aorta was narrowed at its origin. The nervous centres, kidneys, and liver were normal. Chemical examination demonstrated the presence of morphia in the nervous centres, the kidneys, spleen, and in largest quantities in the liver.—*Revue de Thérapeutique*, November 1, 1887.

ANTIPYRIN HYPODERMATICALLY, FOR PAIN.—FRÄNKEL, of Breslau, has used a fifty per cent. solution of antipyrin in distilled water, of which he commonly gave half an ordinary hypodermatic syringeful (three and three-quarters grains, of antipyrin). The dosage was increased three or four times this quantity with good results. A cutaneous surface, about two inches in diameter, was usually anæsthetized by the injection. He found an injection of three and three-quarters grains of antipyrin to equal about one-third of a grain of morphia, and in a comprehensive series of painful affections he obtained results which led him to consider antipyrin a positive anodyne. Two cases of severe pain from acute inflammation of the middle ear were benefited at once, and especially illustrated the value of the drug.—*Wiener medizinische Presse*, October 30, 1887.

AN APPARATUS FOR TESTING THE EYESIGHT OF CHILDREN.—DR. COHN, oculist at Breslau, has invented a new apparatus for testing the eyesight of children. This is a matter which is scarcely attended to at all in this country. Periodical tests have shown that there is much more small mischief in the eyes of young students than is generally supposed, which can easily be stopped if the necessary precautions are taken in time. Dr. Cohn's invention consists of a white board twenty-five centimetres square, to which are fastened six rows of hooks, shaped thus ⊐, one centimetre square. He who possesses a normal eyesight will be able to tell, at a distance of six metres, in ordinary daylight, in which direction—upward, downward, to the right, or to the left—the hooks, which are painted of different colors, are turned. Pupils who cannot do this injure their eyes by constantly looking at the blackboard. The same board may be used to determine whether the ordinary daylight is sufficient for the rooms. As soon as the teacher cannot distinguish the direction of the hooks at a distance of six metres without straining his eyes, the gas ought to be lighted at once.

THE TREATMENT OF CHRONIC LEG ULCERS WITHOUT REST.—BAUM, in the *Deutsche medicinische Wochenschrift*, No. 27, 1887, affirms that by adopting the following mode of treatment, ulcers of the leg may be cured while the patient follows his usual employment. First, the whole leg is most carefully washed with soap, shaved, and brushed with sulphuric ether. Then the ulcer is carefully disinfected with a three per cent. carbolic solution, applied by cloths dipped in it, which are kept on for half a day. The leg is then carefully dried and strapped, the strips crossing in front and overlapping at the edges. The plaster must be spread thickly on the linen; breadth of each strip, four to five centimetres (1½ to 2 inches). Above this strapping eight layers of carbolic gauze are laid, and fastened with a calico bandage.

Every second day the bandage is taken off, and the carbolic gauze, especially over the situation of the ulcer, is thoroughly sprayed with a twenty per cent. carbolic spirit, then a fresh bandage is applied.

This treatment is continued for four weeks. On removing the whole dressing, the ulcer is found, in most cases, completely healed up. If a small spot should still be open, a small similar dressing is put on for a fortnight.

SUPRAPUBIC PROSTATECTOMY.—At a recent meeting of the Clinical Society of London, MR. MCGILL read a paper on suprapubic prostatectomy, and related three cases where the operation had been successfully performed. The operation consists in opening the bladder above the pubes in the usual manner, and removing with scissors and forceps that portion of an enlarged prostate which prevents the outflow of urine. Case 1 had suffered from urinary symptoms for seven years,

and had not been able to pass urine without a catheter for seven months. Six calculi, weighing 174 grains, and a portion of the prostate as large as a walnut, were removed by suprapubic incision. The patient made a speedy recovery, and did not require to use a catheter. Case 2: Symptoms of prostatic enlargement for two years, acute symptoms for a fortnight, fetid urine, and frequent micturition. The patient was treated for three weeks by ordinary methods without benefit. The middle lobe of the prostate, the size of a bean, was removed with immediate benefit. He left the hospital on the twenty-seventh day with the wound healed, and passing urine without difficulty. Case 3: Prostatic symptoms for six years. Acute symptoms of greater or less severity for three years. On admission into hospital, the patient was found to be extremely ill. He vomited all his food, had constant diarrhœa, and passed putrid urine, which deposited one-third of its bulk of pus. On opening the bladder, the ureters were felt to be much dilated. The projecting portion—the enlarged prostate—was removed. He made a quick and satisfactory recovery, and was able to micturate without difficulty. The benefits derived from the operation are of two kinds: first, acute symptoms are relieved by the drainage of the bladder; and, second, the cause of these symptoms is removed by excision of a portion of the enlarged prostate. As yet the operation has only been practised in acute and urgent cases; it is not improbable that in the future it may be resorted to before any acute symptoms intervene.

Mr. Christopher Heath spoke of the great advantage of the suprapubic drainage in cases of long-standing prostatic enlargement with its consequences. He considered Mr. McGill's action as a new departure. Some years ago Sir William Ferguson tried the removal of enlargements of the prostate by the perineal incision as in lithotomy, but the hopes raised by this method did not appear to have been fulfilled. Mr. McGill's mode of treatment may be said to have opened up a great field for enterprising surgery.—*Lancet*, November 19, 1887.

The Treatment of Tuberculosis of the Larynx by Curetting and Lactic Acid.—Heryng reports, in *L'Abeille Médicale* of November 7, 1887, 36 cases of tubercular ulcers of the larynx, treated by this method, with 27 cures. The bacilli were found in the matter removed.

Carcinomatous Infection.—At a recent meeting of the Berlin Medical Society, Von Bergmann expressed his belief in the possibility of particles of carcinomatous matter causing local infection when transferred to favorable portions of the body. He instanced examples of carcinoma of the mouth and tongue which had been followed by carcinoma of the stomach and intestine. Also the direct transference of the contagion of carcinoma from the tongue to the adjacent tissue of the mouth has been noted.

Hahn reported an experiment he had made, in a patient suffering from disseminated carcinoma, in whom he had transplanted portions of three cancerous nodules. Growth and development of typical carcinoma followed.

Virchow thought that the transplanted cancer may have grown with the hypertrophied and irritated integument, without a real infection from carcinoma having occurred.—*Deutsche medicinische Wochenschrift*, Nov. 10, 1887.

Iodoform, Deodorized.—Cantrelle, pharmacist at Paris, has found, of all the ways devised for hiding the odor of iodoform the following combination is the best:

Iodoform	gr. 15.
Menthol	gr. ¾.
Essence of lavender (of best quality)	gtt. 1.

In addition, the hands may be washed in water containing a little lavender brandy or essence. Cocaine may be added, when instant anæsthesia is required, as follows:

Iodoform	gr. 15.
Cocaine	gr. ¾.

—*Bulletin Général de Thérapeutique*, Nov. 15, 1887.

The Cardiac Apex Beat in Children.—Gundobin, of Moscow, has examined 300 children, to locate the apex beat. In 14 it was felt in the fourth intercostal space; in 60 between the fourth and fifth; in 220 in the fifth intercostal space, and in 6 cases in the sixth intercostal space. In 190 children it was in the mammary line; in 80 cases it was external to the line, and in 30 cases it was internal. Gundobin has found that the location of the apex beat with reference to the mammary line, is dependent upon the relation between the length, breadth, and depth of the thorax. In newborn children these measurements are of equal length, and in children two weeks old are eight centimetres (3.12 inches) in extent. As children grow the antero-posterior diameter increases less than the others. So long as the other diameters remain of equal length, the apex beat is always external to the mammary line. When the difference between the two diameters is one inch, the apex beat is on the mammary line; when the difference is one and three-quarters inches to two inches the apex beat is inside the mammary line. In children one year old the apex beat was external to the mammary line. In those two years old in 90 per cent. it was external; in children three years old it was external in 28.5 per cent.; between four and five years in 5 and 5½ per cent. In children from five to eight years old the apex beat was in the mammary line in 100 per cent. As age increased the apex beat was within the mammary line until at thirteen years 85 per cent. showed the heart's beat internal to the nipple line. In children of all ages the apex was external in 17.6 per cent., upon the line in 67.4 per cent., and internal in 15 per cent. Regarding the location of the nipple, in only 65 out of 100 children is it constant, when chest measurements are the same; the difference being from one-third to one-half an inch. The distance of the apex beat from the median line increases as the child grows older.—*Centralblatt für Kinderheilkunde*, No. 18, 1887.

The Treatment of Spinal Disease by Continuous Extension in the Horizontal Posture.—Fleming, in the *Glasgow Medical Journal* for November, 1887, describes his method of treatment as follows:

The arrangement I now adopt consists of a strong

elastic cord six inches to a foot in length, one end of which is made fast to the top of the bed, and the other to the centre of a piece of wood rather longer than the greatest diameter of the head. The head stall—made after the pattern of the one used for suspension in Sayre's method, but of chamois or other soft leather, and rubber-tubing in place of side straps—is connected to the ends of this wooden yoke. A broad towel is tightly pinned or sewn round the pelvis, and to this, in the middle line behind, is firmly attached the end of a piece of strong calico bandage. The other end of this is tied, at about the level of the feet, to the cord passing over the common extension pulley at the end of the bed, and a weight, proportioned to the body weight of the patient, put on. The bed is covered with a macintosh sheet freely dusted with powdered boric acid, and the arrangement is complete. It will be seen that, while the whole spinal column is thus acted upon by the extensile force, the arms and legs are quite free, and the patient can turn round and lie on the back, face, or either side at will, without for a moment relaxing the extension. The object of the smooth vulcanized rubber sheet is to reduce the great friction between the body and the rough surface of the sheet, which it was found entailed a considerable increase of weight.

In the majority of cases in which pain has previously existed it is almost immediately relieved. The patient experiences a sense of comfort; sleep and general condition improve. In some cases—indeed, where attainable, probably in nearly all—the use of massage and electrical stimulation of muscles is advisable, and can be employed without even momentary interference with the extension. In many cases it is advisable, after the cessation of all symptoms under this treatment, to make the patient for some time wear a poro-plastic or other jacket, or, in cases of disease of the upper part of the spine, my pneumatic collar or Hillard's pelvic jury-mast.

GUAIACAL.—This substance is the active principle of creasote, and is used by SAHLI in tuberculosis, as follows:

R.—Guaiacali	. . . .	gr. 25 to gr. 30.
Aquæ	. . . .	℥ 45.
Spirit. vini	. . . .	℥ 5.—M.

To be put in darkened bottles.

Sig.—Teaspoonful to dessertspoonful two or three times daily.—*Correspondenzblatt f. Schweizer Aerzte*, Nov. 20, 1887.

AN ARTIFICIAL ATMOSPHERE FOR PHTHISIS.—Doubtless a perfect atmosphere for cases of chest disease, and especially phthisis, must remain for a long period a utopian idea. The subject of an artificial atmosphere was raised recently at the Biological Society of Paris by M. d'Arsonval, who described several apparatus constructed by him for permitting patients, and especially phthisical ones, to respire an artificial atmosphere, and he showed a means by which the inspired air should be uncontaminated by the fluid in the expired air. Dr. Brown-Séquard, in the discussion thereon, said it would be very important to settle this point in the hygienic treatment of *poitrinaires* and others. He has tried to employ an atmosphere containing a rather larger percentage of oxygen than the normal of ordinary air; but he found that when the oxygen was in too great a quantity, irritation resulted, causing considerable distress, even when the carbonic acid eliminated remained normal. If, nevertheless, a mixture in determined proportions of carbonic acid and oxygen be made in an artificial atmosphere, these phenomena of intolerance are no longer produced. It is known that carbonic acid, besides its anæsthetic property, exercises a cicatrizing effect on wounds. It is possible to comprehend how, in cases of tuberculosis, a diminution of reflex sensibility, and consequently a lessening of cough, may be afforded, whilst at the same time the pulmonary lesions may be favorably influenced, by carbonic acid.—*Lancet*, November 19, 1887.

TUBERCULOUS ERUPTIONS.—At a recent meeting of the Berlin Medical Society, BAGINSKY reported two cases of general tuberculosis in which, in addition to the ordinary lesions of pulmonary tubercle, well-marked local tuberculous eruptions appeared on the velum palati, on the gums, and on the tonsils. The secretion when examined revealed the bacilli of tubercle in abundance.—*Deutsche medicinische Wochenschrift*, Nov. 10, 1887.

THE TREATMENT OF SCIATICA BY MASSAGE.—In the *Practitioner* for November, 1887, DR. ECCLES reports good results in cases of the most severe type, being characterized by the acuteness of the local suffering and the severity of the constitutional disturbance attending it. Of the six cases referred to as of a doubtful nature it is only necessary to note that they occurred in subjects of a distinctly anæmic type, the sciatic affection apparently being a concomitant of the general ill-nourished condition rather than its primary cause.

In these cases general corporeal massage was systematically performed, with frequent meals at regular intervals, consisting chiefly of milk, butcher's meat, and farinaceous puddings. Rest and the avoidance of all pressure upon the nerve trunk was strictly maintained for periods varying from four to ten weeks, with the result that not only was the sciatic pain removed, but the patients all improved in respect to their weight, appetite, and physical strength.

In the five cases in which neuralgia of the sciatic, supraorbital, facial, and temporal nerves was the most prominent feature, pain being complained of in one or other of these situations at intervals, sometimes in the sciatic nerve and the face on the same side coincidently, the treatment employed was in all respects identical with that previously described in referring to the neuritic cases; but the progress of the patients was not so steady as in the two foregoing classes, nor was the result so satisfactory in two cases, as the patients have since suffered severely from "neuralgia," which has not yielded to remedies except temporarily.

In one case, it is true, the effects of the treatment appear to have been so far permanent that for nearly twelve months the patient has enjoyed immunity from pain; but this must be attributed, perhaps, as much to the improved circumstances of her life as to the fact that while under treatment she decidedly gained weight and the power to sleep; which she had lost for some months previous to coming under treatment.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,
PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, DECEMBER 10, 1887.

THE CROWN PRINCE'S CASE.

THE late reports concerning the distinguished sufferer at San Remo inform us that his condition has undergone considerable change for the better, so that there is no question at present of any operative interference; the acute symptoms pointing toward prospective tracheotomy having subsided, and his general health remaining excellent.

If the disease in the larynx of the Crown Prince of Prussia be carcinoma, the clinical course has been different from what is usual in that disease. It was only at the end of several months of close and continuous observation that a fresh projection was detected, half an inch below the original site of disease, which had meanwhile become cured. This projection, too, as far as the meagre descriptions indicate, may have been simply due to an abscess from perichondritis of the arytenoid cartilage at its base, the rupture of which could well be followed by the remarkable relief reported—relief which could hardly be expected to follow the supposed ulceration of soft carcinoma. The irregular outline of intralaryngeal abscess closely resembles the irregular outline of small, diffuse carcinoma.

In the *Berliner klinische Wochenschrift* of November 21, is published an official communication from Prof. Virchow to the Berliner medicinischen Gesellschaft, of which he is president, in which he repudiates all responsibility for the assertion that the Crown Prince's disease is not malignant, or for the plan of treatment adopted in consequence of his failure to find any evidence of malignancy in the fragments submitted to his inspection. It was to these fragments alone that his opinion was applicable, and not to the entire seat of the disease, of the conditions of which he had remained in ignorance. He refers to a statement in Morell Mackenzie's own monograph upon "Growths on the Larynx," 1871, that the microscope cannot be relied on for differential diagnosis, several cases having come under his notice where the histological features were decidedly those of cancer, while the clinical history was of a totally opposite character, and *vice versa*.

Virchow has been personally informed by Dr. Schmidt that the left vocal cord is at present in no way involved in the disease; the tissues submitted to operative procedure having healed without recurrence of morbid growth. Therefore, it cannot be taken for granted that the fragments examined were fragments of the carcinoma, even should the disease be cancer. In several collections of preparations of laryngeal carcinoma Virchow has observed none which showed entirely independent warty formations along with the cancer. In conclusion he declares that he has afforded no occasion for delay in the discovery of the other diseased portion of his Highness's larynx, which now appears to be under treatment; and he states that as months elapsed without hearing of any other diseased place than the one submitted to operation, the belief might well have been entertained that there was no other disease present, and that the prognosis was far more favorable than has unfortunately proven to be the case.

Reading between the lines we should say that, from the reports which have reached him, Virchow considers the case to be carcinomatous, notwithstanding the absence of corroborative histological evidence in the fragments of tissue which he has examined.

The present diagnosis of malignancy appears to be based on the physical appearance of the diseased portion of the larynx, without any support derived from examination of fragments, or any attempt to remove portions for that purpose. While the great probability is that the distinguished laryngologists, English and German, are correct in their opinion as to the cancerous nature of the disease, the clinical features cabled from time to time do not yet exclude a certain amount of doubt as to the accuracy of their diagnosis.

Carcinoma of the larynx usually presents as a supraglottic mass which extends downward; rarely as an infraglottic mass extending upward. When unilateral it begins usually in the vicinity of the ventricular band, extraventricularly or intraventricularly, or upon the vocal band. In the case under notice the disease in the vocal band has been cured without recurrence, and has been pronounced not to be malignant. Had it been in continuity with the present seat of the diseased portion of the larynx that fact would have been elicited gradually, and not by the sudden announcement of a swelling,

the evolution of which belongs rather to the clinical history of abscess of the larynx than to that of malignant growth. This circumstance and the site of the new manifestation lead us to hope that, after all, the alarm will prove to have been uncalled for, and that the Fatherland may still have a fair chance to be governed by the Prince it loves so well.

GALL-STONES AND PERNICIOUS ANÆMIA.

IN the *Berliner klinische Wochenschrift*, Nos. 44 and 45, GEORGI relates an interesting case of profound anæmia, which he tries to connect etiologically with the presence of a large number of calculi in the gall-bladder. The patient, a man aged thirty-six, had all the symptoms of advanced anæmia, with retention of subcutaneous fat and a light icteric hue of the skin. The blood changes were most marked; hemorrhage occurred from the bowels; there was a slight fever, and the case ran a rapidly fatal course. There were found, post mortem, fatty degeneration of the organs, a lymphoid state of the marrow, an increase in the amount of iron in the blood-making organs, and 175 calculi in the gall-bladder. The liver was fatty and bile-stained; the ducts not dilated. He had never suffered from gall-stone colic, but at times during the illness the stools were clay colored.

It is suggested that the small gall-stones in passing the common duct produced more or less obstruction and retention of bile, and an elaborate and lengthy account is given of the destructive influence of the bile acids upon the blood corpuscles, to which, in this instance, the anæmia is attributed. In support of this view the author has collected from the literature eight cases of pernicious anæmia associated with icterus. PROFESSOR EWALD, the editor of the journal, adds the report of a case of fatal anæmia with jaundice, but without any involvement of the liver or its ducts; and, as opposing Georgi's view, refers to the cases of chronic obstruction to the ducts, which may persist for months or years without inducing profound anæmia. The light lemon-colored tint of skin in pernicious anæmia is really—just as in malaria—a mild hæmatogenous jaundice, due to the dissolution of red corpuscles with diffusion and imbibition of the coloring matter. It is of various shades of intensity, and to this cause rather than any actual obstruction, the evidence for which is very doubtful, we should be inclined to attribute the light jaundice in the case under consideration.

THE FIRST FIFTY SANGER-CÆSAREAN OPERATIONS OF CONTINENTAL EUROPE.

WE promised several months ago to report the results of the first fifty cases, taken chronologically, so soon as we could feel satisfied that we were in the possession of them. It now appears that the list was completed in March, 1887, and that the success of the operation was fully up to our anticipations. To have saved forty women out of fifty, with forty-eight of their children, is certainly a great triumph in obstetric surgery, and must be a source of gratification to Dr. Sänger and those who have carried out his ideas of multiple seroso-serous suturing of the uterine wound.

Of the first twenty-five women operated upon, nineteen were saved, and of the second twenty-five, twenty-one. Engaged in the fifty operations were thirty-one distinct operators belonging to Germany, Austria, France, Italy, Russia, Poland, and Switzerland. Since the completion of the first fifty, there have been quite a number of operations, and the successful proportion is being still kept up. Prior to 1887, the Sänger cases of the United States were all fatal, because operated upon *in extremis;* but during this year there have been, in all, three of this class of operations, two of them in hospital, saving all of the women and two of their children, the third child being delivered moribund, after an active labor of four days. In this case a wide resection of the muscular coat, including a small fibroid, was made; and because of the existence of numerous other fibroids the ovaries were removed to establish the menopause. The woman was also rachitic, and had a badly deformed pelvis; still, the multiple suturing saved her.

We hope to see the Cæsarean operation in the United States differently conducted in the future, and women subjected to the knife in good season, so as to save both child and mother. The failures in the first five operations under the Sänger method in the United States we hope have taught a good lesson. The fact is established, that to be successful it should take precedence of the forceps, turning, and craniotomy, trials of which, only waste valuable time and add to the risk of the knife. No hospital Cæsarean case was ever saved in the United States, until it was done in case 10th, under the Sänger method, tried as soon as possible after the commencement of labor. Hospital operation 11 being also elective and promptly performed, was equally successful, although the woman was much broken in health from cancer of the cervix. The first fifty Porro-Cæsarean operations of Continental Europe, in chronological order, saved twenty-one women and forty-one children. We have not seen any report as yet of a Sänger operation having been performed in Great Britain. As but twenty-nine women have been saved in that country under one hundred and fifty old Cæsarean operations, we may be permitted to suggest that it might be well to give the plan a trial, in view of what has been accomplished under it in German hospitals, and very recently in New York and Baltimore under Professors William T. Lusk and John G. Jay, respectively.

We look for an entire change in our own country,

in the manner of conducting cases of very difficult labor. Take away the fear of the consequences of the Cæsarean operation, and midwives as well as accoucheurs will look to it, not as a last resort, but as a means of delivery, to be considered promptly, where the measure of pelvic obstruction renders the extraction of an unmutilated fœtus impossible, except under the knife, and through an abdominal incision. We believe that the Sänger operation promptly conducted is less dangerous to the woman than craniotomy, where the true conjugate of the pelvis is reduced to 2½ inches.

LAPAROTOMY IN RUPTURE OF THE BLADDER.

In the current number of The Medical News may be found a report of laparotomy for intraperitoneal rupture of the bladder, which, although it terminated fatally, illustrates what, in our opinion, is the proper mode of procedure in similar cases. Had the operation been practised soon after the occurrence of the accident, it is highly probable that the result would have been favorable. Be this as it may, laparotomy, with suture of the rent, in cases of intraperitoneal laceration, is the only treatment that holds forth the slightest prospect of success, and should be resorted to as soon as the diagnosis is made, although our text-books generally do not recommend such a course.

We quite agree with Dr. Fox that catgut is not a safe material for suturing the bladder; and we believe that interrupted catgut sutures are also unfitted for closing the edges of the abdominal incision. In similar cases we would advise that the peritoneum be approximated with the continued catgut suture, and the superficial wound with the continued silk suture.

THE INFLUENCE OF ALCOHOL ON THE ACTION OF PEPSIN.

This subject is so time-worn and threadbare that it seems scarcely worth while to bring it before our readers once more, and, but for an exhaustive article in *Les Nouveaux Remèdes* of October 24, 1887, we should not do so.

The experiments described, while interesting from a general point of view, are absolutely worthless so far as any practical value is concerned, for experiments on digestion in the test-tube can never be relied upon as a basis from which to draw conclusions as to the influence of *pure alcohol* in the stomach. We have already pointed out that while, chemically, alcohol retards the action of pepsin, physiologically it so irritates and stimulates the gastric mucous membrane as to cause a large flow of gastric juice, which is capable of overcoming any influence it might exert for the moment on the small amount of pepsin present in the stomach.

The results reached in the article quoted are in direct agreement with all other like series of experiments, and could not well be otherwise, if correctly performed, so many uniform results having been reached already by other observers. As we have heard a well-known therapeutist remark, "They told me that alcohol retards digestion in the test-tube, but I have always objected to having my stomach compared to a piece of glassware."

Dr. Charles T. Parkes, formerly Professor of Anatomy in Rush Medical College, Chicago, succeeds the late Professor Gunn in the chair of surgery in the same institution.

The Philadelphia Board of Health has fined a physician $100 for not reporting to the Board two cases of leprosy under his charge, in accordance with the law requiring the reporting of contagious diseases to the Board.

A Spanish translation, by Professor Ramor de la Sota y Lastra, of Dr. J. Solis Cohen's monograph on "Croup in its Relations to Tracheotomy," has just been published at Seville.

In the *British Medical Journal* of November 5, is a timely editorial on woollen winter underclothing. The *Journal* regrets that underwear made upon the Continent, and especially in Germany, has, "by dint of diligent puffing," obtained a position of apparent superiority that is not deserved. It calls attention, among others, to the all-wool clothing of the Donegal Industrial Fund, made in Ireland, and asserts its superiority on hygienic grounds and on artistic merit and durability over the imported hosiery, and urges upon physicians to help to dissipate the absurd claims made for some Continental manufactures of woollen wear that are now finding their way to these shores.

Dr. Thomas L. Janeway, of New Brunswick, New Jersey, died November 28, at Eureka Springs, Arkansas, aged forty-three years. He graduated from Rutgers College in 1863, and from the College of Physicians and Surgeons, New York, in 1867. After graduating he took up his residence for some time in Germany, continuing his medical studies, and part of the time acted as surgeon in the German army. In 1877 he returned to New Brunswick and entered upon medical practice. Latterly his health has been infirm from Bright's disease, and at the time of his decease he was on his way, accompanied by members of his family, to California to spend the winter for the benefit of his health. The deceased came of a family of great worth and intelligence, and eminent in theology as well as in medicine.

ACCORDING to a press cablegram Dr. Sommerbrodt, the eminent laryngologist, of the Breslau University, lectured last Tuesday on the case of the Crown Prince. He stated that he was inclined to the conclusion that it is a case of simple perichondritis, with an abscess formation, and not of a cancerous nature. He thought that some difficulty is likely to be presented in the extrusion of several pieces of dead cartilage. He considered that the prospects of the Prince's recovery are hopeful.

REVIEWS.

IMPOTENCE, STERILITY, AND ALLIED DISORDERS OF THE MALE SEXUAL ORGANS. By SAMUEL W. GROSS, A.M., M.D., LL. D., Author of a Practical Treatise on Tumors of the Mammary Gland. Third Edition. 8vo. pp. 172. Philadelphia: Lea Brothers & Co., 1887.

As Professor of the Principles of Surgery and of Clinical Surgery in the Jefferson Medical College, the utterances of Dr. Gross are entitled to most respectful attention, and that the value of this practical treatise has been appreciated by the profession, is proved by the speedy call for a new edition of it. With the decision borne of experience, Professor Gross lays down rules of practice which are reliable, and based not only upon experimental knowledge, but upon the observation and judgment of others. Working in a field which has been but casually explored by others, the author of this practical treatise has produced a compend containing pretty much all that the present state of our knowledge enables us to state confidently. The expression of the opinion that the fault in unfruitful marriages lies with the husband in one case out of every six, will be a surprise to many, and the application of the rule should save many women from serious and needless operations. What effect it may have in promoting the happiness of such unions, where the condition is irremediable, must remain a problem for future solution. The book has the commendation of the profession, and needs none from us.

VISITING LISTS.

THE MEDICAL NEWS VISITING LIST, 1888. Philadelphia: Lea Brothers & Co.

THE PHYSICIAN'S VISITING LIST FOR 1888. Philadelphia: P. Blakiston, Son & Co.

ALTHOUGH the first of these Lists has been before the profession but a few years, it has won favor which demonstrates its adaptation to the wants of the practitioner. In its present revised edition it contains the data indispensable in diagnosis and treatment, and as a specimen of the bookmaker's art is handsome and durable.

The alterations embodied in the List for 1888 bring it fully up to our practical knowledge in therapeutics, the new remedies introduced being those which have proved of value. The illustrations, tables of the metric system and various clinical memoranda furnish the physician extensive information in the most convenient form. The arrangement of the different editions cannot fail to satisfy the most varied practice, and the Visiting List will prove itself a welcome and useful companion.

The well-known Blakiston Visiting List is somewhat different in plan and finish from the previous. The articles likely to prove of most value are the review of new drugs, which is fully up to date, and the memoranda for the examination of urine. The selection of new material has been judicious, and the physician will find the requisite data for ordinary medical practice at his disposal in this convenient-sized pocket volume.

SOCIETY PROCEEDINGS.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 1, 1887.

THE PRESIDENT, A. JACOBI, M.D., IN THE CHAIR.

DR. J. W. STICKLER, of Orange, New Jersey, read a paper on

FOOT AND MOUTH DISEASE AS IT AFFECTS MAN AND ANIMALS, AND ITS RELATIONS TO HUMAN SCARLATINA AS A PROPHYLACTIC.

He said that he had two reasons in presenting the present paper; first, because it gives the result of investigations which he had been making during the past four years; and, second, because it points out the way in which such results may be turned to practical account. It has long ago been shown beyond question that foot and mouth disease may be communicated to the human subject in either of two ways: (1) through the agency of milk from affected animals, and (2) by the accidental introduction of virus into open wounds.

Having referred to the general symptoms of the disease as it occurrs in animals, he mentioned those which it presents in man; stating that it is characterized by glandular enlargements, vesicles in the mouth and upon the hands and feet, and, in some cases, by a scarlatinal eruption in different parts of the body. This was the case with Hartwig and others who purposely contracted this disease by drinking milk from infected animals. Instances of this kind varied somewhat from those in which the affection was caused by virus introduced into the system in other ways.

Dr. Stickler then gave some account of the sudden and severe epidemic of sore throat which occurred in Dover, England, in 1884, and attacked the inmates of the best houses in the place, and said that it was conclusively proved that the outbreak originated from milk obtained from cows suffering from foot and mouth disease. In the majority of the cases the two principal symptoms were inflammatory sore throat and enlarged cervical glands; while in many instances vesicles were also noted. The sequelæ in general resembled those of scarlet fever. An investigation of 182 of the cases made at the end of two years after the outbreak showed the following points:

(1) None of the patients had since had scarlet fever.

(2) Members of families who had previously had scarlatina, as a rule, escaped the epidemic, while those who had not had scarlatina were generally attacked.

(3) Sixteen of the patients had already had scarlatina.

(4) Four of these were very mild cases.

(5) Two of these had had scarlatina when very young.

(6) In ten cases it was doubtful whether the patients had had scarlatina or not.

He then related the histories of those cases in which he inoculated children with virus from milch cows and subsequently exposed them to the contagion of scarlet fever. The first was a child, eight years of age, who, after it had entirely recovered from the effects of the inoculation, was taken to the room of a scarlet fever patient and made to inhale the breath of the latter and place its head upon the pillow used by him. Yet, notwithstanding this exposure, the child did not develop scarlet fever. The second was a child, four years of age, in whom the inoculation produced much greater constitutional disturbance than in the previous case. The throat and mouth became sore, the temperature went up to 103°, and there was a scarlatinal eruption followed by desquamation of the cuticle. This child was afterward directly exposed to the contagion of scarlet fever in the same way, and did not contract the disease. The third child inoculated was ten years old, and though during the three years since the inoculation was made abundant opportunities for infection have been met with, up to the present time he has escaped scarlet fever. Dr. Stickler said he was well aware, however, that at this stage of the investigations now being made no positive conclusions could be arrived at.

While foot and mouth disease is essentially the same in man as in animals, there are some differences, and he now proceeded to describe in detail the symptoms met with in the latter. There are four marked stages in its history in animals; viz., (1) fever, (2) eruption, (3) desiccation, and (4) desquamation. In milch cows the flow of milk becomes merely suppressed, while the milk is of a yellow color and readily coagulates when boiled or exposed to slightly elevated temperature. There are vesicles in the mouth and throat, and unhealthy ulcers and erosions are sometimes left. Thomas had stated that scarlet fever is the only disease in which the mucous membrane will tear away, but he was probably not aware that this is also the case in foot and mouth disease. Repeated attacks of the affection in the same subject are supposed to be rare, but authorities differ very greatly in regard to this point.

Klein had claimed to have discovered the germ of foot and mouth disease, and said that it could not be distinguished from the germ of the disease caused by milk, which occurred at Hendon, and was unquestionably scarlet fever. In order to test the transmissibility of scarlet fever to the lower animals, Dr. Stickler inoculated two colts by injecting virus into the jugular veins and also giving them mucus from the mouths and throats of scarlet fever patients to swallow. In one colt the temperature went up to 103½° and in both there were sore throat, redness of the mucous membrane, cough, and difficulty of deglutition. In one of the cases there also resulted desquamation. Having repeated these experiments in a considerable number of other animals, he was convinced that it is possible to inoculate the lower animals with scarlatina.

In inoculating human beings with virus from animals the lesion was found to be a mild one, and he believed that this virus could be used in such a way as to prevent scarlet fever. Four years ago he had inoculated twelve cases with good results. Out of thirteen other children, who were already exposed to the infection of scarlet fever, five escaped the disease entirely, while eight were attacked with it. None of the cases, however, were severe, and the question arose whether the severity of the disease was not mitigated by the inoculation. During the last year he had inoculated two children. In conclusion, he said that while it was by no means proven that scarlatina could be prevented by such inoculations, the results thus far obtained were very suggestive, and he hoped to pursue the investigations in which he was engaged still further.

Dr. Andrew H. Smith said that the author of the paper had certainly made out a very excellent case for the efficacy of inoculations against scarlet fever. He would like to inquire whether it was an easy matter to procure virus, so that the supply could be kept up in case the method came into general requisition.

Dr. Stickler replied that the foot and mouth disease is extremely common in Europe. In this country, however, it is very rare. There had been an outbreak of it in Maine about two years ago, and he had also been told that it had occurred in the West. The disease which affected the cows at Hendon was not so frequent. This he believed to have been genuine scarlatina, and he had no doubt that milch cows could be readily inoculated with the virus of scarlatina derived from the human subject.

Dr. Andrew H. Smith said that he found that if the virus, derived from cows inoculated in the manner suggested by Dr. Stickler, were employed, the children thus treated would be subject to all the dangers of the unmodified disease, as was the case in smallpox when the latter was transmitted from person to person by inoculation.

Dr. Finley said that he had seen a great deal of foot and mouth disease in Scotland. It is regarded as an epizootic aphtha, and one attack of it confers no immunity whatever from subsequent attacks, as he had known cattle to suffer again from the disease within six months after having had it, and it is exceedingly common for the same animals to have it more than once. In the case of sheep, however, it really seemed that one attack was protection against subsequent ones, as he did not remember ever to have seen a recurrence of the disease in an animal of the bovine tribe.

Professor Law, of Cornell University, said, that as regards the prophylactic form of foot and mouth disease in relation to scarlet fever in the human subject, he had to confess that he was still a sceptic. In Great Britain there are frequent outbreaks of the disease, which affect not only the cattle, but the people coming in contact with the latter, and he thought that if foot and mouth disease prevented scarlatina, scarlatina ought to be a much less common disease there than in this country, where epizootic aphtha is almost unknown. Such is not the case, however, as the statistics show that during the last five years ninety thousand deaths were due to scarlatina in Great Britain. Then, again, an attack of foot and mouth disease in cattle confers a very limited, if any, immunity from subsequent attacks, and, like Dr. Finley, he had known it to recur within six months in the same animal. Recurrence of the disease is very common in his experience, and, therefore, he would hardly suppose that inoculation with it would confer immunity from scarlatina for any length

of time, if at all. While it is a very contagious disease when there is direct exposure to it, he believed that it differs from scarlatina as to its contagiousness under other circumstances. His own personal experience also tended to throw doubt upon Dr. Stickler's hypothesis. While he had been over and over again exposed to any amount of morbid products from cases of foot and mouth disease, he had never suffered from the affection; but the very first time that he was exposed to the infection of scarlatina he contracted that disease. His system had been susceptible to the one, but not to the other.

These points, therefore, seemed to militate against the protectiveness of one disease against the other. Still, it did not follow that the immunity conferred by foot and mouth disease might not be more extended in a race less susceptible to its influence than the bovine. As regards foot and mouth disease, he would strongly suggest that the investigation into its prophylactic power should be carried on on the other side of the Atlantic, as it would be a very serious matter if the disease should be introduced among American cattle; and he had no doubt that there would be a general outcry among the cattlemen if it were known that experiments were being made with the virus of the disease in this country.

Again, if we employ the virus of scarlatina for making inoculations, do we not more widely disseminate the disease? While he had great respect for the ability and achievements of Pasteur, he could not but believe that he had increased the spread of anthrax by scattering broadcast his modified anthrax virus, for he was convinced that a matured virus could, under certain conditions, be rendered potent and dangerous. In the same way he feared that rabies would only be increased by the dissemination of his attenuated virus of that disease, and he said that he believed it to be a fact that there had been more rabies among dogs in England since the discovery of Pasteur than ever before. These considerations, in his opinion, condemned the method, and he thought that the living germ of the same disease should never be used for inoculations, on account of the danger of spreading the affection involved.

DR. MCLEAN said that he did not doubt that the Hendon epidemic was one of true scarlatina, but it was not proved that the scarlatina came from the cows. He denied that there is such a disease as bovine scarlatina, except, possibly, in cases where the disease is transmitted directly from the human subject by inoculation. In the Hendon outbreak the disease may have been conveyed by the milk, but if this was the case, it did not come originally from the cows. The milk was no doubt contaminated from other sources, as has frequently been noticed in epidemics of typhoid fever and other affections, and it is well known how excellent a medium milk is for the conveyance of infectious diseases. Again, he did not think it susceptible of proof that foot and mouth disease is prophylactic of scarlatina, as he believed this to be a specific disease, the germ of which is capable of giving rise to epizootic aphtha, and to nothing else. So far as he was aware, there had been but two outbreaks of foot and mouth disease in this country—one in Maine and the other in the vicinity of New York City, extending up the Hudson as far as Poughkeepsie.

DR. JOHN C. PETERS said that a great many of the most distinguished veterinary authorities believed in the occurrence of scarlatina in horses and cattle.

DR. J. LEWIS SMITH said that since the time of Jenner the hope has been awakened that some of the other infectious diseases, and especially scarlet fever, might be prevented, as smallpox has been, by the substitution of a milder and modified disease derived from the lower animals. As regards scarlet fever, two propositions of great interest and importance have arisen. First, is there a disease in the bovine race, which is true scarlet fever, or which communicates genuine scarlet fever to man? and secondly, if there be such a disease, does it communicate a modified and mild form of scarlet fever to man? Many instances have been recorded in the last five or six years, in which epidemics of scarlet fever have arisen from the use of milk furnished by healthy cows, and infected with the scarlatinous germ after the milking, but in the St. Marylebone and Hendon epidemic, occurring two years ago, and described in the *British Medical Journal*, May 29, 1886, the outbreak of scarlet fever appeared to be clearly traced to diseased cows. Now the point he wished to call attention to is this: The sickness of the cows was mild, not appreciably impairing their appetite, nor diminishing their milk, but the disease, which the use of the infected milk produced, is described as an "intense outbreak of scarlet fever." Instead of a mild disease being propagated from the cow, for which we were looking and hoping, the reverse occurred. A mild form of the disease in the cow produced a severe one in man, so that, if we inoculate with the bovine scarlatinous virus, may we not produce severe and fatal epidemics?

PROFESSOR LAW said that, unfortunately, veterinarians had given the name scarlatina to an affection in which there was redness of the mouth, but which was non-contagious and totally distinct in character from true scarlet fever. The name had necessarily given rise to much confusion.

DR. STICKLER, in closing, said that if he produced only a slight and harmless attack of scarlatina by his inoculations, he could see no objection to the use of the scarlatinal virus; and when the terrible effects of the unmodified disease are considered, he thought it of extreme importance that a method of protection should be secured, if possible. As to the disease from which the Hendon cows suffered, it had, he thought, been positively demonstrated that it was nothing else than scarlatina, since it was precisely the same affection as was ordinarily produced in cows by the inoculation of scarlatinal virus from the human subject.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, November 23, 1887.

THE PRESIDENT, J. SOLIS COHEN, M.D., IN THE CHAIR.

DR. CHARLES B. PENROSE read a paper on

ELEVEN CONSECUTIVE CASES OF ABDOMINAL SECTION FOR DISEASE OF THE UTERINE APPENDAGES.

Abdominal section is at present such a common operation, and the diseases for which it is performed are so well recognized, that I shall not report these cases in detail; I shall simply tabulate them, consider them col-

lectively, and call attention to any special point of interest which may have occurred in the history of any case.

Case.	Age	Married or single	Disease.	Date of operation (1887).	Part removed	Complete closure of wound, or drainage.	Result
I.	30	Married.	Salpingitis and cirrhotic ovaries.	Feb. 16,	Both tubes and ovaries	No drainage.	Recovery.
II.	24	"	Pyosalpinx and cystic ovaries.	Mar. 14,	Right tube and ovary.	" "	"
III.	32	"	Salpingitis, multilocular cyst of ovary.	April 8,	Left tube and ovary.	" "	"
IV.	26	"	Double pyosalpinx and ovarian abscess	May 19,	Both tubes and ovaries.	Drainage.	"
V.	37	"	Double pyosalpinx, ovarian abscess, and hæmatocele.	May 25,	" " " "	"	"
VI.	30	"	Salpingitis and blood cyst of ovary.	June 20,	Left tube and ovary.	No drainage.	"
VII.	23	"	Salpingitis and abscess of ovary.	July 3,	" " " "	" "	"
VIII.	33	"	Salpingitis, blood cyst of ovary, uterine fibroid.	July 13,	Both tubes and ovaries.	Drainage.	"
IX.	22	"	Double pyosalpinx.	Aug. 9,	" " " "	"	"
X.	43	"	Dermoid cyst of ovary.	Aug. 17,	Left tube and ovary.	"	"
XI.	22	"	Double pyosalpinx.	Oct. 23,	Both tubes and right ovary.	"	"

These cases were operated upon during the year 1887. They all recovered, and are at present well and able to attend to their various duties. In five of the cases the appendages were removed on only one side. In one of these cases (Case II., pyosalpinx and cystic ovaries) he found it impossible to remove the left tube and ovary. They were firmly adherent in a knot on the side of the uterus, and the uterus was bound down in the hollow of the sacrum. In the other cases of unilateral removal he intentionally left the appendages upon one side. With the exception of the case of dermoid cyst, the women were young, and desirous of having children; and at the time of operation he could discover no sign of any pathological condition in either the tube or ovary. He is aware of the fact that in cases of tubal disease it is often unwise to perform a unilateral operation and to leave even an apparently healthy tube, as it may, in many cases, become subsequently diseased from an infecting focus in the uterus. Though sufficient length of time has not yet elapsed to come to any definite conclusion with regard to his cases, yet so far he has had no cause to regret having left the sound tubes; and in one case the patient has become pregnant since the operation.

A point of interest in connection with the first case (salpingitis and cirrhotic ovaries) is the length of time during which the patient was fed by the rectum. She began to vomit as she recovered from the influence of the ether; and she continued to vomit everything which was administered by the mouth for thirty-six days after the operation. There was no apparent cause for this excessive vomiting. The operation was simple, and was not followed by any obvious symptoms of peritonitis. The rectal injections, by means of which this woman was nourished for over a month, consisted of pancreatized milk, eggs, and whiskey. Two-thirds of a quart of milk, one egg, and three ounces of whiskey were administered in four or five doses during the twenty four hours. During this prolonged course of rectal feeding she lost many pounds in weight. No food at all was taken by the mouth; the very small quantities which were occasionally administered experimentally were always immediately rejected. When she finally became able to take food by the mouth it was necessary to give it in the form of twenty-drop doses of soup or beef-tea.

In investigating the histories of the cases of pyosalpinx, it was difficult to determine with any certainty the origin of the trouble. He could not in any case obtain a clear history of gonorrhœa; though in several he had reason to suspect it. In four of the five cases of pyosalpinx the patients attributed the origin of their disease to a miscarriage. In Case V. (double pyosalpinx, ovarian abscess, and hæmatocele) the active suffering dated from a violent fall upon the ice several years before the operation. The fall was followed by bleeding from the vagina, which lasted several days; and from that time until the time of operation she suffered with great pain in the lower part of the abdomen, which rendered it difficult for her to walk erect, and with evening chills after any exertion during the day. It is probable that in this case the fall had caused the partial rupture of a previously distended tube.

In all the cases of pyosalpinx there was a history of repeated attacks of pelvic pain and inflammation, which often confined the patient to bed for several weeks. In two there was also ovarian abscess. In these cases the abscess cavity in the tube communicated directly with the abscess cavity in the ovary, and the origin of the ovarian abscess was obvious. In Case VII. (salpingitis and abscess of ovary), however, there was no pus in the tube. The tube was enlarged, adherent, and its fimbriated extremity was closed; and it did not communicate with the cavity of the ovarian abscess. The ovarian abscess contained about half an ounce of pus and had a distinct pyogenic membrane. He thinks that abscess of the ovary is of more frequent occurrence than works upon gynecology admit. And though it probably is in general due to ovaritis caused by inflammation of the tube, yet it is not always associated with pyosalpinx.

In two cases of double pyosalpinx (Cases V. and IX.)

a thin purulent fluid was found in the peritoneal cavity, and the intestines were found to be deeply congested when the abdomen was opened. The patients had probably been suffering for some time with general chronic peritonitis excited by the escape of pus from the distended tubes. The symptoms, however, before operation had not pointed to general peritonitis, the patients having only complained of pelvic pain and pain in the back. The chance that such a condition may occur in connection with pyosalpinx is a strong argument in favor of removing these abscesses by abdominal section, instead of evacuating them by the vagina, as is so often done.

The danger of assuming any case of peritonitis in a woman to be idiopathic, without a thorough vaginal examination is obvious. He has the report of a case which occurred recently, where the patient was treated for several weeks for idiopathic peritonitis, and an operation done a few hours before death revealed double pyosalpinx and a ruptured ovarian abscess.

In six of the cases reported, an abdominal drainage tube was used. The average time of convalescence in these cases was no longer than in the cases where a tube was not introduced; and the severity of the symptoms following the operation—the elevation of temperature, the rapidity of the pulse, and the pain—were much less marked in the drainage tube cases than in the others. The absence of pain in the drainage tube cases is probably due to the fact that most of them were cases of pyosalpinx where the tissues which were ligated and cut were so far degenerated that their sensibility was much diminished.

He thinks that the danger of abdominal hernia following the use of a drainage tube is exaggerated. In one of his cases there is now a small hernia, but it occurred above the position of the tube and was probably due to some error in introducing the sutures. In some thirty drainage tube cases which he has seen in the practice of Dr. Joseph Price, there has, as yet, been no hernia. It is probable that hernia is due more frequently to a long or a high incision, and careless suturing, than to a drainage tube.

The average length of time before the glass drainage tube was removed in his cases was about five days. The shortest time was two days, and the longest eight days. In but one case did the discharge from the tube become purulent. The use of a cotton rope to act as a capillary drain adds greatly to the value of the glass drainage tube. It prevents any fluid from remaining in the bottom of the tube, and it removes the deposits of fibrin from the perforations in the glass.

Case X. Dermoid cyst of the ovary. He reported in detail. The patient was forty three years old. She had had three children and five miscarriages. She had first observed the tumor eighteen months before the operation. It rapidly increased in size, and when removed it was about six inches in diameter. It had never been accompanied by pain. The rapid growth of this cyst and the late period of life at which it was first observed are very unusual. The patient also had a much distended gall bladder, and at the operation a calculus was felt obstructing the cystic duct. During the operation the dermoid cyst was ruptured, and the contents, consisting of very oily material and many fine hairs, escaped into the abdominal cavity and were removed with great difficulty. It was only after thorough sponging and irrigation that the peritoneum was cleansed. A drainage tube was introduced.

The patient suffered from severe shock after the operation. For the first three days the temperature remained normal or slightly subnormal. The pulse was about 115. There was considerable abdominal distention and pain; there was not much discharge from the drainage tube. On the third day large quantities of bloody serum began to flow from the drainage tube. At the same time the tympany and general abdominal pain became much increased. The temperature ranged between 97.5°–100.5°. The pulse was 130 to 140. The respirations were 40 or over. The tongue was coated, and there was constant hiccough and occasional vomiting. The bowels had not been moved, and there was no escape of flatus.

An ounce of sulphate of magnesia was administered daily, for several days, and many turpentine enemata were given. The enemata were retained for a few minutes, and when they were rejected a large quantity of flatus escaped. The bowels were not moved, and there was no escape of flatus at any other time. As the abdominal distention and pressure increased, large external hemorrhoids, which looked almost like a prolapse of the rectum, appeared.

On the fifth night a rectal tube was introduced, but it rendered but little service. Most relief was obtained from the turpentine enemata, and the patient frequently asked for them herself.

The hiccough and vomiting ceased on the sixth day. The discharge from the drainage tube continued to be very profuse, though of lighter color. The abdominal distention, the pain, and the hemorrhoids were unchanged.

On the seventh day after the operation the suture at the upper angle of the abdominal wound was removed, and the muzzle of a long syringe was introduced among the intestines in order to determine whether there was any collection of fluid in the abdomen which was not carried off by the drainage tube. No fluid was found, and the wound was reclosed.

On the eighth day the bowels began to act. There was profuse watery diarrhœa for twenty-four hours, accompanied by the escape of large quantities of flatus. At the same time all the symptoms of peritonitis began to abate; the abdominal distention rapidly decreased; the discharge from the glass drainage tube became so slight that it was removed. The hemorrhoids began to diminish in size, and by the tenth day they had disappeared. The diarrhœa ceased in two days, without treatment; and three weeks after the operation the patient was able to leave her bed.

He reported this case at length on account of the interesting phenomena attending the development and the subsidence of the peritonitis; and because it was treated throughout by sulphate of magnesia and rectal injections, and not by opium. It was not found necessary to use opium in any of the cases reported in this paper.

DR. J. M. BALDY said that in many cases of pyosalpinx if a wealthy woman refuses to take the risk of the knife, she can, by proper treatment, be made comparatively comfortable without great risk of her life. However, the majority of cases of pyosalpinx, even among the wealthy, demand surgical interference sooner

or later. If, on the other hand, the patient has to work for her living, and is suffering with recurring attacks of peritonitis, he thinks that there the operation is called for always. The risks of the operation are comparatively slight. It can be performed by any general surgeon if he has a cool head and good surgical resources.

The use of salines in the treatment of peritonitis is a point of extreme interest. From what he has seen of such cases he has no doubt that the treatment by opium is a great mistake. Where there are the signs of beginning peritonitis, the use of large concentrated doses of salines rapidly relieves them. While the use of opium favors the occurrence of adhesions, salines would naturally tend to do away with trouble of that kind. Opium shuts up all the avenues of escape for the product of inflammation, and then tends to increase the trouble rather than to alleviate it.

Dr. J. Price was surprised at what Dr. Baldy had said with reference to pyosalpinx when he realizes how much trouble may come from a little pus. A case of pyosalpinx is always in danger. They suffer constant pain, they go down rapidly and die.

Dr. J. C. Da Costa could not agree with Dr. Price with reference to pyosalpinx. Others who have had a large experience, when asked with reference to their method of treating this affection, also differ from him. One gentleman, with a large experience in the removal of ovarian tumors, had told him that he had seen many cases of pyosalpinx, but that they had all recovered without operation. His experience is much the same.

Dr. J. Price said that it is never safe to allow the pus to remain. It is not necessary always to remove both ovaries, as is often done in operating for ovarian tumors.

Dr. M. Price challenged the statement that salpingitis does not cause much trouble. He has recently had a case which had been under medical treatment for five years. Two years ago an abscess burrowed down through the cellular tissue and discharged between the bowel and vagina. This case had been operated on five different times for fistula in ano, with entire removal of the recto-vaginal septum by operations, and until four weeks ago it had not been suspected that it was a case of pyosalpinx. These cases cannot be cured by simple medical treatment. There is no single case, that he has seen operated on, which stood one chance in fifty of living six months if the operation were not done.

Dr. W. H. Parish had no doubt that those who advocate this operation will agree that not all cases of disease of the appendages demand operation. August Martin has said that three-fourths of the cases of disease of the tubes and ovaries do not require operation. There are also cases of gonorrhœal affections of the tube which do not demand the operation. He has seen one case where the inflammation of the tubes followed the occurrence of gonorrhœal inflammation of the vagina, and in which the trouble subsided; the woman subsequently became pregnant.

With reference to the removal of ovaries and tubes that contain pus, he said that we all know that these cases may continue for years, but suffering from repeated exacerbations of inflammation. These patients are always in danger from the thinning of the tubal or ovarian wall, with the escape of pus, and the occurrence of general peritonitis. If we look over the records of any hospital or board of health, he thinks that we shall now find few deaths compared with the past, recorded as due to pelvic abscess and general peritonitis. He thinks that many cases of pelvic abscess and of general peritonitis have been in their origin cases of pyosalpinx. He is strongly in favor of the removal of the tubes and ovaries where there is pus. While a patient may enjoy a certain amount of comfort with pus in the tubes, yet she will be liable to frequent exacerbations, and may have her life placed in great danger at any moment.

He is sure that the operation for the removal of tubes and ovaries in pyosalpinx or ovarian abscess has come to stay, no matter what the future position of the operation for other conditions may be. He thinks that those who urge the treatment of these cases without operation are doing great injustice to a considerable number of patients, and also no little injustice to the surgery of today. His own experience with the operation warrants his endorsement of it.

Dr. Penrose said that such tubes as he had shown are useless and dangerous to the woman. They could not permit the passage of spermatozoa or ova. He thinks it is proper to open an abscess wherever it occurs, and not to trust to nature; and when possible to make a complete removal not only of the pus but of the abscess walls, as we do in pyosalpinx. In cases of pyosalpinx said to have been cured by medical treatment there is always an element of doubt with regard to the diagnosis. Such cases may sometimes occur. But there are few physicians skilful enough to make a positive diagnosis of pyosalpinx before the abdomen is opened. All of the cases on which he has operated had had several months or years treatment in the hospitals before the operation was performed.

CORRESPONDENCE.

LAPAROTOMY FOR STAB-WOUNDS OF THE ABDOMEN.

To the Editor of The Medical News,

Sir: I trust you will pardon my presumption in criticising a statement in the editorial of December 3d, on "Laparotomy for Gunshot Wounds of the Abdomen." You say: "In stab-wounds the lesion must be limited to the region of the wound, hence it is not necessary to perform median section, and make an extensive examination of the bowels; but in gunshot wounds, unless the bullet is of very small size median section had best be performed."

In view of my own experience with stab-wounds of the abdomen, in which abdominal section was performed, which is limited, I admit, to three cases, I must take exception to this statement. If the surgeon merely enlarge a wound in the lateral part of the front of the abdomen, and endeavor to examine the condition of the intestines, he will find that he is obliged to work through a very thick portion of the abdominal wall, and that he is very much restricted in making a thorough exploration of the contents of the abdomen.

Stab-wounds, if made by long knives or stilettoes, are liable to injure the intestine in as many portions as a bullet, and I do not think that your statement is correct, which says that the intestinal lesions in stab-wounds must be limited to the region of the wound. In one of

the cases in which I was satisfied with enlarging the original wound, I spent a great deal of time, on account of the difficulty of working through the thick abdominal wall, in sewing up two intestinal wounds, after which I closed my incision. The patient died a few days later, and the autopsy showed active inflammation of the peritoneum, and a third wound of the intestine which I had overlooked. The wounds which had been treated by suture were in good condition and in process of cicatrization.

In another case in which I at once made median section, I was able to explore the abdominal cavity with more satisfaction, sutured the wounds which were found, and was gratified by the complete recovery of my patient. These two cases, which occurred in the Pennsylvania Hospital, convinced me that in most cases it is better at once to make an incision in the median line rather than to enlarge the original wound, especially if that wound be so far away from the median line as to involve the oblique muscles of the abdomen.

This opinion is strengthened by a case which I had a few days ago at St. Mary's Hospital, and in which, after enlarging the wound, I was obliged to content myself with suturing the single wound discovered in the intestine, and rapidly replace the protruded bowels, because of the approaching dissolution of the patient, who was almost moribund when admitted.

At a recent discussion in the American Surgical Association, in commenting upon this subject, I took occasion to say, in referring to the first case here mentioned, that I believed death occurred because of the method in which I did the operation. My words at the time were as follows: "I very unwisely, as I now think, enlarged the wound instead of making a median section, hence, I had to work through a thick, muscular part of the abdominal wall and found it very difficult to examine the gut properly. As the result, the time occupied was long, and, on account of the patient showing symptoms of collapse, I closed the wound, thinking I had sutured all the intestinal punctures."

The fact that stab-wounds of the abdomen, treated by laparotomy, have not been so frequently reported as gunshot wounds so treated, has induced me to take the liberty of making this criticism.

Yours very truly,

JOHN B. ROBERTS.

1617 WALNUT STREET, December 6, 1887.

NEWS ITEMS.

THE MEDICAL CORPS OF THE NAVY.—The Washington correspondent of the New York *Times* states that it is probable that a bill will be prepared by the Surgeon-General of the Navy having for its object the improvement of the condition of the assistant and passed assistant surgeons of the navy. This bill he will present to Congress. Secretary Whitney will, of course, be consulted before any steps are taken in the matter. If the Secretary approves the plan, every effort will be made to secure the passage of the bill. It will provide for better pay for these officers, and in other ways increase the inducement to enter the service. It is at present an impossibility to fill existing vacancies in the corps. There are thirteen places to be filled. The examination for admission is extremely difficult, and while many apply for appointment, few answer the requirements. The Surgeon-General desires to keep up the present high standing, but knows that if the examinations remain as rigid as now, and the inducements to enter the service are no greater, there will be even a greater number of vacancies than now. At this time thirteen assistant surgeons are needed. Notice has been received from the Medical Board in Philadelphia that Dr. George McCaw Pickrell, of Richmond, Va., passed an examination for appointment as assistant surgeon. If he accepts a commission, there will be twelve vacancies yet to be filled. These will be readily disposed of if the salaries of the assistant and passed assistant surgeons are increased sufficiently to compensate for delayed promotion.

THE NEW YORK CANCER HOSPITAL.—The project of establishing a special hospital for the treatment of cancer, which was inaugurated three years ago by the incorporation of the New York Cancer Hospital, has now been carried out in part by the completion and equipment of one pavilion, intended for female patients only, which opened its doors on December 7th.

The necessity for such a hospital has been acknowledged by the highest medical authorities, and its advantages will be appreciated by all. It will supplement the work of general hospitals in caring for patients whom they do not receive; and, being devoted exclusively to cancer, it will offer the best possible opportunity for the treatment of that disease. Its object will be, furthermore, to test and compare the results of different methods of treatment, to collect statistics for study by the accurate observation of a large number of cases, and to try new remedies.

To carry out these objects, the present building has been constructed after the most approved plans, and with a view to the needs of this class of patients. The situation is healthful, opposite Central Park, and the grounds are ample, embracing a plot fronting on Eighth Avenue, and extending two hundred feet on 105th and 106th Streets. There are four circular wards, which is the form best adapted for ventilation and freedom from dust. These will accommodate forty-four patients, while sixteen private rooms will give place for twenty patients, who desire such accommodation, or for those who require isolation. A well-appointed operating-room, an autopsy building outside the walls, and a separate laundry building and boiler-house are other features of the hospital. The present pavilion has all the accommodations for the executive work of the entire building when completed, and the laundry and boiler-house have been constructed with the object of supplying this addition.

All patients suffering from cancer, whose condition admits of cure or relief, will be admitted by the superintendent with the approval of one of the medical officers of the hospital.

Patients living out of town should submit to the superintendent an application in writing, accompanied by a statement of their case by some responsible physician, before presenting themselves at the hospital.

The charge for board in the wards and private rooms will be at rates fixed by the Executive Committee. These rates will include all expenses except those of a special nurse. All charges may be remitted in whole or part by the Executive Committee.

The staff of the hospital is as follows:

Attending Physicians and Surgeons.—Drs. James B. Hunter, A. Brayton Ball, Clement Cleveland, Francis P. Kinnicutt, and William T. Bull.

Assistant Physicians and Surgeons.—Drs. B. Farquhar Curtis, J. S. Hawley, H. C. Coe, and W. G. Thompson.

The Medical Department of Dartmouth College conferred the degree of Doctor of Medicine upon 26 graduates at its recent commencement on November 22d.

A French Edition of Mundé's Work on the Use of Electricity has been received. It is translated by Ménière, editor of the *Gazette de Gynecologie.*

Fire in the Laboratory of L'École Pratique de Médecine at Paris, recently caused damages estimated at $20,000. Its source was a burning gas jet. Inflammable chemicals aided the spread of the flames until the Physiological Laboratory was set on fire, where much valuable apparatus was destroyed.

Contagious Pillows.—The *Lancet* is exercised over the dangers of contagion from pillows, and expresses its fears as follows:

Trade, we know, has always had its tricks, and with most of those who practise them it matters little whether they are or are not as harmless as they are profitable. If goods look well from the outside, and if they sell well, questions relating to their internal quality and their real value are too often settled by reference to that convenient rule of doubtful equity—*caveat emptor*. The principle of this adage was probably never quite a fair one. In all cases requiring technical knowledge, and their name is legion, it must allow the dealer a distinct advantage over the purchaser. We must remember also that the former may himself have been deceived. It is not he who is primarily responsible for the hidden faults of quality by which the most cautious buyer may be defrauded. It is the maker, who, with his eyes open, provides for a cheap market not only cheap and inferior, but essentially bad material. Let us quote an example. A correspondent exposes the dangerous but common practice of stuffing pillows with rags and scraps of clothing of every variety and degree of dirtiness. He suggests with much force that some of those outbreaks of fever which arise from time to time in schools and families from no apparent source, domestic or external, may be traceable to this dishonest and filthy custom. The maxim wherein cheap and nasty are interchangeable terms, is fitly illustrated by our correspondent's description, and the remedy for the evil he denounces is largely in the hands of the public. In part, also, it is within the power of the sanitary authority. The agents of that body must, and constantly do, destroy what they can of unwholesome bedroom litter in houses where fever has been prevalent. If they will exert their discreetly unsparing zeal for cleanliness wherever, among rich or poor, the tradesman's heedless trick is planting the seeds of disease, we may expect to see some change or the better, at least in one false custom of our time.

St. Jacob's Oil in England.—The following endeavor to protect the British public against the use of a secret nostrum, as narrated by the *Lancet* of November 19, 1887, is certainly worthy of imitation:

Mr. Justice Kay, in the Chancery Division, in the case of C. A. Volger and Co. *v.* Middleton, was asked the restrain the defendants from advertising and selling an oil as St. Joseph's Oil, as being an infringement of the plaintiff's trade mark, and calculated to deceive the public. Mr. Justice Kay said that both the plaintiffs and defendants were vendors of quack medicines which were largely advertised to heal all manner of external injuries. He declined to rule that the use of any saint's name in the calendar was an infringement of the plaintiff's trade mark. But lest either party should use his judgment as an advertisement, he hoped they would add that no one should employ either preparation except under medical advice. The judge's counsel is excellent. It is too much to expect that the parties to the suit will publish it. But we gladly give it publicity and praise.

Market Brands of Condensed Milk.—From the *American Analyst* of November 15, 1887, we learn that the Dairy Commissioners of New Jersey have caused analyses of the samples of condensed miik sold in that State to be made, with the following results:

Milk condensed without cane sugar is better for infants and invalids, but not keeping well, even in sealed cans, is of doubtful value. Milk preserved with cane sugar, if carefully prepared, keeps well in cans and does not spoil very rapidly, even after the cans are opened, provided the latter are kept dry and no water is mixed with it. The very large amount of cane sugar necessary to preserve milk renders it, however, an unwholesome food for infants, and such milk can by no means be regarded as a good substitute for fresh milk for this use. Condensed milk preserved with sugar is not fit food for infants. The directions on the cans in general state that, by adding a certain quantity of water, the condensed milk can be made to resemble cream; by adding more, it becomes the equivalent of milk. This can never be true; cream contains from three to four times as much fat as the average condensed milk, and no dilution with water will make such milk resemble cream, except outwardly.

Many manufacturers make false statements as to the quantity of fresh milk condensed to produce the contents of the preserved milk cans. The condensation is rarely more than threefold and usually somewhat less. A well-made condensed milk, with cane sugar, should show no undissolved sugar and be of a nearly white color, having but a faint yellowish tinge. It should have no cheesy taste or smell and should dissolve readily in about four parts of cold water. Especially should it dissolve without showing separated flocculent particles of casein or curds. Out of sixteen samples, analyzed, two of which were condensed without sugar, the analyst found that only nine were in good condition and well put up. Of the other seven one had fermented, one contained a considerable amount of undissolved cane sugar, a third was stiff, had a cheesy smell, curdled, was of a brownish color and altogether of an inferior quality. Two others had attacked the metal of the can. One was a dark brownish glutinous mass, with a smoky, cheesy taste and odor. Glucose had been used as a substitute for cane sugar. Another sample

was still brownish in color and cheesy. These facts show the error that it is necessary to exercise in purchasing and using condensed milk.

Shall the Language of Prescriptions be Simplified?—*The Lancet* of November 19, 1887, writes as follows on this point: "There is among medical practitioners no appearance of opposition to substitute for the names of chemical terms hitherto used in prescribing their simple and common preparations or ingredients in the vernacular. The reform is one which has our approval. In making this admission, however, it is necessary to define with some precision the extent of its application. For the purpose of the present argument, a prescription may be conveniently regarded as consisting of a professional and a popular part, the former being concerned with the selection of drugs and their quantities, the latter with directions for their use. The first great principle that should belong to such directions is, we take it, clearness. That meaning may be plain beyond all degree to misunderstanding on the part of unprepared persons, a point which is to be expected in words of vague and abbreviated sense charged in regard of their single current ambiguity. The advantage contested by accustomed scientific language in the case of such words as 'ad libitum' or 'quantum sufficit' is that of precision to the person to whom its employment, good, and to the readiness to come to more or a choice in the matter of interpretation, is not difficult to gain. These editors, among all parties, have been in common ground that has led to their notifying their wish and intention on the sole and their simplest and surest means of communication is the native tongue. In our instances where a word is translated into the vernacular of a prescribed measure. These are the special subjects of governance, and a close and exact attention to the use of such words without any ambiguity, and to the means of treatment, is of the last importance. Whether for the purpose and to allow of advantage by the use of the extreme medium of a compromise is decidedly preferable to any other course. We are disposed to opinion that the best and most practical result of the reform in prescribing which is now in progress will be to leave the body of the prescription in the convenient Latin and the form, and to insure the most accurate observance of instructions to the patient by expressing these in the language of every day life."

Deodorization of Hands Impregnated with Iodoform.—Iscovesco, in the *Bulletin de la Société Pharmaceutical Society of Bordeaux*, advises the vigorous scraping of the hands, upon washing them in water to which is added fragments of the shell of Cuttle fish, when the odor disappears completely.

The Duty of the State and Society in Checking Inebriety.—The International Congress of Hygiene at Vienna, in a full and interesting discussion on inebriety, urged upon the State and society the duty of working to check inebriety by the spread of information regarding the evils of alcoholism, the further passing of mild, non-injurious laws regarding the promotion of the hygiene of the poor, the proper segregation and medical care of the inebriate. It is the especial duty of the State to see that the sale of highly alcoholic liquors is lessened as much as possible by taxation; to secure the sale of pure liquors only; to maintain proper police supervision of drinking shops; to commit drunkards to proper institutions for treatment as promptly as possible. The continued treatment, medical and hygienic, of the drunkard is of paramount importance.—*Wiener medizinische Presse*, October 30, 1887.

The Examination of Water.—Dr. Parkes, of London, after reviewing the various methods of examining water, concludes that chemical analysis, aided by microscopic examination, is sufficient in the great majority of cases to determine the amount of organic pollution of a water, and whether it is of recent date. In many cases the source of the pollution, whether from sewage or vegetable matters chiefly, can also be determined; but there is no possibility of ascertaining whether the water thus polluted is actually potent for evil or whether it may not be entirely harmless. Chemical analysis is powerless to deal with those cases of infinitesimal pollution of a pure water with infective material from the human body. Cultivation tests are equally powerless to cope with such cases. The only possible way of ascertaining the probable effects on the human system of drinking such water, is for the operator to apply to the experiment on his own person—a course not likely to be pursued. The cultivation tests, as now practiced, add very little to the results obtainable by chemical analysis. Micro-biology must undergo further development before germ-culture methods can be expected to throw much light on water pollutions. Hence, the sanitary survey of the source of the water, as far inside of storage, should always be carried out whenever any doubt exists as to the freedom of the water from all possible sources of contamination.—*Pharmacist*, November, 1887.

Official List of Changes in the Stations and Duties of Officers Serving in the Medical Department, U. S. Army, from November 29 to December 5, 1887.

Burtonshaw, H. P., *Surgeon and Assistant Surgeon*.—The leave of absence granted by Orders No. 52, Fort Myer, Virginia, November 23, is extended twenty three days.—*S. O. 255, Division of the Atlantic*, November 28, 1887.

Official List of Changes of Stations and Duties of Medical Officers of the U. S. Marine Hospital Service, for the Three Weeks ending December 5, 1887.

Wyman, Walter, *Surgeon*.—Granted leave of absence for four days, November 29, 1887.

Williams, L. L., *Assistant Surgeon*.—Granted leave of absence for twenty-one days, November 18, 1887.

Kinyoun, J. J., *Assistant Surgeon*.—Leave of absence extended seven days, November 29, 1887.

Wyman, D. B. M., *Assistant Surgeon*.—Granted leave of absence for fourteen days, December 5, 1887.

The Medical News *will be pleased to receive early intelligence of local event of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local letters containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course it necessarily for publication.

ORIGINAL LECTURES.

ANTISEPTICS: HOW USED AND HOW MADE AT THE NEW YORK HOSPITAL.

A Clinical Lecture.

BY ROBERT F. WEIR, M.D.,
SURGEON TO THE HOSPITAL.

IN beginning my annual course of clinical lectures I wish briefly to place before you in a practical way how antiseptic dressings are made and used in this hospital. I have little or nothing new to present to you concerning the great truths upon which the antiseptic treatment is based. It is known to you all that we are continually surrounded by germs of many varieties. Miquel has found, for instance, that the ordinary atmosphere of a large city contains over 2000 bacteria per cubic yard, while the air of a room of an old house in winter will show bacteria to the amount of 45,000 per cubic yard, and again that the wards of a long-used hospital will hold as many as 90,000 germs in the same space. This same observer has shown, and others have confirmed it, that sea air contains scarcely any of these micro-organisms, and that mountain heights are as nearly free from them for obvious reasons; also that there are more of them to be encountered in our houses and hospitals in winter than in the spring time and in summer.

But all these microörganisms are not infectious, or, speaking more strictly to what chiefly interests us, are not capable of begetting inflammation and suppuration. Only relatively few of them can do this. I will not stop to enumerate even this short list of infectious germs. I shall only dwell upon the two facts, that one of them, the so-called staphylococcus pyogenes, is the factor in producing suppuration in the large majority of instances. Reliable authorities say that they exist in seven-eighths of the cases, and that no formation of pus can be brought about clinically or experimentally save by the aid of such or similar organisms, or by the ptomaines or juices that they create. With these facts at hand you can easily grasp the subject of antisepsis.

There is perhaps one other point that can here be appropriately placed before you; it is that the living tissues of the body have a certain power of resistance to the evil influence of germs, and it requires, according to the Scotch observer Cheyne, an appreciable amount of infectious germs to make an inroad upon the system. This explains why we are not all destroyed whenever a scratch occurs on the finger, etc.

From the foregoing remarks you can readily see that the destruction of infectious germs or the hindering of their natural multiplication is the end of our antiseptic treatment. Lister's dictum, that you should act as if you saw germs lighting on every wound you have to do with, leads to a correct treatment. You should try to kill them as you would a flea, and you have a better chance with the germ than you have with the insect. Cleanliness alone will not do this—wash your hands as you will, your ordinary instruments, or your sponges with soap and with water, and yet in testing all these with the well-known culture tests, colonies of bacteria will be developed, this Kümmel[1] has fully proven. Cleanliness, personal and otherwise, is of great moment, and it will make a vast improvement in your surgery; but unless you conjoin with it large experience and marvellous skill, you will hardly equal the tyro who adds to cleanliness the use of antiseptic measures. Look for a moment at this table, which shows you at a glance the impression antisepsis has made upon the surgical world. Here are the names[2] of the masters of the chirurgical art acquiescing in using the principles just set before you. Their opponents who are worthy of such a rank, if named could be counted on the fingers of one hand.

TABLE I.

No.	Surgeon.	Locality.	Antiseptics.
1	Mitchell Banks,	Liverpool,	Sublimate and carbolic spray.
2	Whitehead,	Manchester,	Carbolic spray.
3	Macewen,	Glasgow,	Strict antisepsis.
4	Ogston,	Aberdeen,	Carbolic acid.
5	Keith,	Edinburgh,	Carbolic acid, except in spray.
6	Annandale,	Edinburgh,	Sublimate dressings.
7	Péan,	Paris,	" "
8	Lücke,	Strassburg,	" "
9	Kœberlé,	Strassburg,	Alcohol flame, carbolic acid, and boiled artificial sponges
10	Czerny,	Heidelberg,	Subhmate.
11	König,	Göttingen,	Sublimate and iodoform.
12	Volkmann,	Halle,	" " "
13	Gussenbauer,	Prague,	Sublimate. "
14	Nussbaum,	Munich,	"
15	Winkel,	Munich,	"
16	Krönlein,	Zurich,	"
17	Kocher,	Berne,	"
18	Billroth,	Vienna,	Sublimate and iodoform.
19	Albert,	Vienna,	" " "
20	Julliard,	Geneva,	Carbolic acid.
21	Terrier,	Paris,	Sublimate and carbolic acid.
22	Championnière,	Paris,	" " " "
23	Bergmann,	Berlin,	Heat, sublimate, and iodoform.
24	Hahn,	Berlin,	Sublimate and iodoform.
25	Esmarch,	Kiel,	" "
26	Schede,	Hamburg,	Sublimate.

A considerable variety of antiseptics are in vogue, and every little while a new one appears which is claimed to possess advantages over its predecessors, but the trials made in the operating-room and in the laboratory show, so far, that carbolic acid and corrosive sublimate

[1] Kümmel: Die Kontakt- und Luft-infection in der praktischen Chirurgie, Centralbl. f. Chirurg., 1885. Beilage 326.

[2] From Senn, Four Months Among the Surgeons of Europe, and other sources.

lead, like Dr. Adhemar's name, all the rest. I have taken pains heretofore to present to you a list of germicides taken from the works of Koch and Sternberg, to show you their relative values, but to-day I can give you, through the kindness of Dr. Weeks[1], of this city, who has kindly placed his advanced proofs at my service, another list, which embraces not only his own bacteriological investigations, but those of other observers. These you will see in Table II.

TABLE II.

From the investigations of Dr. Weeks, of New York.

	Antiseptic.	Strength	Duration of exposure to destroy vitality of germs
1.	Corrosive sublimate,	1 to 500	10 seconds.
	" "	1 to 1000	45 "
	" "	1 to 2000	1½ minutes.
	" "	1 to 5,000	3 "
	" "	1 to 10,000	5 "
	" "	1 to 20,000	12–15 "
2.	Bichloride and mercury [illegible].	1 to 10,000	4 days
	Sublimate [illegible],	1 to 10	4 seconds.
	" "	1 to 25	5 "
	" "	1 to 50	12 "
	" "	1 to 200	1 minutes.
3.	Chloride [illegible],	1 to 25	15 seconds
	" "	1 to 50	1 minute.
	" "	1 to 200	4 minutes.
4.	Arsenic,	Nascent upon dried germs, very powerful when active principle [illegible]	
	"	[illegible]	4 12 seconds.
	"	75 per cent.	2 30 "
	"	50 per cent.	12–15 minutes.
5.	Salicylic acid, [illegible]	[illegible] water	
	4 [illegible] solution]		
	" "	1 to [illegible]	1 minute
	" "	1 to [illegible]	4 "
6.	Permanganate of potash, [illegible]	make a mixture [illegible] in 1½ parts water	
	" "	1 to 10	25 seconds.
	" "	1 to 100	1 minute.
	" "	1 to 200	2 "
7.	Chlorine water, very unstable, [illegible]		
8.	Hydrogen peroxide,	" "	[illegible] "
9.	Iodine and [illegible]	[illegible]	[illegible]
10.	Iodoform [illegible]	[illegible]	[illegible]
11.	Carbolic acid,	1 to 20	2 hours.
12.	Thymol,	[illegible]	[illegible]
13.	Benzoic acid,	[illegible]	[illegible]
14.	Cinnamon oil, [illegible]	[illegible]	[illegible]
15.	Iodoform, [illegible]	[illegible]	[illegible]
16.	Boiling water, [illegible]	[illegible]	[illegible]
17.	Boiling water, [illegible]	[illegible]	[illegible]

Whoever ignores you that has kept abreast with the current literature will not be surprised at two things met with in the list. First, that the fact taught us several years since by Koch, has been confirmed by Dr. Weeks, that oily solutions or mixtures, of the various antiseptics have no value other than is slowly exerted by the fatty matters themselves; and, second, that iodoform, concerning the power of which in germs much has lately been written, exerts its germicide action but slowly. On this point of the value of iodoform in controlling inflammation—ordinary and tuberculous—I may say that the clinical experience of surgeons is in favor of its usefulness, and is decidedly opposed to the laboratory deductions. The discussion of this subject, however, has developed the fact that this substance in dry powder often contains germs, and that it works best when acted upon and changed by wound secretions. Practically, it is nearly always used here in a dampened condition in conjunction with the moist sublimate gauze, and in this combination it is leaned on heavily as a supporter of antisepsis.

To the list of chemical germicides must be added one other which possesses advantages beyond these in safety, cheapness, and accessibility. I refer to the action of heat. A temperature of boiling water will destroy the life of surgical germs, though in some varieties a greater heat is necessary to kill the life of the more resisting spores. Freshly boiled water cooled in covered vessels or by the admixture of water boiled and cooled the same day is coming here more and more into use for the purposes of washing or irrigating wounds, and in Germany the dressings are also sterilized before each operation by heat and used without any medicated impregnation.

If you watch the preparations and the antiseptic technique of this amputation of the forearm, which will be now performed by the House Surgeon, you will gather the main points of the antiseptic treatment of a wound. You will notice first that the instruments, which are either made, handles and all, of one piece of steel, or that the handles are of hard rubber baked on so as to leave no crevices,[1] are, with the needles, scrubbed with green soft soap and water and placed in boiling water for ten minutes, and then into carbolic acid water, 1 part to 20, for at least the same time. The ordinary yellow soap contains germs in abundance according to Eiselberg, but it can be used if previously soaked for half an hour in 1 : 1000 sublimate solution. All the sponges which have been cleansed by Keller's[2] method, or by washing

[1] This article is entitled "The Antiseptic Value of the Topical Remedies used in Ophthalmology, and the Methods of Sterilizing Instruments: Tested Bacteriologically"—and was read before the Section on Ophthalmology and Otology at the Academy of Medicine, October 17, 1887, by Dr. John E. Weeks, and will appear in full in the next number of The Archives of Ophthalmology.

[1] Some excellent ones are now made in Germany by heavily electroplating over wooden handles. This obviates the too great weight of metal handles.

[2] In this method the new sponges, after having been rid of the sand by shaking and beating them, are thoroughly washed in warm—not hot—water, for if hot water is used it deteriorates the quality of the sponge substance, and tends to fix the dirt within its meshes. This is particularly so if the sponges have already been used at an operation. The sponge is then placed in a 1 to 1000 solution of permanganate of potash for twenty four hours. If the permanganate is found to be losing its beautiful pink color, a little more may be added. At the end of this time the permanganate of potash is washed out with warm water. The sponges are now bleached by immersion in a solution composed of one part of sulphite of sodium to one hundred parts of water, to which has been added a one fifth part of a watery solution of hydrochloric or oxalic acid of a strength of 8 parts to 100. They are stirred up with a stick for a few minutes, until they whiten; if left longer they will become friable. Then they are washed out with water again, and left for some time in running water. The sponges

simply with green (or whale oil) soft soap and water, are taken from the jars, where they have been soaking several days in a 1 : 5000 sublimate solution, and squeezed out in a similar fresh solution placed in glass basins.

In the meanwhile the hand and forearm, after the Esmarch bandage has been put on, have been scrubbed diligently with soft soap and a brush, which attention has already been given by the operator to his own hands, and finally, after this has been done the parts are washed off with 1 : 1000 sublimate solution, or with alcohol, and in particular cases with both fluids. The operator then dips his hands in the basin containing a 1 : 1000 sublimate solution, and taking a knife handed him by a similarly prepared assistant, he begins cutting.

Discard for the present the steps peculiar to the amputation, and fasten your attention only on the antiseptic details. During the operation, from time to time, a 1 : 5000 sublimate solution (for stronger ones prove at times poisonous to the system) is allowed to trickle over the cut surface from a douche bottle, or from a sponge, and this is always thoroughly done before the wound is sutured. All the vessels are tied with catgut, prepared either by immersion for 12 to 48 hours in a watery sublimate solution of 1 : 1000, or in oil of juniper for 10 days, according to Cavel, and then kept in 95 per cent. alcohol until used. The drainage is effected by rubber or glass tubing, horsehair, or bundles of catgut, of relative value in the order named. These are also kept ready for use in sublimate solutions of the same strength. Neuber's bone drains have fallen into disuse with us; they not only drain poorly at times, but also render infection of the wound possible from their animal structure.[1] The sutures are likewise of catgut, a little heavier than that used for ligatures, and they are introduced with straight Hagedorn needles, which are supplied with a large eye, and admit, therefore, the ready carrying of catgut, and withal they are very sharp, penetrating the skin most readily. I prefer to employ now, and where I specially want primary union, a wrinkle of Kümmel's, though perhaps it is a refinement. I mean the loosely felted spun glass, which, duly sublimated, is laid on the sutured wound, and over this is put the absorbent dressing.

Observe the word *absorbent*—we are striving for a dressing that will not only prevent decomposition of the discharges, but one, also, that will promote dryness of the wound; for it has been found that germs require for their increase from fifty to seventy per cent. of moisture. The old Lister dressing, shut in with its rubber or Mackintosh covering, was an error in this respect. Now with the capillarity of my spun glass at work, all discharges are carried into my mass of mussed up sublimated gauze, which has been dusted on the surface next the wound with iodoform, and which is covered with a number of such clumps of gauze, and finally with a thick layer of absorbent (not borated, for this has no value) cotton, and the whole secured by a wet sublimated gauze bandage. If the wound is a large one, or one likely to have much secretion, or one where a redressing is to be postponed for a long time, small bags of sublimated peat (which is preferred by me to most of the other absorbents of like nature, such as wood-wool, moss, etc.) are placed next the wound, first duly dusted with iodoform.

A card has just been sent down to me by one of the students, asking why I do not use iodoform gauze over my wounds. I am glad the question has been put. My omission to use this kind of gauze is intentional. I found, several years since, that the iodoform gauze made then and now with some sticky substance impregnated in it, to hold in its meshes the iodoform, is apt to dam up the secretions from the wound and prevent the same from being freely sucked up by my absorbent material beyond; and though some improvement has been made in the gauze (of which that made from the rather expensive ethereal solutions is the best), yet, I now only use this form of gauze in open wounds, or where I wish to pack cavities, or to arrest hemorrhage by pressure, etc.

Now let me tell you how the sublimated gauze is made. The slight aniline color you see that it has, is given to it simply to distinguish it from the unimpregnated kind. You understand you may, at a pinch, use almost any loosely woven cotton or linen material, mosquito-netting or old napkins for instance. The gauze we have is made specially for the hospital, and is, indeed, nothing but cheese-cloth, which you can render absorbent by boiling in water to which a slight amount of soda is added to remove its greasiness, and then drying. You can also buy it in a better form of Am Ende,[1] who has devoted a good deal of time to the careful making of antiseptic preparations. But remember not to purchase the impregnated gauze, for unless it is carefully kept in a damp condition, and properly wrapped up in an impermeable wrapper such as rubber or gutta-percha tissue, or put in an air-tight glass jar, the bichloride will soon become changed into the comparatively inert calomel. In fact, even in quite freshly made but dry gauze, a large quantity of calomel will soon be found, and this and the remaining bichloride can perceptibly be shaken out of it; also, germs find a lodgement in the dry gauze. This will be alluded to in a few moments. By chemical tests I have found that well-preserved damp gauze had not appreciably changed its strength one month after its manufacture.

---

are afterward put into a carbolic acid solution, 1 to 20, or in a solution of 1 to 1000 of the bichloride of mercury, and kept there until used.

Sponges so prepared, such as we use at this hospital, cost but about one cent and a half each: and at that price they may be thrown away after use at an operation. This is my custom in private practice; at the hospital it is the rule that, if the operation is one upon the rectum, the vagina, or other parts where contamination is likely to take place, the sponges used are afterward destroyed; in amputations and other cleanly operations upon the otherwise healthy subject, the sponges are cleansed for subsequent use. In all abdominal operations new sponges are employed. The sponges that are to be again used are washed thoroughly in running water, and afterward kept for some some hours in a weak carbonate of soda solution, to dissolve out the fibrin, etc., and then placed in the antiseptic solution as before.

The simpler plan, advocated by Kümmel, of only washing the sponges with green soft soap and water, and then placing them in a 1 to 20 carbolic solution, or in 1 : 1000 sublimate solution, has been followed by me for too short a time to speak positively as to its merits.

[1] So much does Kocher, of Berne, object to this influence that he has, according to latest reports, discarded catgut, and now uses only silk, freshly boiled.

[1] No. 1300 Broadway, New York.

The formula for making the sublimate gauze is this: One part of sublimate and two parts of common salt are dissolved in five hundred parts of water; the gauze is soaked in this for an hour, wrung out, and partially dried in a clean room. That is to say, it should not be made or handled in a hospital ward or sick room, and it should be kept in a moist condition in glass jars. The chloride of sodium is intended to prevent the conversion of the sublimate into calomel. Chloride of ammonium will also accomplish this. A small quantity of glycerine is of service in like manner, especially when the gauze is likely to be kept some little time. Here, however, gauze is used so rapidly that this precaution is not followed. This gauze has been made of this increased strength by experience which is supported by the recent tests of Schlange, to be presented in a few moments.

For making iodoform gauze I find the following gives the best results, and it can be made very rapidly, as you will see, for the nurse will make some while I describe the process: 3 drachms of powdered iodoform are mixed up with 6 ounces of ordinary Castile soapsuds, using a 1 to 5000 solution instead of ordinary water; this makes a temporary emulsion, which is poured over 3 parts by weight of absorbent gauze, which is equal to $2^1/_2$ yards, and evenly distributed through it by a short rubbing process. This will make a 10 per cent. gauze, and the soap will hold the iodoform satisfactorily in the meshes of the gauze. For a 25 per cent. gauze the iodoform needs to be increased to 7 drachms, the other proportions remaining the same.

When we wish to use iodoform in deep cavities, where frequent redressing is not desirable, as, for instance, after extirpation of the rectum or of the tongue, an iodoform gauze of a more adherent nature is often employed. This is prepared by pouring over 5 yards of absorbent gauze a mixture of

Iodoform	℥iiiss.
Resin	℥iss.
Alcohol	℥iv.
Glycerin	℥v.

I have said nothing so far concerning the spray; you will have already noticed that we do not use it often. It is of value, as Cheyne has proven, but irrigation so satisfactorily destroys the germs, that the spray is only now employed where irrigation is impracticable; as, for instance, in certain operations on the brain, or in the large cavities of the chest and abdomen, and in some of the operations on the joints; in all these I frequently use the spray.

Every conscientious surgeon will admit that his use of antiseptics is not always certain in controlling inflammation and suppuration. Theoretically this should be so. The gross errors we have learned, it is true, to avoid. With a well-trained staff of assistants, a surgeon versed in antiseptic work will have a success which may be claimed as a marvellous one; but even with such a person untoward results are likely to happen at any time. These accidents are not always easy of explanation, but the investigations of our German colleagues have shown us in what direction we should carry our researches in explaining these mishaps, which, were it not for the resistance of the tissues to germ influence, would be even more numerous than they are.

Several years ago I was led to point out the errors of the Lister dressing,[1] which from the volatility of the carbolic acid often became unreliable, and by a faulty method of preparing catgut often did damage. Since then Kümmel, of Hamburg, has also taught us how common infection of a wound is by the contact of sponges and instruments used, and by the hands of the surgeon and his assistants. He has, moreover, showed us how to avoid these errors by the procedures enumerated in a preceding page.

A more recent observer, Schlange,[2] of Berlin, has exposed to us that defects of no mean order are to be met with in our supposed aseptic sublimate dressings. He has proven after examination that all antiseptic bandage materials made by manufacturers contain without exception more or less microörganisms which are capable of liquefying gelatine—*i. e.* producing putrefaction; but that recently prepared moist gauze or gauze that has been rendered sterile by heat or boiling water can be considered free from germs; one might, therefore, consider that our use of the moist sublimate gauze can still be relied upon in spite of its occasionally irritating or blistering the surrounding skin.

The possibility of another error must also be kept in mind. It is that the value of the protection of the sublimate gauze where blood or other secretions are absorbed by it, is much impaired by the conversion of the sublimate into the inert albuminate of mercury. Schlange mixed equal parts of a 1:2000 sublimate solution and blood together and introduced in this mixture different bacterial germs, which rapidly went on to full development unhindered by the sublimate. Similar germs introduced into a solution of sublimate of the same strength without the blood admixture were rapidly destroyed. Moreover, as previously spoken of, the drier the wound can be kept the less will be the chance for germs to develop.

All these facts show us the weak points of the sublimate dressing, and the reasons why a recently boiled water and a dressing recently heated to the same degree of temperature offer ideal materials. It is perhaps a little more troublesome to make a dressing in this way than it would be to resort to the easier handled sublimate solutions and dressings, but a little ingenuity, in the possession of all of us, will obviate these difficulties. I shall certainly attempt to overcome them, and hope before the close of the winter to inform you of the value and of the simplest forms of preparing, and, what is more important, keeping the heated dressings.

A CASE OF SUBDIAPHRAGMATIC ABSCESS.[3]

BY FRANCIS J. SHEPHERD, M.D.,
DEMONSTRATOR OF ANATOMY IN MCGILL UNIVERSITY; SURGEON TO THE MONTREAL GENERAL HOSPITAL.

THE following case came under my observation some months ago, and is of interest because of its comparative rareness.

[1] "The Weak Points in Lister Dressing," etc. THE MEDICAL NEWS, May 5, 1883.

[2] Ueber Sterile Verbandstoffe, 1887, xvi. Congr. der deutsch. Gesellsch. für Chir. Berlin.

[3] Read before the Montreal Medico-Chirurgical Society, December 6, 1887.

John R., aged sixty, carter, was admitted into the medical wards of the Montreal General Hospital under Dr. George Wilkins on April 14, 1887, complaining of a swelling in his right side.

History: More than a year before he had, after exposure, become thoroughly chilled and for a day or two was out of sorts; he then suffered from very acute pain in the epigastric region. He was confined to bed for less than a week, and then went about his work as usual, but never felt quite well. In two weeks the severe pain returned and was felt most in the right hypochondriac region. The pain was increased by inspiration and movement of the body. He also states that for a short time his skin was of a yellow color. He remained in bed a week when the pain left, and he got up and went about, but was unable to work.

In the middle of April, 1886, he had another severe attack of pain in the right hypochondriac region, and this time he remained in bed until the middle of July, 1886. He now first noticed a swelling in his right side immediately below the costal margin. He has never been confined to his bed since July, 1886, but has always suffered from slight pain in the right side—the swelling gradually increased. A couple of weeks ago, the swelling causing discomfort and rapidly increasing in size, he entered the General Hospital. During the whole period of his illness he never had rigors or marked shortness of breath.

The following was the condition of the patient on his admission to the hospital. I am indebted to Dr. Wilkins for allowing me to make use of this note from his case book.

"Well developed man, not emaciated or anæmic, skin cool and moist, no hectic, no jaundice, temp. 98.5°. Respirations and pulse normal. Bowels regular. Appetite good; sleeps well, but always lies on his right side. No history of dysentery or diarrhœa. In the right hypochondriac region is a large, painless, smooth, elastic, fluctuating swelling extending below the costal margin to within half an inch of the umbilicus, and laterally to near the median line; the lower border of the swelling is convex and yields to pressure; right side of the chest, from the third rib downward, is expanded; the intercostal spaces widened and bulging. Percussion note dull in front, and in the axillary line from the third rib downward; posteriorly it is dull from the middle of the scapula. Breath sounds are completely absent over this area. In upper part of right lung breathing is feeble and somewhat tubular in character. Left lung and heart normal. Urine healthy. It is not possible to make out area of liver dulness, or to feel the lower border of that organ."

On the 18th of April, Dr. Wilkins aspirated the fluctuating swelling in its most convex portion below the ribs, and drew off twenty-five ounces of creamy, sweet-smelling pus. This was examined microscopically, but no hooklets of echinococci were found; the fluid consisted of pus, blood, and some necrotic tissue. After the aspiration the patient felt much more comfortable, could sleep on his right side, and had no pain or nausea. He was transferred to the surgical ward and placed under my care.

On the 23d of April, having placed the patient under ether, I made a vertical incision in a line with the nipple, some four inches long, commencing immediately below the costal margin on the right side. This incision was over the most prominent part of the tumor. The parts were carefully incised, and when the wall of the abscess was reached it was found to be adherent to the abdominal parietes and to consist of a thick mass of inflammatory tissue. When the abscess cavity was opened there was a great gush of pus, and afterward each inspiration caused the contained fluid to flow out more freely. To facilitate the exit of the pus a large rubber tube was introduced so as to act as a siphon—in this way some eighty ounces of pus were drawn off.

The patient's condition now became alarming, his breathing became shallow, pulse hardly perceptible, and extremities cold. So the further evacuation of the pus was discontinued (although, apparently, as much remained behind as had been taken away) and restoratives applied. On exploring the cavity, the diaphragm could be felt above, reaching as high as the third intercostal space in front, and a probe introduced through the wound could be felt behind, between the fourth and fifth ribs; below, a thick mass of inflammatory tissue separated the abscess from the cavity of the abdomen. The liver could not be felt or seen, and there was no liver substance in connection with the abscess. Owing to the collapsed condition of the patient, the wound was rapidly sutured, a large drain introduced, a thick sublimated jute dressing applied, and the patient put to bed.

Under the influence of heat and stimulants he soon rallied. During the next three days there was a large discharge of pus and the dressings had to be changed twice daily. The temperature never rose above 99° F., the patient rapidly improved, and the abscess cavity, in a remarkably short time, was reduced to a very small size.

By the first of June the discharge of pus had almost ceased, the abdominal organs had resumed their normal position and the area of liver dulness was normal in extent. The breath sounds over right lung still continued feeble. The patient rapidly regained flesh and strength, and when discharged in August there was a narrow sinus, some four inches deep, which discharged a thin sero-pus. For the last three months patient has been at work and says he feels perfectly well. The sinus has, however, not yet completely closed. Breath sounds can be heard over the whole of the right lung, but at the lower part both in front and behind still rather feeble.

Remarks.—When first seen this was thought to be a case of either liver abscess or echinococcus disease. The absence of constitutional symptoms, the slow growth of the tumor, its smoothness, elasticity, and painlessness pointed to echinococcus disease, whilst the history of a chill, frequent attacks of severe pain, the jaundice in early stages, made one think it possible that it might be a case of liver abscess. The absence of a history of rigors and sweatings was a remarkable feature of the case.

The man, although a fairly intelligent Irishman, was not very observant, and did not give a very

connected history of his case, so that the facts were difficult to get at, and when obtained did not contain the whole truth. However, the aspiration showed the case to be one of abscess, and microscopic examination failed to disclose any evidence of echinococcus.

From the fact that when the tumor was opened no trace of the liver could be found, I have not the least doubt in my mind that the case was one of abscess which had originated between the diaphragm and the liver, and that the latter organ had been pushed downward and backward by the gradual collection of such a large amount of fluid.

I had intended making a counter-opening posteriorly to facilitate drainage, but the collapsed condition of the patient after the evacuation of so large an amount of pus warned me to complete the operation as soon as possible, and to get him back to bed. The result was quite as satisfactory as it would have been had a posterior opening been made. When abscesses are above the diaphragm a dependent opening is much more important than when they are below that structure. In the latter case the pressure of the abdominal walls on the contents of the abdomen always tends to obliterate any cavity that may exist. In this case it was remarkable how soon such an enormous cavity disappeared.

THE GERMICIDE POWER OF SULPHUR DIOXIDE.

BY HERMAN M. BIGGS, M.D.,

DEMONSTRATOR OF ANATOMY, BELLEVUE HOSPITAL MEDICAL COLLEGE; ASSISTANT IN THE ARNEILIE LABORATORY OF PATHOLOGY; PHYSICIAN TO THE NEW YORK CITY HEALTH BOARD.

At the suggestion of Dr. W. M. Smith, Health Officer of the Port of New York, the writer undertook a number of experiments during the summer of 1885 to determine the disinfecting power of anhydrous sulphurous acid as used by the so-called "vacuum process." For various reasons the experiments were not reported at that time, but as the gas was then used for disinfection under quite new conditions, it has seemed advisable now to report the results as then obtained.

The vacuum process consists in principle in the exhaustion of the air from an air-tight receiver, in which the goods or materials to be disinfected have been placed, and in the subsequent introduction of the gas (as derived from liquid sulphurous acid) in pure form and under pressure. In the employment of the gas in this manner, as compared with its use in any previous experiments, two new factors come into action. The first consists in the formation of a vacuum and the consequent withdrawal of the air from the minutest pores of the materials to be disinfected, thus insuring penetration of the gas to every particle of the material; and the second, in its use in a volume of 100 per cent., and at any required pressure, varying from twenty to one hundred pounds to the square inch. The importance of these new features will be readily perceived when we consider the methods that have been previously employed in such experiments.

In the usual methods of disinfection with the gas, as well as in the various experiments which have been made from time to time to determine its disinfection power with the single exception of some experiments made by Dr. Sternberg, in which the gas was used in as high as 20 per cent. volume), the gas has been generated by burning a certain amount of sulphur to each cubic foot of space. In many instances this has been done in rooms which could not be tightly closed, and where the escape of the gas was necessarily very large.

Under these conditions the free sulphur combines in the process of combustion with two parts of oxygen from the air to form SO_2. It should be remembered, however, that combustion ceases from lack of oxygen when the oxygen of the air has been somewhat reduced, so that under the best conditions only four or five per cent. in volume of the gas is available. But probably not so much as this is ordinarily available, because SO_2 is much heavier than atmospheric air, the diffusion is not very rapid, and in the upper portions of the rooms in which the experiments have been conducted (as has been shown experimentally) the strata of air contain still less than in the lower. The diffusion of the gases would rectify this, however, if the exposure continued for a longer period of time. Then further, it was apparently shown in Sternberg's experiments that under these conditions the penetrating power of the gas was quite slight, even when the exposure continued for many hours; for instance, when the gas was effectual in destroying the life of certain microorganisms exposed to its full action, it was ineffectual under exactly the same conditions, if the rags previously soaked in culture fluids were slightly protected from its direct action, as when placed, for example, in the pocket of a coat hanging in the room.

The conditions in the above experiments are essentially different from those obtaining in the present investigations. In these a vacuum is first produced, thus absolutely insuring penetration of the gas and its full action upon every part of the materials to be disinfected, and then the gas in 100 per cent. in volume is introduced under high pressure.

Considering the results previously obtained in biological experiments with SO_2, at first thought it would seem probable that even better results might have been predicted under these conditions than were obtained.

In all the tests about to be described, the gas as used was derived from the liquid anhydrous sulphurous acid. The experiments were primarily undertaken to determine the practicability and efficiency of the "vacuum process" for the disinfection of rags in bale, and they will be divided into two classes, viz.:

1st. Those made in the Carnegie Laboratory in which infected rags were exposed to the gas in much less than 100 volume per cent. and without pressure.

2d. Those made at the Polhemus Chemical Company's Works, in which rags similarly treated were introduced into the centre of a tightly packed bale of rags and the bale then subjected to the process, as described in detail below.

The action upon different microorganisms was tested by exposing to the gas rags which, after

sterilization, had been soaked in cultures of the various germs. After exposure, culture tubes were inoculated with these rags. Control cultures were also made in each case by inoculating similar tubes from the same rags after infection, and previous to exposure to the gas. Some of the tests were made from the infected rags which had been exposed in a moist condition to the gas, and others after they had been dried at a low temperature. Tubes of sterilized beef peptone gelatine were, for the most part, used for the inoculations.

The cultures were made in two ways: the so-called "rag cultures" by simply introducing after exposure a small piece of the previously infected rags into a tube of prepared gelatine; and the "puncture cultures" by first soaking these rags in sterilized distilled water, and then inoculating gelatine tubes with a minute drop of this water by means of a platinum wire.

In the following experiments the mere presence of bacterial growth in cultures made after exposure is not to be considered of so much importance, unless this growth proved to be due to the development of the microörganisms that were exposed to the action of the gas; for in the methods used it was impossible absolutely to exclude all foreign microörganisms, and the cultures made after exposure were used rather as provisional tests in which the proof of the destruction of the organism exposed was complete, if no growth of any kind occurred.

The result was the more satisfactory if this was accomplished when impure cultures were used. But, on the other hand, if developments of any kind did occur, plate cultures were made and all germs present were isolated, and thus it was determined whether the cultured germs or the impurities were the source of the bacterial growth. The cultures after exposure were made in the open air of the laboratory, by transferring the rags to the culture tubes. In cases where moist rags were exposed, it was found necessary to neutralize with carbonate of soda the acidity produced by the SO_2 in solution on the moist rags, or the culture fluids were rendered acid by this and were thus made unfit for use as culture media. Owing to this fact, and because fluids are rendered antiseptic by the solution of the gas in them in small quantity, the method used in these experiments seemed to be the most practicable one, although it is open to objections in some respects.

The first series of experiments, namely, those made in the Carnegie Laboratory, were designed to determine the efficiency of the gas as a disinfectant when used in a large volume per cent.

The second series—*i. e.*, those made with the bales of rags—must show both the penetrating power of the gas and its disinfecting value when present in a pure atmosphere under pressure.

In the first series of experiments the rags were exposed to the gas in a three gallon glass jar which could be rendered air-tight. The rags were suspended in this jar, and then the liquid SO_2 was either thrown directly into it from a siphon, or was drawn into a graduate which was then placed in the jar. It was always the design to use as large an amount of the SO_2 as possible. The amount varied in the different experiments, from half a fluid-ounce to two and a quarter fluid-ounces. In some instances the liquid SO_2 had not entirely volatilized at the end of the exposure.

In the experiments first made, no especial care was taken to charge the rags with pure cultures of microörganisms before exposure to SO_2, or to prevent the access of spore-bearing or other foreign germs. It was deemed a better proof of the disinfecting power of SO_2 to destroy the cholera spirillum, for instance, when in impure cultures with other germs present, than to destroy this germ when alone, and it was thought possible that it might destroy all forms of organisms. It was due to such impurities, probably, that colonies of spore-forming bacteria developed in some of the tubes inoculated with the rags that had been exposed to the gas.

No reference will be made to the control cultures in reporting the results of the following experiments, inasmuch as development occurred in all of nearly one hundred control cultures, with the exception of three or four wire cultures, in which non-development was probably due to the acid reaction of the gelatine.

First series of experiments made at the Carnegie Laboratory in the manner just described:

Experiment I.—Cultures of the comma-bacillus of Finkler and Prior were used. Moist rags exposed. Puncture cultures made in the manner described above. The time of exposure to the gas was twenty minutes.

Result: No development occurred in any of the cultures.

Experiment II.—Cultures of the comma-bacillus of Finkler and Prior were used. Moist rags exposed. Plate cultures were made from the water infected as above. Time of exposure twenty-five minutes.

Result: No development occurred in the plates.

Experiment III.—An impure culture of the cholera spirillum was used. Two rag cultures and two puncture cultures were made. Time of exposure was about twelve minutes. Moist rags exposed.

Result: No development of any kind in either of the puncture cultures, or in one of the rag cultures, but in the second rag culture a growth appeared which proved to be a thick spore-forming bacillus. This bacillus was used in one of the subsequent experiments, series No. 2. There was no development of the cholera spirillum in this culture.

Experiment IV.—Cultures of cholera spirillum and the comma-bacillus of Finkler and Prior were used. Moist rags exposed. Two rag cultures were made from each of the germs exposed. Time of exposure about thirty minutes.

Result: No development occurred in any of the tubes.

Experiment V.—Cultures of cholera spirillum and of a micrococcus obtained in pure culture from an erysipelatous bleb (which, for convenience, will be called streptococcus erysipelatus in the following experiments, when it is used). Time of exposure twenty-five minutes. Three rag cultures were made of each of the germs.

Result: No development in any of the tubes of either germ.

Experiment VI.—Cultures of the comma-bacillus of Finkler and Prior, and impure cultures of streptococcus erysipelatus were used. Rag cultures made. Time of exposure twenty-five minutes. Moist rags exposed.

Result: No development in any of the tubes of either germ.

Experiment VII.—Old plate cultures of a bacterium found in green pus were exposed. These plates contained many colonies of large size of this germ and also numerous colonies of air germs. Wire cultures were made, whole colonies of the germs being introduced into the culture media. Length of exposure about thirty minutes.

Result: No development in any of the cultures.

Experiment VIII.—Threads were dipped into cultures of streptococcus erysipelatus and then dried. Cultures were made upon agar-agar and in gelatine from these threads after they had been exposed. Length of the exposure about forty-five minutes.

Result: No development in any of the cultures.

Experiment IX.—Rags soaked in decomposing infusion of hay five days old, which contained many spores. Rags then exposed to the gas for forty-five minutes, and at the same time half a glass of the infusion was placed in the vessel used for the exposure.

Result: Puncture cultures made from the infusion, before exposure, showed bacterial growth after twenty-four hours; those made from the same infusion, after exposure, did not show any development until the third or fourth day. Cultures made from the rags that had been exposed did not show any development on the eighth day. This non-development in the rag cultures was apparently due to the acidifying of the gelatine by the rags introduced, as will be seen later. These cultures were not neutralized. Decomposition in the infusion exposed was arrested, although the development occurring in the cultures made from this showed that the spores were not destroyed, and the arrest of the decomposition was probably due to the presence of sulphurous acid in solution in the infusion.

In other experiments which were made with decomposing infusion of hay, development appeared in the cultures made from rags after exposure in dried condition for eighteen hours, and in moist condition for three hours, although when the cultures were not neutralized after the exposure of the rags in moist condition no development occurred.

Experiment X.—Cultures of mycoderma rosa that had been dried for more than three months on slices of potato were exposed to the action of the gas for forty-five minutes. Cultures were made after exposure on agar agar and on potato.

Result: Development occurred in all the cultures on the second day, showing that these germs were not destroyed by the gas.

Experiment XI.—Cultures of staphylococcus pyogenes aureus on agar-agar were exposed for forty-five minutes, and then other tubes were inoculated from these cultures.

Result: No development occurred.

The method of exposure of the rags in the second series of experiments was as follows: the infected rags, either moist or after being previously dried, were introduced at the laboratory into sterilized glass tubes which were open at both ends. These tubes were then plugged with sterilized cotton and the ends covered outside by filter paper. In this condition they were taken to the Pollock Chemical Company's Works, where the experiments were made. The following method was employed to show the penetrating power of the gas. A sharp-pointed hollow drill, with a tight screw-cap on one end, and perforated by a dozen or more small holes, just at its middle, was driven into the centre of a bale of rags. Then the glass tubes containing the infected rags were introduced into its lumen, and the cap was set in white lead to insure its being air-tight. Now the only manner for the gas to enter the interior of the tube was for it to pass to the centre of the bale and enter by the perforations in the tube situated there. Aside from the *a priori* reasoning which would indicate that the gas must penetrate every pore of the material after the production of a vacuum, it seemed certain that if the gas reached the centre of the bale, entered the interior of the drill, and then passed through the cotton plugs to the infected rags in the tubes, that it must reach every part of the bale. After the drill had been thus introduced, filled with tubes and closed, the bale of rags was placed in an air-tight cylinder, a vacuum of 28 or 30 inches was produced and the gas was then introduced in pure form under pressure. The amount of vacuum, the pressure, and the duration of the exposure are noted in each of the experiments, and all were conducted in the same manner. After the exposure, the tubes containing the rags were returned to the laboratory without removal of the cotton plugs, and cultures were made from them, as described above.

Second series of experiments made at the Pollock Chemical Company's Works:

Experiment I.—Vacuum, 29 inches; pressure of gas, 35 pounds; exposure, 25 minutes. No spore-forming germs used. Cholera bacillus, streptococcus erysipelatus, and two tubes containing vaccine points exposed. Cultures neutralized after exposure. A number of inoculations were made from each of the kinds of germs exposed. Two tubes inoculated with the vaccine points exposed.

Result: No development occurred in any of the cultures. (The vaccine points were exposed with intention of using later for vaccination, and the culture tubes were inoculated with them simply as an experiment. A micrococcus in pure culture, however, did develop from quills not exposed and nothing developed after exposure.)

Experiment II.—Pollock Chemical Co. Works. Vacuum, 29 inches; pressure, 20 pounds; exposure, 20 minutes. After this pressure was reached, impure cultures, cholera spirillum, bacillus subtilis (spores) and spore-forming bacillus found in Exp. III., first series, were exposed. Puncture cultures and rag cultures were made of each. One-half the cultures were neutralized by a solution of carbonate of soda after the introduction of the rags.

Result: Bacillus subtilis. Development occurred in all the tubes on second or third day. Cholera spirillum. No development occurred in either of the

two puncture cultures. In three out of six rag cultures, development took place on the second or third day, but even on the ninth no liquefaction of the gelatine had taken place, showing absolutely that the growth was not due to the cholera spirillum, as this liquefies gelatine by its growth.

Microscopical examination, moreover, showed that the growth in all three of the tubes was due to a large rod bacillus.

Spore-forming bacillus (third germ exposed). No growth appeared in the puncture cultures, but development occurred on second or third day in all the rag cultures which had been neutralized. In those remaining acid no development took place.

Experiment III.—The first public experiment was made on August 26, 1885, in the presence of Dr. J. S. Billings, of the U. S. Army; Dr. W. M. Smith, Health Officer of the Port of New York; Dr. Janeway, and Prof. Chandler; Dr. Taylor, of the New York Board of Health; Dr. Raymond, Health Commissioner of Brooklyn; two representatives of the Boston Board of Health, and numerous others. The bale of rags used was a large one, but had been used in previous experiments, and was not very tightly packed. Seven tubes were employed which contained rags infected with the following germs: two prepared from cultures of the cholera spirillum, rags moist in both; one containing rags soaked in a decomposing infusion of hay, and then dried; two prepared from cultures of streptococcus erysipelatus, in one of which the rags were dry and in one moist; two from cultures of the staphylococcus pyogenes aureus, in one of which the rags were dry, and in the other moist, and one from bacillus subtilis without spores, rags dry. The vacuum obtained was twenty-nine inches, pressure of gas twenty-five pounds, and the time of exposure thirty minutes. A number of control cultures were made from each of the germs employed, with the exception of bacillus subtilis, and in each case abundant development after twenty-four to seventy-two hours followed.

Cultures made from rags exposed to SO_2 and results:

Four tubes were inoculated with rags containing the cholera spirillum and one puncture culture on agar-agar and one in gelatine were also made from these rags. Two cultures from dried rags containing staphylococcus pyogenes aureus and two from moist rags, and one puncture culture on agar-agar, and one in gelatine were made. The same cultures were made as of the previous germs from rags containing the streptococcus of erysipelas. Two cultures were also made from dried rags containing bacillus subtilis (no spores), thus making in all twenty cultures prepared from rags exposed.

No growth appeared in any of the tubes, with the exception of two tubes of the staphylococcus pyogenes aureus, in each of which after the lapse of six or seven days, half a dozen or more small colonies appeared which were transferred to other culture media, and which proved to be identical (so far as could be determined) with the germs exposed.

This is the first failure to destroy a micrococcus or bacillus (not forming spores) which has occurred in the numerous experiments.

The same germ under the same conditions was used in several experiments following, and no development occurred. In this experiment the development that appeared was very late; the colonies were few in number and of small size.

As the bale of rags used in this experiment was not very tightly packed, and there might be some question raised as to the sufficiency of the proof of the penetration of the gas, several more experiments were made in which bales especially prepared for the purpose were employed.

Experiment IV.—On September 25th, an experiment was made at the Pollock Chemical Co. Works, in which a bale of Chinese rags was used. This was very tightly packed but was of small size. Drs. W. M. Smith, Health Officer, and G. M. Sternberg, of the U. S. Army; Dr. Taylor, of the New York Health Board, and others were present. Cultures of the cholera spirillum on moist rags, the streptococcus of erysipelas on both moist and dry rags, staphylococcus pyogenes aureus on both moist and dry rags, and vaccine points were exposed. The vaccine points were furnished by Dr. Taylor, of the New York Health Board, and were returned to him after the exposure, to be tested by vaccination. The rags were prepared in the same manner as in the previous experiments, and cultures were made after the method previously described.

Conditions of the experiment: Vacuum 29 inches; pressure, 28 pounds; time of exposure (after the above pressure was obtained), 30 minutes.

The usual controls were made and development occurred in all on the second or third day. Inoculations were made from rags after exposure as follows: Four tubes from cholera spirillum by puncture, two tubes from streptococcus erysipelatus on dried rags, and the same from moist rags, and the same inoculations were made from the moist and dry rags containing the staphylococcus pyogenes aureus.

Result: No development occurred in any of the tubes. Dr. Taylor reported that no results were obtained from the vaccinations made with the vaccine points exposed in this and previous experiments. Successful vaccinations were obtained in each case from similar points that had not been exposed.

In order to show that the non-development in the rag cultures was not due to the presence of SO_2 introduced with the rags (as was suggested), when after the lapse of fourteen days, and no development had taken place in two rag cultures of erysipelas, and two of staphylococcus pyogenes aureus, they were inoculated from the corresponding control cultures. Marked growth was apparent after forty-eight hours. This was also done in two cases with cholera tubes in previous experiments, with the same results.

A number of other experiments were made at the Pollock Chemical Co. Works, and at the Carnegie Laboratory in the same manner, and the same general results were obtained.

As will be seen by reviewing the results obtained in the previously detailed experiments, the sulphur

dioxide has never failed to destroy the organisms exposed in these investigations, with the exception of spores of different forms of bacilli, of mycoderma rosa (when dried for months on potato), and on one occasion apparently the staphylococcus pyogenes aureus. There seems to be no question that it will not ordinarily destroy spores. The reason why it did not destroy mycoderma rosa, is probably because the gas could not penetrate the very dry hard potato. There seems to be no satisfactory explanation for the appearance of the staphylococcus pyogenes aureus on one occasion, excepting that the organism was not killed by the exposure. Under the same conditions in many other experiments, it was destroyed.

It will be noticed that the cholera spirillum was used as one of the organisms exposed in most of the experiments, and that the rags were more often in a moist than in a dry condition. There seemed to be an immediate danger, at the time the experiments were made, of the introduction of cholera by rags, and it was deemed of the greatest importance to determine the action of the gas on this organism. An interesting point came up in this connection. The cholera spirillum is destroyed by drying or by acids, so that if the rags are thoroughly dry, there is little danger certainly from the usual forms of the cholera spirillum, and if moist they are rendered acid, so that this would prevent the development if it did not destroy the germs.

In reviewing the results obtained in these experiments, the following conclusions seem to be justified.

1. Sulphurous acid gas in 100 volume per cent. under pressure, with an exposure of thirty minutes will ordinarily destroy most forms of microörganisms, either in dry or moist condition, with the exception of the spores of bacilli.

2. It will not destroy the permanent spores under any conditions, but retards their growth.

3. When used by the vacuum process, access to every part of the material to be disinfected is insured.

I wish to acknowledge my indebtedness to Dr. Frank Grauer, of the Carnegie Laboratory, for valuable assistance rendered in the conduct of these experiments.

A CASE OF COMPOUND, COMMINUTED, DEPRESSED FRACTURE OF THE SKULL;

EXTENSIVE LACERATION OF THE PERICRANIUM; WITH REPRODUCTION OF BONE.

BY JAMES STRATTON CARPENTER, A.M., M.D., OF POTTSVILLE, PENNSYLVANIA.

THE studies of Dr. William Macewen, of Glasgow, on "the osteogenic factors in the development and repair of bone," to which THE MEDICAL NEWS has recently called attention, are such as will readily excite clinical observation on the part of every one desirous of ascertaining, as far as may be possible, the truth or falsity of the results there attained.

And it is to be deemed worthy of congratulation, that the application of such crucial tests to this new theory, as clinical observations afford, are comparatively easy, and within the reach of the every-day practitioner—not restricted to the limits of the physiological laboratory.

It is, then, in this spirit, that I venture to present the history of the following case of a compound, comminuted, depressed fracture of the skull, desirous only of furnishing a single instance where there is satisfactory evidence of the reproduction of bone, independent of any periosteal contribution to that end.

CASE.—Charley F., aged eleven years, while in a fight with another boy, was struck on the head with the pointed edge of a half-brick thrown at him while his head was pressed to the ground, and permitting no rebound from the blow. Hemorrhage was very free, but there was only momentary loss of consciousness, and a half hour later the boy was brought to my office by his mother, having walked nearly three-quarters of a mile from his home. Examination showed an ugly, gaping wound over the right parietal eminence, into which the finger could be readily passed, detecting a depressed fracture at the seat of injury, there being a cone-shaped depression, the open, or convex surface being internal.

The next day, the patient under chloroform, assisted by Dr. John T. Carpenter, I dissected up the flap over the wound; the probe could be passed nearly one-half an inch below the external surface of the skull before it was arrested at the apex of the cone formed by the four depressed portions of bone, and as it was impossible to release the fragments, trephining was determined upon.

When the teeth of the trephine had nearly penetrated the vitreous table, the upper edge of one of the fragments was loosened by it, and I was enabled, with slight effort, to draw it free from the remaining ones; and, this vantage gained, all the fragments were detached without completing the trephining through the sound portion of bone.

The finger could now be passed through the perforation made by the missile, and the dura mater readily felt, as well as the pulsating of the cerebral vessels, so that there was nothing left behind as an irritating point, nor was there any doubt as to the entire removal of the bone at the seat of fracture.

The case pursued a very satisfactory course after the operation, temperature being normal, and the only suspicious symptoms, which prevailed for the first thirty-six hours, were overcome by free use of the mild chloride, bromide of potassium, and slight doses of morphia as required. The only dressing employed after suturing the flap was a cloth kept constantly wet with alcohol and water, and union occurred by "first intention" over the entire wound excepting at the seat of one suture which suppurated slightly, but gave no trouble.

REMARKS.—It was found, after removing the depressed fragments, that quite an extensive laceration of the pericranium had been effected by the blow, and that not enough was obtained to cover over the external table for an extent of nearly a square inch of surface, including the opening left by the depressed fragments. Then, too, the trephine had itself produced a circular fracture of the skull, and, as the diploë had been cut through, it was feared that the severing of the blood supply from this

area might greatly increase the danger of necrosis, which, in accordance with the long-taught theory, might well be feared from such a loss of the pericranium, as before stated.

No such result, however, occurred, and at the last meeting of the Schuylkill County Medical Society, I presented the subject of this paper, that the members might see indubitable evidence of genuine bone production effected under such unfavorable conditions, and as contrary to all the previously entertained ideas on this subject. It was six months from the date of the boy's injury, and there was no doubt, on examination by the different members present, of the reproduction of bone in this case, the seat of fracture being firm, and in no wise different from other parts of the cranial surface, except as shown by the clean line of cicatricial tissue marking the flap that had been dissected at the time of the operation.

In order to give greater weight to the evidence here brought forward in favor of the general proposition regarding the osteogenic function of the periosteum in the development of bone, viz., "that the periosteum does not generate bone," let me state in conclusion, that at the time of the operation I had no knowledge of the recent publication of Dr. Macewen on the subject of bone reproduction; and that it was only after reading the editorial mention of the results arrived at by him in his investigations on this subject, that this case offered itself to my mind as affording unbiassed testimony in support of the new theory so recently proclaimed by him.

PHONATORY PNEUMATIC DISTENTION OR HERNIA OF THE LARYNGEAL SAC.

A CLINICAL NOTE.

By J. SOLIS COHEN, M.D.,
OF PHILADELPHIA.

A case of stenosis of the larynx following evulsion of morbid growths after splitting the larynx externally came under my care a little more than a year ago. The stenosis was due to cicatricial adhesions, and to recurrences of growth about different portions of the glottis, chiefly in the posterior and interarytenoidal portion. By intralaryngeal procedures, including incision, evulsion, chemical and electric cauterization, and careful forcible distention, the most of it at the hands of my colleague, Professor A. W. Watson, of the Polyclinic, continued for a year or thereabouts, the stenosis has been wholly overcome. During a considerable portion of this period phonation took place by use of the ventricular bands only, and good phonation it was, too.

Within a few months the following unique phenomenon has been observed: In phonation the vocal bands become approximated naturally, but, if the phonatory effect be continued, the two ventricular bands are forced together in close apposition, and in further continuance of the phonatory effect the sac of Hilton on the left side suddenly bulges forward with an audible jerk into the interior of the larynx as if shot out from an air gun, presenting much such a picture as though the horn of the hyoid bone had just undergone dislocation; and in another second the right sac is thrust forward in a similar manner, but to a less extent. The sac in the left side looks like a small globular tumor the size of a small cherry, of much paler aspect than the remainder of the larynx by reason of distention of the mucous membrane.

HOSPITAL NOTES.

TREATMENT OF TYPHOID FEVER IN THE HOSPITALS OF NEW YORK, BOSTON, AND MONTREAL.

NEW YORK HOSPITAL.[1]

During the early part of this summer the routine treatment of typhoid fever in Dr. Peabody's wards, if the patient entered during the first ten days of the disease, was a calomel purge immediately followed by naphthaline in doses of ten grains every three hours. The first seven cases died (two having entered the hospital moribund), one of septic infection, one of acute mania, and the three others simply from the intensity of the poisoning, the lesion being very extensive.

Since August 14th we have had but one death in twenty-one cases—two of these are still sick, but doing well—of this number, thirteen have had absolutely no treatment *directed to the intestines*, eight have had naphthaline, and among these the one death occurred.

When the temperature rises high enough to make the daily average about 103°, antifebrin is given, either in large doses at long intervals, or in continuous doses of two grains every two hours during the day, and three grains every three hours during the night. Some patients have had two grains every hour during the day. In no case was any bad result noticed; on the contrary, the patients were quieter, slept better, and temperature, pulse, and general condition were much improved.

Whiskey is given when pulse, tongue, and condition indicate the need of stimulation, the amount varying from three to eight ounces during the twenty-four hours. Fluid extract of digitalis is added occasionally in small doses.

When there is insomnia, it is almost always relieved by morphine, generally given hypodermatically, as so many of the patients have a greater or less tendency to vomiting. In a few cases the bromides, or urethan have been tried, but not with such good results as morphine. In cases of delirium with great restlessness, hyoscin hydrobromate, given hypodermatically in doses of one-hundredth of a grain, has been tried with very good effect. It has been followed by several hours of quiet sleep.

Diet is of milk, patients taking generally from four to five pints daily. If the stomach is at all irritable, milk with lime-water, or peptonized milk is given. Some patients take beef tea well, and have from one to two pints of this daily in addition to the milk.

In a few cases nourishment by the rectum has been tried for short times, with the effect of relieving an irritable stomach. Laxative enemata are given every other day if patients have no movements from the bowels; and in almost all of our cases this has been necessary,

[1] Reported by Dr. George A. Richards, House Physician.

as patients have been generally constipated, diarrhœa being the exception rather than the rule, during the summer just passed.

Counting three cases not already entered in this report, as they were not here during Dr. Peabody's service, there have been thirty-one cases treated here since last April with eight deaths, a mortality per cent. of almost 26. This very high rate is to be explained partly by the fact that several patients entered late in the disease, and in very bad condition.

St. Luke's Hospital.

In Dr. Francis Kinnicutt's wards the treatment is essentially general and symptomatic. During the past several years, when it has been possible to establish the date of the beginning of the disease, occasionally one or more moderately large doses of calomel have been given in the first days of the fever, but never with the result of *aborting* the disease. So many factors are involved, that it is difficult to give a trustworthy opinion in regard to the alleged power of calomel given at the inception of the disease, *at least* to influence favorably its subsequent *course*. Naphthaline given in frequently repeated doses, to the amount of sixty grains daily, has also failed in any abortive effect.

Rest, quiet, fresh air, and a very carefully regulated diet of mixed liquid food constitute the general treatment. Increased fever and intestinal irritation frequently have been observed to follow the ingestion of large quantities of raw milk, and in such cases a reduced amount of peptonized milk has been given.

The symptomatic treatment may be summarized as follows: Urethan is considered by far the safest and most efficient hypnotic. Its not sufficiently well recognized antipyretic properties increase its value. It is given in doses of thirty to forty grains, repeated in an hour or two, if necessary, to relieve insomnia. Believing that excessive diarrhœa has its source often in the presence of undigested food in and catarrhal inflammation of the bowel in addition to the specific lesion, the stools are carefully examined in such cases. The presence of curds demands a more careful regulation of the diet. A combination of naphthaline and bismuth has been found efficient in controlling the catarrhal inflammation and in correcting fetor.

Recognizing the fact that paralysis of the bowel and thereby ultimate constipation may proceed from a *deep* ulceration, laxatives are not given after the first week or ten days. Small enemata every other day are used to relieve constipation. Since the discovery of the new group of antipyretics, they have been employed, almost to exclusion of baths in any form, to control what is believed to constitute harmful autumnous pyrexia.

The general rule adopted is to give antipyretics only when the temperature reaches 103°. Kairin, hydrobromate, thallin, antipyrin, and antifebrin have been successively used and their effects very carefully observed. As the result, antifebrin is at present almost exclusively employed. Very exceptionally have any of these failed to relieve.

In combating heart failure, alcohol is chiefly relied upon. Where heart weakness proceeds from degeneration of muscle fibre, a minimum effect may be expected from any method of treatment; if failure is owing more to impaired nerve force or influence, which is more often the case, the use of alcohol gives the happiest results. Alcohol is rarely given in the early stages of the disease, very commonly in the third and fourth week. Many cases are treated throughout, without its employment. Its use is restricted to combat *special* symptoms. Sir William Jenner's rule is largely the guide in its administration. "When in doubt in an individual case of typhoid fever, abstain from giving it; where there is a question of the larger or smaller dose, prescribe the latter."

Dr. Beverley Robinson's general treatment of typhoid fever is expectant; he does not believe that there is any known specific for this fever and is very doubtful as to the power of any drug, in use at the present time, to abort this disease. His treatment naturally depends upon the stage of the malady at the time it comes under his care, and whether it has a tolerably mild course without complications, or whether the disease from the beginning is marked by more than ordinary severity and is accompanied by manifest departures from what is usual, and the complications indicate special severity of the attack, or march of the affection.

The cases of typhoid fever which he has treated during several years past, have been, as a rule, of moderate severity. Diarrhœa has not been very frequent, temperature rarely going beyond 104° at any time, and then only during brief periods, heart complications have been occasional, pneumonia rare, and nervous symptoms showing either ataxia, or great adynamia, in relatively few instances; he recalls not more than three or four cases of intestinal hemorrhage.

In the incipient stage of typhoid fever a mild saline cathartic preceded by one or two grains of calomel, or double that quantity of blue mass, is prescribed. Later, and so long as the development of typhoid fever appears doubtful, small doses of aconite, ammonia, and spirit of Mindererus, or neutral mixture, are the means he employs to subdue febrile excitement. If fever still continues, with marked elevation of temperature in the afternoon, after a few days, and other symptoms point more surely toward the typhoid state, these agents are abandoned for tonic doses of quinine, milk diet, which is insisted upon, and occasional tepid sponging of the trunk and limbs with lukewarm water and vinegar. Complications are treated as they arise, bronchitis, or pneumonia with tincture of iodine, turpentine stupes, or Corson's paint, to the chest walls; chloride of ammonium, moderate doses of digitalis, and moderate stimulation with whiskey internally. If the heart becomes irregular or notably weak and frequent, or a blowing murmur shows itself at the apex, he now orders tincture of strophanthus in five-drop doses every six hours, besides using mustard poultices or dry cups to the chest, and beginning, continuing, or increasing the alcoholic stimulant. Nervous derangements are influenced favorably by ether in the form of perles, by musk, or by a mixture of lavender, chloroform, ammonia, and camphor. Hemorrhage is controlled with turpentine and opium. High temperature is controlled by antifebrin in five grain doses, repeated two, or more times, in the twenty-four hours, or whenever the body temperature goes beyond 103 Fah. in the axilla.

The diet is usually limited to milk during the duration of the fever. This is given to the patient every two

hours, as much as he will drink; nausea, or disgust for food, being to some extent relieved by the addition to the milk of lime water, Vichy, or Vals water, or by the alcoholic stimulant administered at the time. If nausea persists and the patient becomes very weak and prostrate, dry champagne is given frequently in small doses. Occasionally, *black coffee* has worked wonders in bringing back to life patients who appeared almost moribund. Solid food, as a rule, is not allowed until all febrile reaction has been absent at least one to two weeks. When begun, he is now using with favorable results what is known as albumenoid food, which seems to be tolerated by the stomach and bowels more readily than beef peptonoids, or other preparations of a somewhat similar character. At a later period, if the albumenoid food and the beef peptonoids have been well supported, and, especially, if no recurrence of the fever take place, farinaceous food is permitted and a small quantity of the light meats once a day.

In very few patients has he found the necessity at any time to treat their febrile condition by means of *systematic cold bathing*, and he regards this treatment as ill-adapted to the large majority of typhoid fever cases met with in New York City, either in hospital, or private practice. Whenever hypostasis of the lungs involves these organs in a considerable degree, he believes frequent inhalations of oxygen gas to be a measure of great practical utility in giving to patients some additional chances of preserving life otherwise imminently imperilled.

The Massachusetts General Hospital.

The plan of treatment of typhoid fever carried out in Dr. Frederick C. Shattuck's wards has again become chiefly a symptomatic one. This summer he tried in six or eight cases the administration of naphthaline, eighty grains a day in divided doses, ten grains of calomel being given immediately on admission to the ward. It has been claimed by some that early cases may sometimes be aborted in this way. One patient thus treated, presenting the important early symptoms, recovered in three or four days; and so did another who received no medicine whatever.

Among the points in connection with typhoid fever in regard to which we are still very ignorant is the question of fact. Does the disease ever abort spontaneously, or in consequence of treatment? Dr. Shattuck gave up the naphthaline treatment because he could not see that in cases in which it received a thorough trial it was productive of any good result, while in two cases it caused strangury, in one other hæmaturia.

This year he has also discontinued the systematic use of internal antipyretics, ordering them only when the temperature is very high and the patient very restless, or, in his judgment, suffering in some other way directly from the effects of the temperature. These indications are seldom present.

Diet. Six ounces of milk are given every two hours. If this is not well borne lime water is added, or the milk is peptonized; or, if there is no diarrhœa, animal broths are allowed. When the evening temperature reaches the normal point, patients who have been on an exclusive milk diet are given broths, then raw eggs, then light farinaceous articles, and meat is permitted toward or at the end of the first week of convalescence. Stimulants are given in such quantities as the pulse, the tongue, and the nervous symptoms may seem to demand.

In cases characterized by constipation, a large percentage the past two years, a plain water enema is given every second day. For sleeplessness and diarrhœa opium is the main reliance. In intestinal hemorrhage opium is given in sufficient quantity to narcotize the patient, stimulants are used according to the pulse, and ergotine is injected under the skin. To moderate the temperature, stimulate the nervous centres, and promote the comfort of the patient he is sponged with water at a temperature of 60°–75°, every two hours if the temperature is 103° or more; every three, four, or six hours according to circumstances if it be below that figure. Sometimes alcohol, or alcohol and water, is substituted for the plain water baths once or twice a day.

It will be seen by the above that the aim in treatment is simply to conduct the patient to recovery, safely and as speedily as is compatible with safety. A certain percentage of patients receive neither drugs nor stimulants, a certain proportion stimulants only, and a certain proportion both drugs and stimulants.

Dr. R. H. Fitz during the past summer made a few attempts in his ward to test the asserted value of naphthaline in checking or overcoming the progress of typhoid fever. The remedy was used in three grain doses, every two hours during the first week of the fever. There was no evidence that any benefit resulted.

Although given in capsules, nauseating eructations were, at times, complained of, and the size of the capsule was inconvenient. The disadvantages being conspicuous, without any evident corresponding gain, the use of the naphthaline was soon discontinued.

Of the newly discovered antipyretic drugs, antifebrin was the one usually employed when there were special indications for their use. The artificial maintenance of a low range of temperature throughout the course of the disease was not deemed important. If an elevation of 105° F. was reached, a sufficient quantity of antifebrin was given to lower the temperature four or five degrees. The production of chilly sensations was considered undesirable. A single dose of five grains often sufficed. If necessary, this dose was repeated at intervals of an hour until fifteen grains were taken. Doses of three grains were found of great benefit in relieving the headache so frequently occurring in typhoid fever. There was no necessarily simultaneous falling of the temperature.

The routine treatment of all cases consisted in a carefully regulated diet and the use of cold sponge-baths every two hours. The diet was chiefly milk, as nearly four ounces every two hours as possible. If the milk was not well borne, it was pancreatized or mixed with lime-water. The use of the exclusively milk diet was maintained until the temperature remained normal for at least a week. Beef tea, strained soups, and broth were then added, and, in the course of three or four days, soft puddings, eggs, and bread.

In the third week of normal temperature there was no restriction as to diet, with the exception that the most nourishing and easiest digested foods were ordered.

Wine or brandy was given after the first week whenever a weak pulse or excessive nervous debility was present.

Dover's powder or morphine, urethan, and chloral

were used as hypnotics, the former, where sleeplessness was accompanied with pain, the latter, where pain was absent.

Constipation was a frequent symptom, and was invariably relieved by enemata as often as once in three days. In one case, irrigation of the colon, twice daily, became necessary. During convalescence a change of diet was often an efficient means of insuring a normal evacuation.

Profuse diarrhœa was controlled by liquid preparations of opium, and intestinal hemorrhage was checked by ten minims of laudanum every two hours.

The Montreal General Hospital.

The cases of typhoid fever treated in Dr. George Ross's ward include a larger proportion of severe and very severe than perhaps elsewhere—the reason being that, owing to the great prevalence of the disease in Montreal at certain seasons, and to the limited accommodation, it is a necessity to refuse a considerable number and receive only those most urgently requiring care. If we come, therefore, to look at the mortality, this important fact must be borne in mind. Here, any method of treatment which will give results approaching the average in other places, must deserve confidence, seeing that we deal with carefully selected bad cases.

The treatment is based upon what might be called an "intelligent expectancy." The diet is composed exclusively of milk and rice water. The amount of milk consumed daily is not considered immaterial. It is not deemed prudent to allow, as is often elsewhere done, milk *ad libitum*. On the contrary, the daily quantity is strictly limited, in the case of adults, to three pints *per diem*. This amount is found sufficient to meet the wants of the economy, whilst the ingestion of more leads to the danger of accumulation of feces and aggravation of symptoms. The milk is frequently diluted with rice water, or, if thought well, with lime water. When the stomach is weak, benefit is obtained by artificial digestion of the milk, but the great majority drink pure milk and appear to assimilate it without difficulty. It is a rule to nurses to supply cold fresh water or ice water to typhoid patients freely, and, during the height of the fever, pellets of ice to suck. When a patient is delirious or unable to make known his wants, he is still to have cold water given him frequently and freely. It is believed that strict attention to this apparently simple item is really a matter of considerable importance. It is a fixed rule to allow no change from a milk diet until the patient's temperature has been normal both night and morning for at least eight consecutive days. During the early stages, and until a material fall in the temperature has taken place, cold sponging of the entire body is carried out every three or four hours, as the case may require: and constant cold is applied to the head by means of a coil through which ice water flows. These measures are relaxed as the temperature falls and the symptoms improve.

In mild cases, or even in those of moderate severity but running a course approaching to the type, alcoholic stimulants are not given, except in small quantities during the later stages; but in all those showing a higher grade of fever, as marked by an elevated temperature and signs of vital depression, whiskey and brandy are employed in amounts varying with the special indications of the case. When the prostration is marked, and the nervous symptoms severe, stimulants are given freely.

As regards medicines, a favorite prescription is one containing gtt. ij each of acid. carbolic. pur. and tinct. iodin., well diluted in water every two hours. It is a rare occurrence to meet with discolored urine from this remedy. No striking results follow its administration. In the later stages, quinine in tonic doses, with or without digitalis, is given. When a case is seen sufficiently early, a full purgative dose of calomel is found to be useful in unloading the *prime vie* and preparing for the siege. We find a large proportion of our patients constipated rather than suffering from diarrhœa. The bowels are never allowed to remain quiescent for more than three days at most. More generally two days only are allowed between evacuations, which, if necessary, are obtained by means of enemata. These are greatly preferred to laxative medicines. In approaching convalescence, great caution is exercised in administering a purgative, since rapid elevation would seem sometimes to follow directly after even a dose of castor oil. The presence of prominent symptoms often leads to the medicinal treatment being, for the time, entirely directed toward counteracting them. For instance, if there be marked gastric irritability, bismuth, bicarbonate of soda, and such like drugs, with effervescents, are given. If the case be especially marked by bronchitis and pulmonary congestion, turpentine in emulsion is relied upon. If tympanites be considerable charcoal is found very useful, sometimes turpentine, together with limitation of the food for a time, and attention to the bowels. If muscular tremor, delirium, and insomnia are a marked feature, such remedies as camphor, valerian, and ammonia are given at frequent intervals. Of the complications, hemorrhage is treated by ice, gallic acid, digitalis, or lead and opium, and the external application of an ice-bag. In peritonitis (without perforation) opium is given in moderate doses, and without any bad effects. When perforation is known to have occurred, hypodermatic injection of morphia and hot applications.

The use of quinine in antipyretic doses, during the active stages of fever, has been entirely abandoned. In some of those unaccountable "excursions" of the temperature which we are apt to witness during commencing convalescence, full doses of quinine are used with very good effect. Of other antipyretics, antifebrin has had a moderate trial in this disease, by some members of the staff. The conclusion arrived at seems to be that the sudden depressions of temperature produced by the drug do not in any way modify the course of the fever, which only subsides at the same time as if this had not been employed. In some cases, decided antipyretic action could not be obtained from it. In others, its ill effects, cyanosis and cardiac depression, were witnessed, but not to an alarming degree.

MEDICAL PROGRESS.

The Bacillus of Cancer.—At the meeting of the Medical Society of Berlin, on November 27th, Dr. Scheuerlen, assistant in the Medical Hospital of Professor Leyden, spoke on the etiology of cancer. He had made experiments with about forty specimens of

cancer of the breast; from every specimen he inoculated twenty culture tubes. Of these 800 inoculations, 400 had been fruitful. He obtained the cancer juice aseptically, and cultivated from it a micr°örganism, which proved to be a spore-forming bacillus. Cultivations were made upon exudation taken by puncture from a case of pleurisy with effusion, put in the sterilizer for five days; and coagulated on the sixth day; cultivations made upon blood-serum, agar-agar, peptone, gelatine, or potato were equally successful. The growth was very luxuriant, taking place in the following manner: The bacilli were first found in the growth; then in from twelve to twenty-four hours spores made their appearance, and covered the entire surface. In microscopical preparations of the cancer-juice itself the same spores were found often in much smaller number than the bacillus, whilst it has never yet been seen in sections. The microbe forms upon the surface of the culture materials a thin film, which is either transparent or of a yellowish-brown. The bacillus can be stained by all the methods in use (very easily by Gram's method); the spores are stained with difficulty, and only by Professor Ehrlich's process for staining the tubercle-bacillus. Both the bacillus and its spores have spontaneous movements. The spores are to be found mostly outside the cells, rarely single, generally in clusters, as though the cells were sprinkled with them. Experiments were made on six female dogs; the cultivations were injected into the mammary gland, but no conclusive results have been obtained. A soft swelling, not distinctly circumscribed, formed at first, and then diminished; it became compact and circumscribed, showing under the microscope a decidedly epithelial character, much related to cancroid. This bacillus Scheurlen believes to be certainly the cause of cancer.

In the discussion which followed, Professor A. Fränkel, one of the first bacteriologists of Germany, objected to the method by which these experiments had been conducted, saying that secondary infections might easily have taken place, such as frequently occur. Neither did the quick growth of the bacillus answer to the slow growth of cancer, as hitherto found in all clinical experience.

At the next meeting another experimenter, Dr. Schill, of Dresden, who has during the last five years been seeking for a microbe of cancer and sarcoma, will explain his results. It seems that he has discovered a bacillus resembling that described by Dr. Scheuerlen.—*British Medical Journal*, Dec. 3, 1887.

Extirpation of the Larynx.—Hahn, at a meeting of the Berlin Medical Society, on November 16, 1887, reported fifteen partial or total extirpations of the larynx. Of these patients two were living; one was operated on seven years before, and was living in good health, aged sixty-nine years. In this case the extirpation was very extensive; the specimen was typical carcinoma. The second case was operated on one and a half years previously, and was partial. It is uncertain whether there is a return in this case, or simply scar tissue which is present. Most of these patients were aged between thirty-five and sixty-nine years. Of all these only two recovered; a third is living, but has a return of the cancer. Hahn believes that carcinoma which shows a tendency to horny or warty growth has a more favorable prognosis than other carcinomata. He thinks that most operations are undertaken too late, and that in carcinomata with a malignant tendency operation is not indicated.—*Deutsche medicinische Wochenschrift*, November 24, 1887.

Antipyrin in Sea-sickness. — The Paris correspondent to the *Lancet* of November 12, 1887, writes as follows:

The Société de Biologie has devoted part of its last two sittings to the discussion of the different means recommended for the relief of sea-sickness. A note was presented by M. Hantz on the best way of administering cocaine, and received without any expression of opinion. M. Dupuy said that sea-sickness was more severely experienced by dyspeptic subjects, and particularly those who had dilatation of the stomach. In eleven cases he had given antipyrin in doses of from 30 to 45 grains for a few days before embarking, and the patients had all informed him that they had been free from sickness. M. Dastre said he had instituted a series of experiments upon animals, imitating as closely as possible the movements of "pitching" and "rolling." He had found that there was an incredible displacement of the abdominal viscera, which strike against the diaphragm and cause the gastric uneasiness. The body struggles with these displacements by means of muscular contractions, and the respiratory rhythm accommodates itself to them. Professor Brown-Séquard remarked that this theory of visceral displacement was very old, and one which he had been able to verify in his frequent passages across the Atlantic. It was evidently the view entertained by Wollaston, who recommended Arago to place a pad over his stomach when he crossed the Channel. M. Maurel had no doubt as to the influence of the stomach, but thought that cerebral shock also played a part in the determination of the symptoms, inasmuch as the sickness always occurs when the boat is going down, never when it is being lifted up. The best preventive was lying on the back. Beyond the statement that sea-sickness is associated with dilatation of the stomach, and the hope held out by M. Dupuy that in antipyrin we now possesss a remedy for it, there was nothing new in the views expressed by the different speakers. I have referred, however, at some length to the subject, because my own seafaring experience has been somewhat extensive, extending over intervals during the last fifteen years, and including some kind of trial of every new drug recommended. Until a month ago the plan I always recommended was to take bromide for some days before going on board, and, if discomfort was felt notwithstanding, the dorsal decubitus was to be adopted. This, together with champagne, is generally what the Transatlantic captains advise. In a recent trip to New York I tried two other remedies. The surgeon of the ship recommended me tincture of capsicum, and I had also taken a supply of antipyrin. As far as one case goes, the result of the antipyrin was most satisfactory, and I can to this extent endorse the experience of M. Dupuy. The capsicum was also serviceable as a palliative, for several persons who had taken it continued to ask for it, but it did not arrest the sickness like antipyrin. A fellow passenger who suffered from dilatation of the stomach with *elapotement* was not sick at all.

THE ANTISEPTIC TREATMENT OF DIPHTHERIA.—We add to the formulæ published in THE MEDICAL NEWS of December 3, 1887, the following, which are quoted from various authors by LE GENDRE, in the *Archives de Laryngologie*, No. 1, 1887:

Carbolic acid by inhalation, may be given by the use of a teaspoonful of the following mixture, added to sufficient water:

R.—Acid. carbolic.	ʒ 70.
Acid. salicylic.	ʒ 14.
Acid. benzoic.	ʒ 28.
Alcohol	ʒ 117.

The strength of the spray should be proportioned to the severity of the disease, the age of the patient, and the size of the room.

The following may be taken internally:

R.—Succi citronis	ʒ ss.
Sodii chlorid.	
Sodii sulphat.	aa ʒ 2½.
Mel.	ʒ 3¾.
Syrupi calcis	♏ 30 to 60.
Sodii carbolat.	gtt. 20 to 30.

A teaspoonful or dessertspoonful may be taken every two hours.

For local application:

R.—Aquæ calcis	ʒ 30 to 75.
Liquor. ferri chlorid.	♏ 30 to 120.
Acid. carbolic.	gr. 1/10 to 15.
Mel. rosat.	ʒ ss to ½.

Also,

R.—Sodii borat.	
Potass. chlorat.	aa gr. 75.
Acid. carbolic.	gr. 4.
Glycerin.	ʒ 2½.
Mel.	ʒ 7½.

The pharynx, and especially the tonsils, may be touched three times daily with:

R.—Tinct. krameriæ	ʒ 2½.
Tinct. benzoin	♏ 75.
Tinct. aloes	♏ 45.

After which insufflation of the following powder should be made:

R.—Tannin	gr. 25.
Sulphur. sublimat.	
Potass. chlorat.	aa gr. 30.

To irrigate the fauces of a child suffering from diphtheria it should be wrapped in a shawl or blanket, its arms by its sides to prevent struggling. It should be held upon the knees and against the breast of one person, whose hands are folded over the child's trunk in front. A napkin may be placed under the chin, and the lips closed, when the child will open its mouth. The fluid should be impelled with sufficient force to excite reflex contraction of the pharynx, when there will be little interference from the passage of fluid into the trachea and coughing.

THE CONVERSION OF BENIGN GROWTHS OF THE LARYNX INTO MALIGNANT.—At the recent Congress of German Naturalists and Physicians PROF. SCHNITZLER read a paper upon the subject of the malignant degeneration of benign growths in the larynx. He first described a case of epithelial carcinoma with secondary growths in the lymphatic glands and pleura, in a patient who some months previously had been operated on for papillomata, the recurrence of which had been treated by cauterization. The patient subsequently came under Professor Schnitzler's care with symptoms of perichondritis, but the carcinomatous nature of the disease was recognized, and the supervention of pleurisy some weeks later was considered to be due to a diffusion of the malignant disease. This diagnosis was confirmed after death, when, besides the laryngeal and pleural carcinoma, there were found necrosis of the thyroid cartilage and gangrene of the right lung. Professor Schnitzler remarked upon the rarity with which benign tumors take on malignant characters, he having seen such conversion only three times among hundreds of cases of laryngeal papillomata. He left undetermined the question whether the operations and frequent cauterizations induced the malignant disease, and said that endo-laryngeal operations upon papillomata should be discountenanced on this ground. He also spoke of the difficulty in the differential diagnosis between benign and malignant growths, as well as between laryngeal syphilis and carcinoma. Dr. Morelli related the case of a man whose larynx was so blocked by papillomatous growths as to necessitate tracheotomy prior to a thyrotomy, with complete ablation of the new growth and galvano-cauterization of the laryngeal wound. The patient left apparently cured, but wearing the tube. After the lapse of a year he returned with evident carcinomatous degeneration of the papilloma, which filled the larynx to the level of the tube, which was partially displaced and blocked by it. This was the only case of the kind that Dr. Morelli could recall within a period of nearly ten years. Dr. Seifert referred to a case published by Böhmer, where papillomata (histologically examined) had been treated by Professor Gerhardt and himself for a year, but which passed into carcinoma, for which extirpation of the larynx was practised; but the patient did not long survive the operation.—*Lancet*, November 26, 1887.

SHOULD LEPERS BE ISOLATED?—The *British Medical Journal* of November 12, 1887, in an editorial upon this subject, concludes as follows: When we consider how long the period of incubation may be, who can be sure that ten, or even twenty years hence traces of that patient may not be found in the development of a case of leprosy amongst some of the people with whom she came in contact? We are decidedly of opinion that a few more cases of leprosy are seen in London than formerly was the case, but this we attribute to the fact that travelling is more general, more usual, and less expensive, and that patients of all kinds come to London for advice in increasing numbers.

Without sounding a note of alarm, or considering that there is any occasion at present for compulsory measures in England, we are yet unable to consider the presence of lepers in England as being absolutely free from danger, and believe that the time will come when cases of leprosy in this country will share the attention

of the sanitary authorities with other diseases universally admitted to be contagious.

Strophanthus.—Hochhaus, in the clinic of Fürbringer, has made an extended investigation on the value of strophanthus, and concludes as follows:

In sixty cases he found that in valvular lesions, with compensation, tincture of strophanthus lessens, invigorates, and regulates cardiac action, relieving dyspnœa and œdema. Digitalis is generally effective in cases benefited by strophanthus, but there are cases not benefited by digitalis, which improve with strophanthus. In comparison between the action of digitalis and strophanthus, digitalis affects the heart more promptly; strophanthus relieves dyspnœa, caused by cardiac disease, more rapidly and effectively than does digitalis. The indications for the use of strophanthus are within more narrow limits than those of digitalis; we have not yet determined clearly these conditions. In degeneration of the heart-muscle, with small, frequent irregular pulse and marked dyspnœa, strophanthus is very effective in relieving dyspnœa, and improved cardiac action follows.

In acute and chronic nephritis, the tincture is less effectual than in other cases; dyspnœa is frequently relieved without the production of diuresis, or lessening the œdema.

Œdema, from cachexia, is sometimes relieved by the remedy. Disturbances of digestion are often produced, which generally subside if the drug be continued.

Regarding dosage, from three to six drops of the tincture should be given in a teaspoonful of water or wine, and when needed, syrup or licorice may be added, in the beginning of treatment, and the amount increased two drops with each dose daily until distinct effects are evident, when the dose last given should be continued; it is not advisable to go higher than from three to twenty drops. From three to five drops is sufficient for a child.

The effect generally appears in two or three days, and endures for one or two weeks, although great variations on this point are observed. A cumulative action was not observed. Strophanthus is not of great and peculiar value, but has a useful action in aiding and supplementing digitalis.—*Deutsche medicinische Wochenschrift*, October 27, 1887.

Ingluvin.—Mohr has found the following a convenient formula for administering ingluvin:

R.—Ingluvin	ʒ i.
Acid. hydrochlor.	ʒ i.
Aquæ	ʒ 7½.

of which two or three teaspoonfuls or dessertspoonfuls may be taken daily.—*Revue Générale de Clinique et de Thérapeutique*, November 24, 1887.

The Decomposition of Salol in the Animal Body.—Nencki, in the *Therapeutische Monatshefte* for November, 1887, reports the results obtained from a series of experiments with the various digestive ferments in their power to decompose salol. He found that the digestive ferments present in the pancreas, liver, and intestine, had equal effects in producing the decomposition. In the stomach the acidity of the gastric juice was a hindrance. What is remarkable, however, is the fact that muscle substance possessed, when the alkaline carbonate was added, a decomposing power equal to that of liver, pancreas, or intestine. Nencki infers that the glycerides of the common fatty acids are broken up in the various organs of the human body; he thinks that the cell elements possess this power. In support of this opinion he adduces experiments made with albuminoids outside the body, in which the effect was much less than that produced by living tissues.

From its quality of being easily decomposed by living tissue in the presence of an alkali, Nencki considers it likely to prove of value as an external antiseptic, by reason of the two efficient antiseptics which compose it.

Ligature and Excision of the Sac in Hernia.—Dr. Poland, in the *Practitioner* for November, 1887, sums up the advantages of ligation and excision as:

Immediate—

(1) In many cases it does not add in any way to the risk of operation.

(2) It shuts off the peritoneal cavity in a few hours.

(3) It prevents hemorrhage into abdomen.

(4) It prevents septic peritonitis.

More remote—

(5) It promotes tendency to radical cure.

(6) It leads to more perfect adjustment of truss and comfort of patient.

Sozoiodol.—Lassar describes, in the *Therapeutische Monatshefte* for November, 1887, this recently prepared substance, which has the formula

$$C_6H_2ISO_3H(OH).$$

It contains 42 per cent. of iodine, in combination with sulphur and carbolic acid. It is easily soluble in water and alcohol, and is not decomposed by substances used commonly as vehicles.

Lassar has used it in 5 and 10 per cent. ointments, in combination with lanoline, starch, oxide of zinc, and chalk, as an alterative and antiseptic.

Nothnagel on Cardiac Medication.—In a recent lecture on this subject, Nothnagel stated that he still preferred digitalis to more recently advised remedies, and did not prescribe convallamarin unless digitalis had proved useless.

Adonis vernalis he prescribes in the tincture, in quantities of 60 minims during the first day of treatment. On the second day the quantity may be increased to 75 or 90 minims, but more than 105 minims in twenty-four hours should not be given. Sparteine has been used in doses of $\frac{1}{30}$ of a grain, as the symptoms demand, for cases where the cardiac rhythm is greatly disordered.

Nothnagel considers caffeine much preferable. He gives it in broken doses of 3 grains, as many as five doses, at intervals indicated by the symptoms, and increases the amount used to 30 or 45 grains daily; with the French, he prefers the benzoate of caffeine. In anasarca he alternates caffeine and digitalis. To produce diuresis, Nothnagel uses calomel and opium, from 8 to 10 grains. The inconveniences of this treatment are the possibility of the calomel decomposing into the bichloride in the intestines, and mercurial poisoning. If no diuresis is produced in three or four days, its use

should be abandoned. The calomel treatment may be intermitted with advantage at any time.

Oertel's method of treatment by open air exercise, in moderate altitudes, he considers inadmissible in all cases of degenerated heart muscle.—*Revue Générale de Clinique et de Thérapeutique*, November 10, 1887.

THE TREATMENT OF PSORIASIS.—BESNIER uses

R.—Naphthol (*ß*)	1 part.
Adipis	9 parts.

The affected part is to be well rubbed with this salve before retiring, and flannel worn during the night; in the morning a bath of hot soapsuds should be taken.

If no improvement follows after five days of this treatment pyrogallic acid is used, 5 or 10 to 100. To avoid irritation friction is employed on small surfaces only, and these surfaces are changed every four days.

For extensive surfaces BESNIER employs a dressing of

R.—Acid. pyrogallic.	
Acid. salicylic.	āā gr. 90.
Ether and alcohol, q. s. to liquefy.	
Add collodion flex.	ʒ 20.

—*Revue Générale de Clinique et de Thérapeutique*, November 24, 1887.

NAPHTHOL AS AN ANTISEPTIC.—The antiseptic properties of naphthol have been known for a long time, but owing to the supposed toxicity of this substance, its employment has been till now limited to the local treatment of certain affections of the skin. At a recent meeting of the Academy of Sciences, PROFESSOR BOUCHARD stated that, after two years of research, he has been able to determine and measure the antiseptic power of naphthol as well as its toxic power, and he has been led to conclude that, in certain circumstances, it is to be preferred to all the antiseptics known, owing to its very feeble solubility. To disinfect a surface easily accessible, the soluble antiseptics suffice, and the same should be employed to effect general antisepsis, but none has as yet been found that can be introduced into the blood in sufficient quantity to destroy the vitality of the microbes without compromising the health or life of the patient. To produce antisepsis in the thickness of the tissues, or in that of cavities reached with difficulty, where continued drainage cannot be practised, the insoluble antiseptics, or those only partially soluble, can alone be employed with advantage. They should be preferred for the interstitial treatment of certain maladies of the tissues, for the antisepsis of serous cavities, and particularly for the antisepsis of the digestive tube, which the author has had especially in view in his researches. The explanation on which the advantage of an insoluble antiseptic is founded is that from the fact of its insolubility it is unabsorbable; it will therefore be found present throughout the length of the digestive tube, and can be administered in sufficient quantity to render all fermentation impossible, without having to fear its general action on the economy, into which its insolubility would prevent its penetrating. It was for these reasons that Professor Bouchard preferred the salicylate of bismuth and iodoform, and Rossbach also, when he employed naphthol for intestinal antisepsis. After having tested the antiseptic property of naphthol in certain microbian maladies, Dr. Bouchard found that in a solution of 5 grains to one quart of diluted alcohol, the naphthol very much retarded the development of the bacillus of typhoid fever, as well as the germination of the bacillus of tuberculosis. Urine, shaken up with naphthol in powder, then filtered and exposed to the air, does not ferment. According to Bouchard, the dose of naphthol which may be considered toxic for a man weighing 140 pounds is about 8 ounces. 40 grains of naphthol per day suffice to procure intestinal antisepsis; the author therefore concludes that the toxic power of this substance has been very much exaggerated, though there can be no doubt that a solution introduced into the organism directly through the veins would prove far more dangerous.—*Lancet*, November 19, 1887.

TREATMENT OF DIABETES, WITH THREATENED COMA.—STADELMANN has employed, with good results:

Acid. citric.	ʒ 2.
Sodii carbonat.	ʒ 4½.
Glycerin.	ʒ 5.
Aquæ destillat.	ʒ 37½.
Spirit. menth. piper.	gtt. 3.

To be taken two or three times during twenty-four hours.

By this combination the acids produced in the disease are neutralized, and the dangers of acetonæmia lessened.

Saccharin may be used advantageously in the following combinations:

Sodii acet.	ʒ 2½.
Aquæ carbonat.	ʒ 22½.
Saccharini	gr. 1½.
Essent. citri	♏ 40.

Which may be taken three or four times daily. Also

Sodii tartrat.	ʒ 7½
Aquæ carbonat.	ʒ 50 to 75.
Saccharini	gr. 5.
Essent. citr.	♏ 75.

To be taken several times daily, as occasion demands. —*Therapeutische Monatshefte*, November, 1887.

ANTISEPSIS OF THE BLADDER AND URETHRA.—At a recent meeting of the French Academy of Medicine, LAVAUX read an account of his method of treatment of the bladder and urethra, with the following conclusions: Continued lavage of the anterior portion of the urethra and intravesical injections without a sound are the most simple and harmless method of genito-urinary antisepsis which can be employed in all diseases of the urethra. The use of antiseptics and hot injections by this method greatly lessens the danger of accidents in rapid dilatation of the urethra. Rapid dilatation, for simple strictures, is greatly to be preferred, with these precautions, to slow dilatation. Intravesical injections, made without the use of a sound, are quite sufficient to maintain the calibre of the dilated urethra. By these methods the indications for urethrotomy are much less frequent. Divulsion of obstinate strictures is rendered much less dangerous by the method.—*L'Union Médicale*, November 3, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

COMMUNICATIONS are invited from all parts of the world. Original articles contributed exclusively to THE MEDICAL NEWS will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

SUBSCRIPTION PRICE, INCLUDING POSTAGE,

PER ANNUM, IN ADVANCE, ... $5.00.
SINGLE COPIES, ... 10 CENTS.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 SANSOM STREET,
PHILADELPHIA.

SATURDAY, DECEMBER 17, 1887.

LEPROSY IN ITS RELATION TO THE STATE.

ALTHOUGH leprosy has long since ceased to be endemic in Europe, and has never existed to any extent in this country, it has in the popular mind the most dreadful associations, and the very rumor of the existence of a case in the neighborhood is sufficient to throw the community into a terror. Unfortunately, the ideas which prevail are derived from the sacred writings, which contain a larger number of references to leprosy than to any other disease, and in which it figures so often as the most condign punishment, or as the type of sin, that we can scarcely wonder at this widespread dread. Admirable in many respects as are the Levitical instructions regarding leprosy, we nowhere else in ancient writings obtain such clear notions of the ignorance which existed of the true nature, or even the modes of recognizing disease. Thus it is probable that all skin affections, from itch to eczema, were regarded as leprosy, which was also thought to attack clothing and houses!

A very practical question has arisen in Philadelphia, which brings into prominence the relation of the State to this disease. A woman and her daughter came here from Brazil some months ago, and have been under the care of Dr. Van Harlingen, who recognized the nature of the disease, but humanely refrained from telling the patients. A few weeks ago he read a paper at the County Medical Society, in which these cases were described, and one patient was shown to the members. The affair, of course, became public; the daily papers took up the matter, and the Board of Health requested Dr. Van Harlingen to give the address of the lepers, and added the disease to the list of contagious affections of which, under a penalty, notice must be given to the authorities. This Dr. Van Harlingen refused to do, and an unsuccessful attempt was made to send the mother and daughter back to Brazil. Ultimately Dr. Van Harlingen gave up the patients, and the Board fined him $100 for failure to comply with the By-law. The lepers are now in strict confinement in the Municipal Hospital, and have been made aware of the nature of their terrible disease. A number of prominent physicians, feeling that Dr. Van Harlingen has been rather hardly treated, have subscribed to pay the fine, and in their letter have reflected upon the action of the Board.

From time to time we hear of lepers reaching this country, either from Norway, the West Indies, or from China, and it becomes a very important question how to deal with such cases. Up to a few years ago, opinion was very strongly against the contagious nature of the disease, but since Hansen's discovery of the lepra bacillus, facts have been accumulating to show that the virus is a fixed contagion, communicable by inoculation, like syphilis and glanders. Yet, so recently as 1881, after reviewing the literature of the world, Hirsch wrote in his *Geographical Pathology*, that "the communicability of leprosy has not been proved hitherto by a single unambiguous fact." It is impossible, however, to deny the contagious nature in view of the facts brought out by Graham, of Toronto, in his investigation into the Tracade lepers of New Brunswick, and by Besnier, of Paris, in a recent article.

In countries where the disease is prevalent, measures for isolation are gaining in favor, and in the Sandwich Islands segregation is said to have notably diminished the number of cases. The gradual disappearance of the disease in Europe was due in great part to the strict measures of isolation, and some idea of its prevalence may be obtained from the fact that more than 130 lazarettos and asylums are known to have existed in England and Scotland during the middle ages.

Having a fixed virus, and transmitted by inoculation only, the risks of contagion from isolated cases in a community are not great; indeed, so far as we know, in not a single instance has the disease been communicated to a native American by the cases which have come to this country from Norway, Brazil, or China. Patients are admitted to the hospitals without any greater fear than pertains to syphilis. While sympathizing then with Dr. Van Harlingen in his endeavor to keep from his patients the knowledge that they were lepers, we must acknowledge that the Board was right in theory in declaring the disease to be contagious, but in isolating the patients in the Municipal Hospital they have taken a very extreme view of the dangers likely to follow from the presence of one or two lepers in our midst.

CREOLIN, A NEW ANTISEPTIC.

This new antiseptic is obtained from coal tar by certain secret processes, and has lately been tried, quite thoroughly, in a purely experimental line, in Germany, by Esmarch, whose results are recorded in the *Centralblatt für Bakteriologie und Parasitenkunde*, Bd. ii., 10 and 11, and by Kortum in a more practical manner in the *Berâner klinische Wochenschrift* of November 14, 1887. Both Esmarch and Kortum report such favorable results from its use that no doubt, long ere this, many German surgeons are putting it to a practical test.

Esmarch in his experiments, made with different forms of microörganisms, found that a 1 to 5 per cent. solution of creolin acted promptly in destroying all their power, even when the spores were dry, in from ten minutes to four days according to the variety of microbe and method of exposure, and the strength of the solution of creolin. Kortum found that in several obstinate cases with stinking pus with ulcers as large as an adult's hand, in eight days the healing advanced so rapidly that only a granulating surface 2½ inches long by ⅓ of an inch wide remained. Other cases progressed as favorably with other lesions with the use of the drug, and if further experience with the substance brings forward facts in support of the statements, chiefly made by Kortum, creolin must immediately take a position side by side with iodoform, or even more powerful antiseptic dressings.

It is described as a dark brown liquid, of tarry smell and oily appearance. When mixed with water it is at first rather clear, if not stronger than a 1 to 1000 solution, but afterward becomes the color of coffee with milk in it. It may be used as all other liquid antiseptics, by ordinary measures or on tampons.

HEMIPLEGIA AND HEMIEPILEPSY IN RENAL DISEASES.

The clinical maxim formerly accepted by all and often invoked in cases of doubtful diagnosis, that limited palsies and circumscribed convulsions do not occur in cerebral uræmia, is subject to exceptions that have recently rapidly increased in number.

In addition to the cases of so-called uræmic hemiplegia recorded by Carpenter, Pätsch and Jäckel, Raymond has recently collected six instances of interstitial nephritis, in aged persons, in which apoplexy, hemiplegia, or partial convulsions occurred without any other discernible cerebral lesion at the necropsy than atheroma of the arteries and a more or less prominent œdema. Almost at the same time Chantemesse and Tenneson published a paper based upon the analysis of five cases of diffuse nephritis in which analogous nervous phenomena had occurred. A little later—*Gazette Médical de Paris*, November, 1886—Florand and Canniot published two cases of the same kind observed in the service of Raymond. Within a few weeks F. X. Dercum has reported two cases of this kind at a meeting of the Neurological Society of Philadelphia, which were published in these columns. Not all these cases are of equal value. Several of them are too complex, too obscure to be looked upon as possessing value as proof of the causal relationship between uræmia and these accidents of cerebral origin. But the fact stands that in uræmia, or, to speak more precisely, in renal disease, both localized paralyses of hemiplegic character and circumscribed epileptiform attacks are met with in the absence of any gross lesion of the encephalon.

These various phenomena are encountered in subacute and acute nephritis; especially may we look for them in chronic interstitial nephritis. The stage of the disease is usually an advanced one, in which uræmic manifestations have already made their appearance; but they have also occurred at a time when no other symptom characteristic of uræmic intoxication had yet shown itself. In some instances they have been preceded or followed by marked stupor or coma; yet again they have suddenly appeared without prodromes and unaccompanied by any other symptoms of cerebral disturbance.

Complete or incomplete motor hemiplegia limited to the extremities, or invading the face, may persist without perceptible alteration till death, or it may gradually improve, sometimes finally to disappear, sometimes to recur at a later period. The latter cases resemble the hemiplegia due to cortical softening from thrombosis. The motor hemiplegia is often associated with a hemianæsthesia, usually of less degree, but likewise variable and liable to the same fluctuations. Chantemesse and Tenneson noted in two cases conjugate deviation of the face and eyes. The partial epilepsy observed in these cases presents the well-known traits of Jacksonian epilepsy. Sometimes it is to be noted that the attack alternates, predominating now on one side, now on the other.

It is a remarkable fact, especially in view of the presumed dependence of these accidents upon uræmia, that there has been observed in a number of cases a high degree of fever. In one instance the temperature just before death reached 105.8° F.

Beyond the variability of the symptoms and the presence of albuminuria, there is nothing at all in the clinical aspect of certain of these cases to warrant us in attributing them to uræmia. Even the presence of albumin in the urine has only a relative value, in view of the fact that albuminuria is by no means rare in advanced senile atheroma. The difficulties of diagnosis are enhanced in cases of latent interstitial nephritis. The clinical picture is that of local cerebral softening, especially in an aged

person with atheromatous arteries. At the necropsy no cerebral gross lesion is found, but the arteries are atheromatous and there is œdematous swelling of the cerebral cortex varying in degree and extent.

What the pathology of these paralyses and localized convulsions may be it is difficult to say. The greater number of authorities attribute them to cerebral œdema of uræmic origin. Others invoke disturbances of the encephalic circulation due to alterations of the lumen of atheromatous arteries and pressure upon vessels. These explanations will scarcely serve. They are too general. Moreover, in many of the cases no mention is made of cerebral œdema, and in those in which its presence is recorded, it is described as a diffuse general condition to which alone hemiplegic phenomena cannot well be satisfactorily ascribed. Must we then, with Chauffard, invoke a uræmic intoxication capable of directly influencing or destroying the functions of the cerebral cells?

This view must be accepted in explanation of certain of the cases. It will not, however, serve for those in which the cerebral manifestations are unattended by uræmic symptoms of any kind; in which they happen in an individual subject, it is true, to chronic nephritis, but in no sense uræmic.

If, then, the semeiology of the cerebral accidents of patients suffering from disease of the kidneys is as yet only roughly sketched out, their pathology remains altogether obscure. The clinical facts are, however, established upon a firm basis, and it may even be questioned whether or not many attacks of hemiplegia and localized convulsions attributed in the absence of post-mortem examination, to local brain lesions, may not have been of this nature. L. Dreyfus-Brisac (*Gazette Hebdomadaire*, Oct. 7, 1887) has in two cases of hemiplegia attributed to nephritis, observed the disappearance of the manifestations of cerebral lesions coincidently with improvement, under an appropriate régime, in respect of the albuminuria, the digestive troubles, and the dropsy.

MEDICAL LITERATURE.

Dr. Skene, in his characteristically able inaugural address at the last meeting of the American Gynecological Society, stated that during the past eight years, 804 books and 7505 journal articles and pamphlets had been added to the literature of gynecology. An inference may be drawn from this of the increase of medical literature in general. The question naturally arises whether this *embarras des richesses* is an unquestionable gain. It indicates, it is true, a wonderful diffusion of printed matter among a limited number of individuals, constituting one of "the learned professions," who, as a rule, lead exceptionally busy and useful lives. This being the case, they have a right to demand of those who purvey to their intellectual wants material which shall be digestible, assimilable, and calculated to insure healthy growth.

A survey leads us to the conclusion that the multiplication of journals has been entirely out of proportion to the demands of the profession, and that the majority of them, like too many of our younger institutions of learning in this country, are leading anything but a vigorous existence, their chief object being, apparently, to satisfy the ambition, of those concerned in their projection. Herein lies a grand indication for reform. Not that we desire to have *less* literature diffused, but *better*. This can be accomplished in several ways. One is concentration; the value of which is apparent enough, if one will but recall the most successful agencies around us for the advancement of knowledge, charity, or commerce. Another, is a more rigid censorship. With two hundred and more hungry editors, eager to grasp at anything which is offered, anything to fill their columns, no matter how immature, how unskilfully arranged, or how inconclusive, what wonder is it that complaints are constantly made of the valuelessness of a very large portion of the current medical literature? It is as ephemeral as the mist before the rising sun. Very aptly does Dr. Skene remark in the address to which allusion has been made, "this multitude of gentlemen, who write more than they read, 'scatter like deer at the sound of the hunter's horn' when compelled to defend themselves in public discussion before a tribunal of competent judges in well-regulated medical societies."

Another means by which the overproduction in medical literature may be checked, is by making the terms between author and publisher analogous to those which obtain in all ordinary business enterprises, a *quid pro quo*. The inducement held out by the majority of publishers to write for glory, with perhaps a score of reprints thrown in, is about as unfair and unreasonable, not to use a harsher term, as anything can be—to the author, if his contribution is worth spreading before the public; to the public, who pay their money to the publisher, if it is not worthy. The excuse that long established custom sanctions such a procedure, is an unworthy one. Custom sanctions many an abuse, which is none the less an abuse. It is noteworthy that there are a few high-minded publishers who do not follow this course, but pay liberally for all contributions as is the custom with The Medical News. In general literature, those journals earn the largest profits which pay their contributors most handsomely. Why would not the same rule apply equally in medical literature? It would lead to the decrease of many current publications—no doubt to a process of consolidation among some of the survivors, to a merciless sifting of wheat from chaff, and to more care and painstaking on the part of authors. All of which

would contribute to the general improvement of medical literature.

DR. H. C. YARROW, of Washington, has been experimenting recently with a view to determine the value of certain reputed antidotes to serpent venom. All of them, thus far, in his hands have proved valueless with the exception of the fluid extract of jaborandi, which seems to possess antidotal powers, at least in the case of mammals, but upon fowls it appears to have no such effect. Dr. Yarrow has given hypodermatically to rabbits four-fold lethal doses of crotalus venom, and then, by the administration of 35 minims of fluid extract of jaborandi, he has prevented any serious results.

The use of jaborandi as an antidote to venom poison was, we believe, first suggested by Dr. Josso, in the *Gazette Hebdomadaire de Médecine et de Chirurgie*, Paris, 1882, vol. XIX. p. 835, and in this communication he reported a case of viper bite cured with an infusion of the leaves.

THE State University of Nebraska has established at Lincoln a patho-biological laboratory for original research into the nature and causes of the contagious and infectious diseases of animal life. It has a general working room, supplied with all the necessary instruments and books of reference; a cultivating room; an autopsy building; and a room for raising and keeping the small animals generally used in experimentation. The laboratory is under the charge of Dr. Frank S. Billings.

The Lancet of December 3d states that Sir Morell Mackenzie continues to receive highly satisfactory reports regarding the present condition of the Crown Prince of Germany. The slight enlargement of the left submaxillary gland which took place at the end of October was followed by a similar swelling on the opposite side after the occurrence of œdema in the early part of November. Considerable diminution has taken place in both these swellings. Sir Morell Mackenzie considers that in view of the fact that there has been no actual microscopic proof of the existence of cancer, the diminution in the size of these swellings is not without a certain degree of clinical importance.

REVIEWS.

A PRACTICAL TREATISE ON MATERIA MEDICA AND THERAPEUTICS. By ROBERTS BARTHOLOW, M.A., M.D., LL.D., Professor of Materia Medica and Therapeutics in the Jefferson Medical College of Philadelphia. Sixth edition, revised and enlarged. 8vo. pp. XXIV. 802. New York: D. Appleton & Co., 1887.

THE appearance of the sixth edition of Dr. Bartholow's book on therapeutics at such an early date shows that it still retains its favored place among American text-books. The profession in general are so well acquainted with the work that it is only necessary to call attention to the appearance of this latest edition.

The articles on the newer remedies of value, such as antipyrine, antifebrin, and salol for example, are quite full, yet their literature is growing so rapidly that important contributions have appeared since this portion of the book passed through the press.

We note the statement that antifebrin acts as an antipyretic by reducing the "ozonizing function" of the red blood-corpuscles, but the only evidence brought forward to support it is that toxic doses of the drug have been found to alter the oxyhemoglobin; yet on the preceding page it is distinctly stated that "there are important differences in the action of moderate medicinal, and of toxic doses, but the effect of the latter on the blood globules introduces a special pathogenic influence which must change the character of the symptoms produced." So far as we know at present, no one has proved that the antipyretic effect of this drug depends on its action on the ozonizing power of the blood any more than it has been proved that quinine does the same thing.

The book has undergone very thorough revision, and stands as a typical representative of American thought and thoroughness, and will continue a favorite with a very large class of medical practitioners.

OPERATIVE SURGERY ON THE CADAVER. By JASPER JEWETT GARMANY, A.M., M.D., F.R.C.S., Attending Surgeon to Out-door Poor Dispensary of Bellevue Hospital, etc. 8vo. pp. IX. 150. New York: D. Appleton & Co., 1887.

THIS work is well adapted to fill the niche for which it was written, but the niche must be a very shallow one. We cannot conceive of any one wanting an operative surgery for the dead room, which must lose its value so soon as it leaves that room. But, while we would far prefer one of the manuals which treat of operations upon the living, there may be those who think differently from us. All such we would advise to invest in this book. They will find it well written, its directions explicit, clearly expressed, and based upon well established precedents and admitted rules of practice.

SOCIETY PROCEEDINGS.

MONTREAL MEDICO-CHIRURGICAL SOCIETY.

Stated Meeting, December 9, 1887.

THE PRESIDENT, JAMES PERRIGO, M.D., IN THE CHAIR.

DR. BELL exhibited a specimen showing

THE DEVELOPMENT OF BONE FROM PERIOSTEUM.

It was a section of the shaft of the femur from a patient whose thigh had been amputated ten days after receiving a compound comminuted fracture of the lower end of the femur and the head of the tibia, opening the knee-joint. Extensive sloughing had occurred, and at the time of the operation the patient was in a sapræmic condition, due to the absorption of putrid material from

the necrotic tissues. Twenty-five days later it was found necessary to reamputate two and one-half inches of the end of the femur because it was exposed, owing to sloughing of the flaps. At the primary amputation the periosteum had been stripped from the bone to the extent of nearly an inch above the point where the femur was divided. The bone removed at the secondary operation showed an undoubted development of bone in the periosteum thus detached.

DR. SHEPHERD said this case was most interesting in connection with the views lately given by Dr. Macewen, of Glasgow, in the October and November numbers of the *Annals of Surgery*. That authority held that periosteum does not initiate the reproduction of bone. In Dr. Bell's case the periosteum had certainly developed bone. He had no doubt, however, as to the correctness of Dr. Macewen's views when he states that periosteum is not the chief factor in the reproduction of bone, this function being performed by the soft tissues enclosed in the osseous tissues.

DR. MILLS regarded the specimen as illustrating the fact that Nature accomplished her ends in various ways —he also said that experiments on animals, etc., often led to false conclusions because of the disturbance of natural processes, but in cases such as the one related, Nature was not interfered with, and the processes were not artificial. Pathology often threw a bright light on physiology and helped to explain many obscure points.

PURULENT MENINGITIS.

DR. JOHNSTON reported a case which had been under the care of Dr. Molson, and in which he had performed an autopsy. Patient was a healthy woman, who, whilst in the sixth month of pregnancy, fell and struck her head. She developed soon after brain symptoms, deviation of the eyes, flexion of the neck to one side, and active delirium. She was admitted to the General Hospital, miscarried, and some days after died. At the autopsy, the ovarian veins were distended but patent, the renal veins free. There was severe parenchymatous nephritis with slight interstitial nephritis. Spleen and liver enlarged and soft. Uterus enlarged, cavity dilated, placental site free from inflammation. On the right side there was purulent meningitis of the inner surface of the pia mater extending to the base in the middle and anterior fossæ of the skull. There was thrombosis of the right lateral sinus and inferior petrosal sinus. No fracture of the base of the skull was found but there was purulent otitis media of the right side with pus in the mastoid cells. The tympanic cavity was covered with granulations. In this case there was no history of ear trouble. Dr. Johnston had no doubt that the otitis was the cause of the meningitis, and that the fall a short time previously had very little to do with the fatal result of the case.

DR. H. L. REDDY related a case of

RUPTURE OF THE HEART.

The patient, a man, aged sixty-eight, had always been in good health. A week ago he left his house at 5 A. M. to go to his work; and whilst going down stairs was seized with severe pain in his chest, after walking a few hundred yards he found the pain so severe that he had to return home. A physician was sent for, who examined him, and found nothing apparently wrong. When Dr. Reddy saw the patient, some hours after, he had vomited once and complained of severe pain in the epigastrium. Pulse normal, and no symptoms pointing to the heart. He gave him a quarter of a grain of morphia, which relieved the pain. A second dose of morphia, a few hours after, completely removed the pain, and then he seemed perfectly well; four days later, whilst sitting in his chair, he suddenly threw back his head and instantly died.

At the autopsy, Dr. Johnston found the following conditions: Pericardium moderately distended with blood, on opening the sac blood and clot to the amount of ten ounces were found, the clot forming a complete mould around the heart. A small laceration, one-half inch long, was found in the anterior wall of the left ventricle, one inch to the left of the septum, surrounded by an area of ecchymosis. On opening the ventricles, the left was nearly empty, endocardium normal, but at the spot of rupture, in separating the trabeculæ, an area of softening was seen through which a bristle readily passed. On transverse incision through the laceration, a thrombosed vessel was seen surrounded by a soft yellow area of necrotic muscle. Subpericardial fat in excess, but heart muscle not fatty on microscopic examination. There was no extreme atheroma of coronary vessels, or systemic system, and no varicose veins of the extremities.

DR. W. G. JOHNSTON exhibited some microscopic specimens of

MUCOUS POLYPI

from the nose. In eight cases the stage was an early one and the condition was strictly that of adenoma of the nasal mucous glands. In those where the stage was later, the cell outlines had disappeared, leaving only areolar tissue infiltrated with mucous fluid. This secondary change, Dr. Johnston said, was probably the reason why these growths were commonly, but wrongly, called myxomata of the nose, and confused with true myxomata, which are tumors of quite a different nature, originating in connective tissue.

DR. SHEPHERD read a paper on a case of

SUBDIAPHRAGMATIC ABSCESS.

(See page 700.)

DR. RODDICK thought that it was not improbable that the case originally had been one of empyema; that the pus had ulcerated through the diaphragm, and got between that structure and the liver.

DR. G. ROSS said that the explanation offered by the last speaker was an ingenious one, but not practicable. The anatomical structure of the parts did not give any likelihood to the supposition. The case had probably been originally one of subdiaphragmatic peritonitis which had become localized. We may have a pleurisy following a subdiaphragmatic inflammation without perforation of the diaphragm, but that such a small opening as would naturally result from an ulcerating empyema could completely drain the pleural cavity and collect below the diaphragm, was not probable. Any empyema would surely come forward more readily than downward.

DR. WILKINS said that when he first saw the case the probability of its being an empyema occurred to him, but he, for various reasons, discarded this idea. From

the early history, jaundice, etc., he was inclined to regard the case as one of abscess of the liver; but against this was the total absence of a history of fever, rigors, or sweating. He had now no doubt that the case was one of abscess between the liver and diaphragm. One feature about the case was the apparently slight amount of pain which pressure on the tumor caused.

DR. SHEPHERD, in reply to Dr. Roddick, said that not one symptom in the early history pointed to an affection of the pleura; the pain was always below the costal cartilages of the right side, and there never was any cough or difficulty of breathing. At the time of the operation there was no pus in the pleural cavity. Fluid always finds its way in the direction where there is the least resistance, and this is certainly not in the direction of the diaphragm. In his experience the pus in empyema always pointed in the neighborhood of the nipple, and when it pointed elsewhere it did so by burrowing beneath the tissues external to the lung wall of the thorax, after perforating an intercostal space.

DR. FENWICK exhibited five calculi which he had recently removed from four patients by

LATERAL LITHOTOMY.

Two cases were in men of middle age, one in a youth aged twenty, and one in a man aged sixty-nine. The last case had been a very difficult one, on account of the great depth at which the bladder was placed and the narrowness of the outlet of the pelvis. The stone was large and composed of uric acid. The patient had, after the operation, a curious diphtheritic-looking patch in the throat, and the wound at the same time had a very unhealthy appearance. The patient, however, ultimately did well. The urine ceased to flow from the wound on the thirty-fourth day. In the three other cases the urine ceased to come from the wound on the sixteenth, eighteenth, and twentieth days, respectively. In the first of these cases, where two uric acid stones had been removed, the man went home well on the twenty-first day. In all but one case a soft catheter had been introduced into the bladder to drain off the urine.

DR. RODDICK exhibited

LIGHT LARGE CALCULI,

which he had removed from an old gentleman, in the same way as the lateral operation. The stones weighed two and a half ounces. At the time of the operation the patient was in a very bad state of health, and there was considerable pus in the urine. He died nine days after the operation of anæmia. No doubt his kidneys were diseased. No autopsy was allowed. In this case the suprapubic operation had been thought of, but the former was preferred, on account of the small capacity of the bladder, which would hold only two ounces of fluid.

DR. G. E. MACDONNELL related a case of

RECOVERY IN CIRRHOSIS OF THE LIVER.

Ascites had been present to a very great extent. The patient, a woman, aged thirty-five, married, but childless, was admitted to the Montreal General Hospital in August, 1885, with a large quantity of fluid in the abdomen. She had suffered during the past year from dyspeptic symptoms, with morning vomiting. There was a history of spirit drinking. Prior to admission she was tapped to the extent of 200 ounces. There was tenderness over the hepatic region. The liver was small, measuring three inches in the right mammary line. She remained in the hospital for ten months, being tapped at first every two or three days, but subsequently at longer intervals; the amount drawn off being at first 180 to 200 ounces, but at the time of her leaving the hospital but 16 to 20 ounces could be obtained. She was tapped sixty times during the year, and taking 150 ounces as an average, altogether 8500 to 9000 ounces were removed. The woman had now gained health and strength, and was apparently well and attending to her household duties. The liver is much the same size, the abdomen now contains no fluid, and the dyspeptic symptoms have disappeared. Dr. MacDonnell said that the total amount of fluid removed in a year was large considering the patient's weight (125 pounds) and size. Much larger quantities have been taken away, but the case is instructive as illustrating the benefit to be derived from paracentesis in cirrhosis.

DR. WM. GARDNER gave the subsequent history of a case of

DERMOID OVARIAN CYST IN A PREGNANT WOMAN,

which he had removed last February, and which he had reported at the time to the Society. The case was one of twisted pedicle, with severe peritonitis. He had removed the cyst and both ovaries, washed out the abdominal cavity, and left a drainage tube in the wound for five days. At the time of the operation the uterus looked large and discolored, and he had suspected pregnancy. Eight months after the operation she was delivered of a healthy child. He thought it remarkable that the pregnancy should have gone on to full term, after the peritonitis, washing out of the abdomen, and drainage, as well as the removal of a large cyst. This was the second case in which he had removed an ovarian tumor in a pregnant woman who had subsequently been delivered of a child at full term.

DR. JAMES C. CAMERON read a paper on

THE DANGERS AND ACCIDENTS OF LOCAL TREATMENT IN PUERPERAL CASES.

He began by saying that the introduction of antiseptics had revolutionized the practice of midwifery, so that results, impossible anywhere a few years ago, are now obtainable. Still the use of antiseptics in midwifery had been abused. Uterine and vaginal douches properly administered in suitable cases are invaluable, but otherwise they may prove dangerous. The opinion appears to prevail among the profession that while the intrauterine douche is generally safe, the vaginal douche is pertectly so, and not unfrequently we find the operation entrusted to the nurse or some unskilled person, as if douching were a trivial matter. Dr. Cameron said that he believed that prophylactic douching during the puerperal state is not only unnecessary, but harmful. He was convinced that the douche is not perfectly harmless, and that it should be used with caution. The chief danger of the douche is in absorption through tears, fissures, or other traumatism. He thought absorption is more liable to take place through the

vagina than through the uterus, because the latter usually contracts fairly and empties its contents. The author of the paper held that the intrauterine douche is more dangerous than the vaginal, because fluid may be forced through the Fallopian tubes into the abdominal cavity, causing peritonitis, as in Völtz's case, or a thrombus may be dislodged from the placental site, and hemorrhage take place; again, air may find its way directly through the uterine sinuses into the veins. He had seen sudden death occur during an intrauterine injection of perchloride of iron for postpartum hemorrhage. Warm water alone should be used when it is necessary to wash away *débris;* in septic cases corrosive sublimate solution is far the most effective, but also the most dangerous. Death has occurred in sixty hours from the effects of an introduction of a sublimate douche (1 : 2000). Patients suffering from anæmia or kidney troubles are very susceptible to the action of mercury; so, too, are those who have recently been under mercurial treatment, or in whom there is a marked atony of the uterus, or extensive traumatism of the genital tract.

To avoid the dangers and accidents incident to injections in puerperal cases, the author said that

(1) The patient should always be placed across the bed in the dorsal position, with hips well raised and thighs everted. In this way, in intrauterine injections, the anterior lip can be more easily seized, and the intrauterine cavity straightened.

(2) The vaginal or uterine nozzle should be inflexible, without a central orifice in the bulb. The openings should be directed slightly backward, so that the injection stream may flow away from the fundus, not toward it.

(3) A sufficient outflow should be secured by keeping the vaginal orifice open. Before an intrauterine douche is given the anterior lip should be seized with a tenaculum, and drawn gently downward until the uterine cavity is straightened.

(4) The quantity of fluid injected should be small (1–2 quarts).

(5) Antiseptic injections should be weak. For an ordinary vaginal douche a sublimate solution of 1 : 5000 is quite strong enough. The stronger solutions should only be used in urgent septic cases. After sublimate injections a pint or two of plain hot water should be employed to wash away any retained sublimate, thus lessening risks of absorption.

(6) The injection should always be used hot (110°–112° F.), for hot water is a powerful stimulant, causing the uterus to contract and expel its contents.

(7) To prevent nervous chill and rise of temperature a glass of brandy, or some diffusible stimulant, should be given fifteen minutes before operating.

(8) During the more severe methods of intrauterine treatment, such as curetting or brushing, the placental site is apt to be disturbed, thus allowing the entrance of air, fluid, or septic matter, so these methods should be at once followed by a small douche of hot water; after which a bolus of iodoform should be passed into the uterine cavity, and the vagina should be packed with iodoform gauze.

Dr. Blackader said he would like to ask the reader of the paper under what circumstances he now advised curetting, and whether he would perform this operation whenever there were any septic symptoms present. He thought that injections should not be given too hot, for he had seen serious symptoms follow the employment of very hot injections, peritonitis even had resulted from the injection of plain hot water.

Dr. William Gardner also condemned the use of too hot injections, and the employment of a syringe with a nozzle with a central opening; he related one case of a woman with prolapsus uteri, who, when employing hot water injections, used such a nozzle. The injection was followed by vomiting and severe pain. Then the case went on to pelvic peritonitis, from the effects of which the woman still suffered. He could mention other cases where serious results had followed the use of injections properly administered.

Dr. Roddick said he was cognizant of not a few cases where serious results had followed the injection of solutions of bichloride of mercury; he thought Condy's fluid a safer antiseptic; but, best of all, is hydronapthol; it has germicidal qualities nearly equal to the bichloride, but no odor or irritating qualities, and there is no danger of poisoning.

Dr. Mills asked whether the danger of absorption is great from the vagina or uterus.

Dr. Cameron, in reply, stated that the value of curetting, in suitable cases, is unquestionable, viz., where portions of the placenta are retained; the brushing out of the uterus would not, in some cases, replace curetting. The danger of absorption is greater through the vagina than the uterus, for the injected fluid, owing to the greater tendency of the vagina to sacculate, remains longer in contact with the absorbing surface. He had written this paper as a protest against the indiscriminate and careless use of injections in the puerpera state.

PHILADELPHIA COUNTY MEDICAL SOCIETY.

Stated Meeting, November 23, 1887.

The President, J. Solis Cohen, M.D., in the Chair.

Dr. Edward Jackson read a paper on

GLEDITSCHIN, SPURIOUS AND GENUINE.

In publishing his observations on the action of the so-called stenocarpine (in The Medical News of September 3, 1887), he stated: "In studying the action of this drug, one cannot but be struck with its similarity to that of cocaine. . . . This similarity of action raised in my mind the question, whether this new drug possessed any power which would not be possessed by a solution of cocaine to which had been added a portion of one of the stronger mydriatics, as duboisine or hyoscyamine." It seemed to him then, however, that the drug did "possess certain powers, in degree at least, peculiar to it. My impression is that the solution used, said to be a two per cent. solution, is a more powerful anæsthetic than the four per cent. solution of cocaine." He also thought that while its influence over the accommodation was more powerful than that of homatropine, that the recovery of the accommodation from its effects was more rapid than from any previously known mydriatic, except homatropine.

In this last respect he soon found he had been in error. A few days after that paper was published he came

across the records of some experiments which he had made nearly six years ago, and some of the results of which he reported in a paper read before the Medical Society of the State of Pennsylvania in 1882; and among them some trials of weak solutions of 1 to 1000 and 1 to 2000 of duboisine and hyoscyamine in his own eyes, where the recovery corresponded exactly to the recovery observed after the use of the alleged new drug. This discovery redoubled his suspicions. He then took twenty-five grains of the solution, dried it over sulphuric acid, and weighed the residue, which he gave to Dr. Henry Leffman, who dried it still further, and weighed it again; its weight, as reported by him, was 1.62 grains. This demonstrated that the so-called two per cent. solution of "stenocarpine" was not what it purported to be.

In his paper, before referred to, he objected to the name stenocarpine as probably not indicating the real source of the drug, and pointed out that Mr. Goodman's description of the tear blanket tree corresponded with that of the *Gleditschia triacanthos*, or honey locust; and stated that "extracts made from the leaves of the honey locust growing near Philadelphia, failed to exhibit any anæsthetic or mydriatic properties." About the same time he wrote to Mr. Goodman asking for specimens of the leaves, and he promised them, but they have not yet been received. Soon after this, however, he obtained specimens of leaves from Jefferson County, Texas, which were pronounced those of the honey locust by Dr. J. T. Rothrock, Professor of Botany in the University of Pennsylvania, who had been the first to suggest to him that the honey locust might be the tree described. These leaves proved as inert as those obtained in this vicinity.

Shortly after this, Dr. J. H. Claiborne published in the *Medical Record* of October 1, 1887, a detailed and illustrated account of the honey locust; stating that Mr. Goodman and Dr. Seward had fully identified it, as the source of the new local anæsthetic, and proposing therefore, to call the "new" alkaloid Gleditschin. The publication of the above facts indicating the fraudulent character of the "stenocarpine" solution was delayed until some of the genuine Gleditschin could be studied. But, simultaneously, Mr. F. A. Thompson, in the *Medical Age* of October 25th, and Dr. John Marshall, in THE MEDICAL NEWS of October 29th, published analyses of the alleged stenocarpine-Gleditschin solution, by which the fraud was fully exposed. They proved that unquestionably the solution contained cocaine and a member of the atropine group. The latter is not, however, atropine itself, as might be inferred from their papers; but on account of the brevity of the paralysis of accommodation it produces, must be, Dr. Jackson thinks, hyoscyamine, duboisine, or daturine.

In the *Philadelphia Medical Times* of November 23, 1887, Dr. Lautenbach published a brief communication entitled "Gleditschin.—A New Alkaloid," with the promise that "in a later publication this subject will be treated of more fully." The promise remained unfulfilled, doubtless on account of his early death.

After reading his account of the substance clearly entitled to the name Gleditschin, he endeavored to obtain some of the unripe fruit, in which, according to Dr. Lautenbach, the drug is to be found. With some difficulty and after considerable delay, a peck of the fruit was obtained, but the pods and seeds were most of them very nearly mature. However, Mr. James A. Kyner, Demonstrator of Chemistry in the Polyclinic, following in the main the method of Dr. Lautenbach, obtained from them a very small amount of a solution of what we believe to be the sulphate of the true Gleditschin. On evaporation it deposits crystals of a narrow rhombic form. When ammonia is added it gives a precipitate, which presently crystallizes in broader rhombs. On the frog it produced the symptoms narrated by Dr. Lautenbach, though his supply of the solution gave out before the stupor was complete. The symptoms reached their height in fifteen minutes after the hypodermatic injection of the solution, were passing off in an hour, and had disappeared entirely in less than three hours. *This solution freely applied to the conjunctiva produced no anæsthesia, or dilatation of the pupil, whatever.*

The analyses and tests above referred to, with several others that have since been published, have pretty well disposed of the alleged new local anæsthetic and mydriatic; and Gleditschin has lost its interest for the ophthalmic surgeon. But the incident, disagreeable as its ending may have been to some, is not without its useful lessons.

First. It is shown that such a fraud cannot be carried far, even with a drug as difficult of positive chemical identification as cocaine. And every such attempt at fraud can only make more brief the period, and decrease the profit, of succeeding attempts.

Second. It has been demonstrated that cocaine can produce anæsthesia through the unbroken skin; although he had pointed out (loc. cit.) that this is extremely superficial; and "To make a painless incision in tissues anæsthetized in this way, one must do it by repeated superficial cuts with the knife, keeping all the time the cut surface bathed with the solution."

Third. Attention has been drawn to the *Gleditschia triacanthos*, and the genuine Gleditschin discovered and studied nine years ago by Dr. Lautenbach, but recently in a fair way to be forgotten. And in the direction of a further study of this substance lies the probable path of profitable future investigation. The leaves have been proven practically inert, and for several months it may be unpossible to obtain specimens of the unripe fruit. But other parts of the plant might be tested for it. In the *Medical Age* of November 10th Dr. Crull states that he has cured gleet with a decoction of the bark of the root of the thorny honey locust (the more common variety), and that taking a tablespoonful of the decoction himself "caused nausea, giddiness, dimness of sight, cold perspiration, and a prickly or smarting sensation of the tongue and throat. These symptoms continued for nearly three hours, when they gradually abated. The evacuation of the bowels the following morning was very bilious and watery."

CORRESPONDENCE.

COCAINE MURIATE IN UNCONTROLLABLE VOMITING.

To the Editor of THE MEDICAL NEWS,

SIR: Though my experience with the new anæsthetic has been comparatively limited, yet I have found cocaine muriate of signal service in a few cases of ob-

stinate vomiting of pregnancy, and in one of uncontrollable vomiting.

Mrs. H. came under my care in August, in consultation with Dr. Ceist. He had been using a combination of cerium oxalate with ingluvin, in proportion of gr. v. of the former to gr. x of the latter, which for a time gave relief. When I was consulted regarding the patient she had retained no food for five days, and was threatened with starvation. I recommended quarter grain doses of cocaine in combination with subnitrate of bismuth and acid. carbolic., with mucilag. acaciæ, to be taken thirty minutes prior to some light nourishment. The patient has had very little trouble since. The cocaine was soon withdrawn, and the case progressed nicely.

It must not be forgotten, in connection with the case, that prior to the pregnancy just spoken of, two abortions were performed to save the patient from starvation.

Very respectfully,

W. D. Jones, M.D.

Richfield, Kan., Dec 8, 1887.

NEWS ITEMS.

Cholera in South America.—Health authorities at our ports of entry should bear in mind the fact that Asiatic cholera has reappeared in South America. Reports published in the Panama *Star and Herald* show that in October the disease broke out afresh in Chili. On October 22d there were 14 cases in the small city of Chillan; on the 23d 28 cases and 16 deaths, and on the 24th 16 cases and 6 deaths. Last year the disease did not appear in Chili until the second week of November, but now it has come before the arrival of warm weather. On November 26th Peruvian ports were closed against vessels from Chili.

A Congress for the Study of Tuberculosis.—A congress of physicians and veterinarians for the study of this subject will be held in Paris, near the quarters of the Faculté de Médecine, from July 25 to July 31, 1888. Professor Chauveau is announced as president, and the other officers will be distinguished members of the Paris faculty and eminent veterinarians. One day will be devoted to the study of anatomical preparations, in the laboratory of Cornil; another will be given to the examination and dissection of tuberculous animals, at the veterinary school at Alfort. French and foreign physicians and veterinarians may become members on the payment of ten francs ($2), and entering their names; they may then take part in the discussions.

The proceedings and results of the congress will be published, in French, in a volume of Transactions and in the journals.

The origin, contagion, diagnosis, and treatment of tuberculosis will receive the most thorough study. Information regarding communications to be offered may be sent to Petit, Secretary-General, 11 Rue Monge, Paris.

The Results of Medical Legislation in Indiana.—The Secretary of the Indiana State Medical Society reports in the *Medical Standard* for December, 1887, that the law, imperfect as it is, has done much good. It has reduced the number of physicians from 4695 to 4136, thus weeding out over 500 pretenders. It has driven others to take a second course of lectures and has forced others to take a first course of lectures and come in under the three years clause. It has driven from the State troops of long-haired, loud-mouthed, slouchy charlatans who made annual tours of the State, accompanied by cheap brass bands, gaily caparisoned steeds, and other paraphernalia calculated to deceive and impress the ignorant.

A Hospital for Employés.—The Cambria Iron Company, whose works are near Johnstown, Pa., has recently erected a hospital for its employés; the sanitary arrangements of the building are described as follows by the *Sanitary News*: A noticeable feature is the ventilation. In the wall back of each bed in the principal ward and about nine inches from the floor will be a register through which the foul odors will be drawn into a duct to the fire where they will be consumed. This floor is of asphalt and can be flooded, the water passing off through deck plates in the centre of the room. While the hospital contains the essential features, there are many new and valuable points about it which recommend themselves to those interested in this class of buildings.

A Copy of Rembrandt's "Lesson in Anatomy" at the College of Physicians of Philadelphia.—Last week a very fine, full-size copy of Rembrandt's famous "Lesson in Anatomy" was presented to the College of Physicians by two friends of the College, at whose order it had been painted at the Hague, where the original is.

Rembrandt is said to have been inspired to paint this picture by a sentiment of gratitude toward Nicolaus Tulpius, Professor of Anatomy, at Amsterdam, who had protected him in his youth. Tulpius is represented with his disciples, of life size, grouped around a table, on which is stretched a corpse; some are seated, some standing, and some bending over the body, while he is demonstrating the anatomy of the arm, which is dissected. The light illuminates one side of the dead body, leaving in obscurity the dresses, the table, and the walls of the room, and the contrast between light and shadow is marvellous. There is, as a critic has said, in the complexion of the group an air of mystery, gravity, and scientific solemnity which inspires reverence and silence.

Rembrandt was only twenty-six years old when he painted this picture (1632), which, by universal judgment, is placed among the greatest triumphs of human genius.

A New Hospital for Toronto.—A subscription of $40,000 heads the list for a new hospital at Toronto. It is confidently expected that the remaining funds needed will be raised without difficulty.

The Illness of the Emperor of Brazil.—From a correspondent of the *Revue Générale de Clinique et de Thérapeutique* of November 24, 1887, we learn that Dom Pedro, now aged about sixty-two, has been suffering for six or seven years with glycosuria which appeared after cerebral fatigue and disappeared after repose. During last February he was taken with more serious manifestations of his malady, while at his country place. After residing for some time in various parts of his kingdom he was sent to Europe, where he

visited Paris, Baden-Baden, and Cannes. It is probable that he will spend the present winter in Egypt and Algiers.

THE DETROIT CREMATORY is announced to be completed and ready for the use of the public.

DOCTORS IN RUSSIA.—A recent report of the members of the profession in proportion to the population in Russia gave one doctor to 18,000 people; this is the only civilized country where overcrowding is not present.

ACCIDENTAL INOCULATION IN A BACTERIOLOGICAL LABORATORY.—A Russian physician studying in Bollinger's laboratory at Munich, recently infected himself with anthrax, through a cut finger. Nussbaum thought best to extirpate his axillary glands at once.

OPENING OF THE PARIS CLINIC FOR CHILDREN'S DISEASES.—Grancher, of Paris, has enlarged and improved his clinic at the Children's Hospital, and has supplemented his own services by an auxiliary staff of specialists, whose service is upon the different days of the week. Facilities for laboratory work in histology, microbiology, chemistry, and photography, are fully provided.

PROFESSOR BOTKIN, Professor of Clinical Medicine in the University of St. Petersburg, and physician to the royal family of Russia, is at present the guest of the physicians of Paris.

PATENT MEDICINES. — Pharmacist Painter, in the *American Druggist*, states that there are 36,500 proprietary medicines in the market. He considers them utterly unworthy of physicians' sanction, and thinks that medicine and pharmacy have been materially injured by them.

AN INSTITUTE FOR CHRISTIAN SCIENCE.—The Court of Appeals of St. Louis has refused to incorporate the "Institute of Christian Science." The Court doubtless recognized the "Institute" as a money-making scheme, under the pretence of religion.

A GRAVE MISTAKE.—The *Practitioner and News* of November 26, 1887, reports the following serious accident, which occurred recently in Detroit: A careful and skilful physician of this city, recently, being about to make a vaginal examination of a patient, ordered a servant of the lady to bring him some lard. The servant understood him to say "lye" instead of lard, and brought a teaspoonful of concentrated lye, which was at that time in use in the kitchen for scrubbing purposes. The physician, not dreaming of such a mistake, and finding the lye about of the consistency and color of lard, anointed his finger and introduced it. The patient complained of atrocious pain, which the doctor thought due to some nervous trouble until his finger began to smart, when he made a closer examination and discovered the unfortunate mistake. The caustic produced extensive sloughing of the vagina and vulva, which will necessarily be very refractory to treatment. The chagrin of the physician may be imagined, though he acted only as any of us might have done under the circumstances.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM DECEMBER 6 TO DECEMBER 12, 1887.

STERNBERG, G. M., *Major and Surgeon*.—Assigned to duty as attending surgeon and examiner of recruits at Baltimore, Md.—*S. O. 285, A. G. O.*, December 8, 1887.

CLEARY, P. J. A., *Major and Surgeon*.—Assigned to duty at Fort Wingate, New Mexico.—*S. O. 285, A. G. O.*, Dec. 8, 1887.

ANDERSON, C. L. G., *First Lieutenant and Assistant Surgeon*.—Assigned to duty at Fort McDowell, Arizona.—*S. O. 285, A. G. O.*, December 8, 1887.

TAYLOR, A. W., *Captain and Assistant Surgeon*.—Assigned to duty at Fort Robinson, Nebraska.—*S. O. 285, A. G. O.*, December 8, 1887.

APPEL, A. H., *Captain and Assistant Surgeon*.—Assigned to duty at Camp at Highwood, Ill., relieving Assistant Surgeon H. O. Parley. *S. O. 285, A. G. O.*, December 8, 1887.

PARLEY, H. O., *Captain and Assistant Surgeon*.—Will rejoin his proper station (Fort Wayne, Mich.).—*S. O. 285, A. G. O.*, December 8, 1887.

HOFF, JOHN VAN R., *Captain and Assistant Surgeon*.—Granted leave of absence for one month, to take effect on or about the 12th proximo.—*S. O. 128, Department of Missouri*, November 30, 1887.

MUNDAY, BENJAMIN, *Captain and Assistant Surgeon*.—Granted leave of absence for one month, to take effect about December 15, 1887.—*S. O. 286, A. G. O.*, December 2, 1887.

BANISTER, W. B., *First Lieutenant and Assistant Surgeon*.—Ordered to proceed at once from Fort Lowell, Arizona, to Fort Wingate, New Mexico, and report to the commanding officer for duty.—*S. O. 8, Department of Arizona*, December 1, 1887.

CABELL, J. M., *First Lieutenant and Assistant Surgeon*.—Ordered for duty at Fort Niobrara, Nebraska.—*S. O. 286, A. G. O.*, December 9, 1887.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, FOR THE WEEK ENDING DECEMBER 12, 1887.

GASSAWAY, J. M., *Surgeon*.—When relieved to proceed to Cairo, Illinois, and assume charge of the Service, Dec. 9, 1887.

IRWIN, FAIRFAX, *Surgeon*.—Promoted and appointed Surgeon from date of oath, December 10, 1887.—December 8, 1887. (Omitted from previous report.)—To proceed to Pittsburg, Pa., Wheeling, W. Va., Gallipolis, Ohio, Evansville, Ind., Cairo, Ill., Little Rock, Ark., Shreveport, La., New Orleans, La., Rome, Ga., Chattanooga and Nashville, Tenn., as Inspector, Nov. 12, 1887.

GUILBEAU, JOHN, *Passed Assistant Surgeon*.—When relieved to proceed to Charleston, S. C., and assume charge of the Service, December 12, 1887.

BANKS, C. E., *Passed Assistant Surgeon*.—To proceed to Portland, Maine, and assume charge of the Service, Dec. 9, 1887.

CARMICHAEL, D. A., *Passed Assistant Surgeon*.—When relieved to proceed to Washington, D. C., for temporary duty in the office of the Supervising Surgeon-General, December 9, 1887.

BEVAN, A. D., *Passed Assistant Surgeon*.—Granted leave of absence for twenty days, December 7, 1887.

GLENNAN, A. H., *Passed Assistant Surgeon*.—To proceed to Key West, Fla., and assume charge of the Service, Dec. 12, 1887.

THE MEDICAL NEWS will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

ORIGINAL ARTICLES.

TWO CASES OF ANEURISM IN GIRLS OF EIGHTEEN AND EIGHT YEARS OF AGE.

WITH A LIST OF REPORTED CASES UNDER TWENTY YEARS OF AGE.

BY W. W. KEEN, M.D.,

PROFESSOR OF SURGERY IN THE WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA; SURGEON TO ST. MARY'S HOSPITAL, ETC.

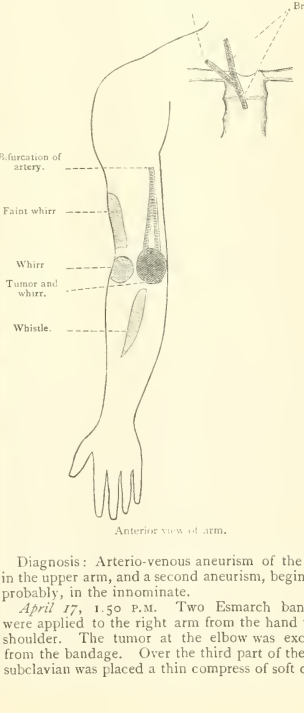
CASE I. *Spontaneous arterio-venous aneurism of the arm, with a high bifurcation of the brachial artery, in a girl of eighteen years; a second aneurism in the chest; apparent temporary cure of the aneurism of the arm from Esmarch's bandage, followed by the tourniquet and digital compression; radical cure by operation.*—For the notes of this case I am indebted to Dr. Florence Sibley-Lee, the then surgical resident in the hospital. Louisa L., a rosy Swedish chambermaid, aged eighteen years, was admitted to my clinic at the Woman's Hospital, at my instance, April 1, 1885. Her father had had a "tumor of the chest" removed. Her mother died six weeks after confinement. Six brothers and sisters are healthy. She came to this country in 1883, when she first noticed diffused red spots on the skin of her right arm and shoulder. These mottled spots still exist, some of the vessels being quite distinct. They exist only in the right arm, shoulder, and upper right chest.

In August, 1884, while walking she was sunstruck. She fell unconscious, and remained so for two days. On her recovery she first noticed a lump on her right arm. It was then small, but has increased considerably since, and now incapacitates her for her work by pain. She has had no after ill-effects from the sunstroke. The lump is just above and in front of the internal condyle, 1½ by 1¾ inches in size. It is soft and compressible, with distinct pulsation; is not tender. Over it, but neither above nor below it, a distinct thrill is felt. A bruit is heard over the tumor, over the outer part of the arm, and down the middle of the forearm, nearly to the wrist. The superficial veins are enlarged to double the ordinary size, and the bruit is heard over them, in the arm and forearm, as indicated in the drawings (Figs. 1 and 2), both as to situation and character. Pulsation is not felt in the veins. The brachial artery is distinctly felt, and its bifurcation at the upper third of the arm, well ascertained. This was confirmed later by the non-obliteration of the right radial after ligation of the ulnar above the elbow. The tumor is connected with the ulnar, the inner branch, compression of which arrests the bruit and thrill. This artery passes behind the internal condyle, as ascertained by its pulsation and by the arrest of pulsation upon pressure on the ulnar higher up in the arm.

Above the outer third of the right clavicle another thrill and bruit are heard and felt; the bruit commences at the junction of the manubrium and gladiolus, and can be heard over the right carotid and subclavian only. No distinct tumor is either seen or felt above either the sternum or clavicle.

The heart and lungs are normal; pulse 69; respirations 24; temperature 99°; general health excellent; urine, specific gravity 1021, and normal, having neither albumen nor sugar.

FIG. 1.



Anterior view of arm.

Diagnosis: Arterio-venous aneurism of the ulnar in the upper arm, and a second aneurism, beginning, probably, in the innominate.

April 17, 1.50 P.M. Two Esmarch bandages were applied to the right arm from the hand to the shoulder. The tumor at the elbow was excluded from the bandage. Over the third part of the right subclavian was placed a thin compress of soft cotton

with a cork over it, and the bandage passed firmly over this, and into the left axilla. At her request no ether was given.

Fig. 2.

Posterior view of arm.

At 2.15 P.M. she vomited some water taken a few minutes before.

2.30 P.M. Pulse had risen to 90. Complains of feeling very hot, especially in the head.

3.10 P.M. Restless and complains of pain in the head and arm. Ice-cap applied. Pulse had fallen to 78.

3.20 P.M. No coagulum perceptible in the aneurism.

3.30 P.M. Restless. Morphia, gr. 1/6, hypodermatically.

3.50 P.M. After being on for two hours, the Esmarch bandages were removed, and a Signorini's tourniquet applied high up on the arm, watched constantly by relays of students. The tumor at the elbow had apparently disappeared, no thrill was felt; a slight bruit, however, was heard. The blood returned to the arm much more slowly below than above the tumor. The thrill and bruit over the subclavian much lessened. Pulse 75.

7.45 P.M. Tourniquet removed after having been in place 4 hours. Pulsation immediately felt in radial and in the arm to within an inch of the tumor, then lost. Neither thrill nor bruit over the tumor. Arm feels "asleep." No thrill in subclavian.

8.05 P.M. Return of thrill and bruit at the elbow, but the pitch of the latter lower and softer. Thrill and bruit returned also in the subclavian.

She passed a fairly comfortable night and the morning pulse was 98 and the temperature 98.4°. In three days all the numbness disappeared and she was as well as before.

May 1. After an interval of two weeks a second similar attempt was made. Her weight had fallen from 142 to 132 lbs. partly owing probably to her much less active life. No ether was given.

1.40 P.M. Bandages applied as before and the arm rolled in cotton.

3.40 P.M. Restless. Morphia 1/4 gr. hypodermatically.

4 P.M. After 2 hours and 20 minutes the bandages were removed and the tourniquet applied. The subclavian symptoms were unaltered.

5.15 P.M. Vomited.

7.45 P.M. Tourniquet removed after 3 3/4 hours, and digital compression of the brachial substituted. Neither pulsation, bruit, nor thrill in the tumor at the elbow.

8 30 P.M. Vomited.

9 P.M. After 1 1/4 hours digital compression stopped. Radial pulse at wrist perceptible, but there was neither thrill, bruit, nor pulsation in tumor. A flannel bandage was applied to the whole arm and the arm secured to the body by a second roller.

2d. A fair night. Morning temperature 98.6°. Pulse 80.

4.10 P.M. No pulse, thrill, or bruit over the tumor, but at its inferior posterior margin a slight pulsation and bruit. Tourniquet reapplied.

7.10 P.M. Tourniquet removed after three hours. No pulsation, thrill, or bruit. Arm bandaged as before.

3d. 1.30 P.M. On removing the bandage slight pulsation was felt. Bandage at once reapplied with a moderate compress over the aneurism. Pulse 78; temperature 99.2 .

4th. Bandage removed and reapplied. Pulse 88; temperature 100.6°. No pulsation, thrill, or bruit.

Menstruation appeared at its normal date. From this date till the 20th she improved daily. The bandage and compress were continued, and she sat up on the 15th for 1 1/2 hours. On the 20th, after 19 days absence, the bruit, thrill, and pulsation returned as before, and the tumor again appeared and increased in size. The subclavian symptoms were unaltered.

29th. 1.15 P.M. Being unwilling to try the bandage again, she was etherized and the following operation was done, Dr. Thomas G. Morton assisting. An incision three inches long was made over the centre of the aneurism. A branch of the brachial, which dipped down beneath a cluster of enlarged veins, presumably the ulnar from its size and position, was first ligated. The veins were very numerous and large and their walls thin and friable, so that they tore on slight attempts at dissection and the loss of blood was very large, but was controlled by two Esmarch bandages applied above and below the seat of the operation pending the ligature of everything that bled. A number of these veins could not be separately dissected, but had to be tied in mass with the surrounding cellular tissue. No distinct point of communication between the artery and veins was found, and no sac was discovered; no evidence of clots from the previous Esmarching

was observed. The operation required 1½ hours. Strict antiseptic precautions were employed (carbolic acid being used). Combined tubular and capillary drainage by rubber tubing and horsehair was provided; the wound was closed by eight silver sutures and dressed with carbolized gauze.

30th, 9 A.M. Pulse 100; temperature 100.2°. Had passed a fair night.

7 P.M. Pulse 103; temperature 100.4°. Wound redressed, rubber tubing removed, moderate bloody serum on the dressings.

31st. Comfortable and bright. Morning temperature 99.8°; evening, 100.5°. Ten grains of quinine in the day.

June 1. Temperature 99.4°.

2d. Temperature 98.4°.

3d. Temperature 98.8°. Most of the horsehair and four sutures removed to-day, at the second dressing. Wound nearly healed. Meat diet, as she was hungry.

7th. Rest of horsehair and sutures removed; no pain. Sleeps and eats well.

8th. Sat up for an hour.

23d. Went out for a walk.

26th. Discharged well. Weight 132 pounds.

At present, November, 1887, she still remains well as to the arm. The symptoms, as to the probable innominate aneurism, remain stationary. She has married, and is pregnant.

The following sphygmograms were taken before the Esmarching at both wrists, and during the Esmarching at the left wrist, and again at both wrists twenty-nine days after the ligation had been done, to show the effect on the arterial tension and the action of the heart. It will be observed that prior to the application of the Esmarch bandage the sphygmograms show a very marked difference in the two radials (Figs. 3 and 4), that of the right or

FIG. 3.

Right radial before Esmarching.

FIG. 4

Left radial before Esmarching.

diseased side showing a far greater excursion—*i. e.*, arterial relaxation—while both curves are about normal. In ten minutes after the application of the Esmarch the left radial curve (Fig. 5) is altered, its

FIG. 5.

Left radial ten minutes after Esmarching was begun.

excursion increasing, its angles, both of ascent and descent, losing their acuteness, and the secondary recoil curve upward in the middle of the descent being lost. These changes go on progressively, especially the increasing range of the excursion, until one hour and twenty-five minutes after the Esmarching had begun (Fig. 6), when the left radial

FIG. 6.

Left radial one hour and twenty-five minutes after Esmarching was begun.

tracing consists of a series of convex curves of almost equal value as to ascent and descent. In twenty-four minutes after the Esmarch bandage was removed, the left radial had regained about its normal excursion, but the curve was indistinct; especially in its descent, a character it retained four hours later (Fig. 7). At this same later period

FIG. 7.

Left radial four hours after Esmarching ceased.

the right radial (Fig. 8) showed its first noticed excursion, but had not regained at all its normal

FIG. 8.

Right radial four hours after Esmarching ceased.

curve. Twenty-nine days after the ligation the two radials were again tested, and with the remarkable result (*cf.* Figs. 3 and 4 with Figs. 9 and 10) that the

FIG. 9.

Right radial twenty-nine days after ligation.

FIG. 10.

Left radial twenty-nine days after ligation.

excursion of the right radial (the diseased side) had dropped to even slightly less instead of nearly three times greater than that of the left. Neither curve was quite normal, however.

CASE II. *Spontaneous aneurism of an interosseous artery of the hand in a girl of eight years; spontaneous cure.*—Miss M., aged twenty-four years, from whose right arm I removed a large horny mole November 16, 1887, was a delicate child. At eight years of age she sprained her right hand while practising gymnastics with an older and larger girl. A tumor appeared in the interosseous space between the fore and middle fingers just above the knuckles. She was taken to the late Dr. Willard Parker, of New York, who diagnosticated an aneurism, both thrill and bruit being present. She felt the thrill herself. Dr. Parker advised care as to lifting, and improvement of the general health, but no operation. In the course of seven or eight years it disappeared spontaneously. The interosseous space at the site of the

former aneurism is, at present, at least twice the width of the corresponding space on the left hand, and has a soft, boggy feel. No present evidence of the aneurism exists.

These two cases are peculiar, by reason of the very early age at which they arose. In vol. lxvii. of the *Medico-Chirurgical Transactions* for 1884, Mr. R. W. Parker has collected all the cases he could find of spontaneous extracranial aneurisms in persons under twenty years old, and the entire list includes only fifteen cases. To these fifteen I add the two reported this evening, and the following eleven additional cases, making twenty-eight in all. Of these I owe the first seven to the efficient search of Dr. William J. Taylor, and the last four to Dr. James C. Wilson.

CASE XVIII. *Aneurism of the left superficial palmar arch and left ulnar.*—Jschi Woinarski (*Australian Medical Journal*, May 15, 1884). At twelve years of age, while lifting a weight in some domestic duties, patient felt something give way in her left hand, and immediately after noticed a pulsating swelling in the palm, and some time after a similar swelling at the inner anterior aspect of the left wrist. Neither rheumatism, scarlet fever, nor hereditary taint existed. Heart normal. After failure by pressure with Martin's rubber bandage he tied the brachial artery with a successful issue.

CASE XIX. *Aneurism of the elbow.*—Mr. Pollock (*British Medical Journal*, 1886, ii. 1033). A boy of fourteen years, with ulcerative endocarditis. The aneurism appeared three days after admission. Death followed, without interference with the aneurism, in a few days, and embolus was discovered at the seat of the disease.

CASE XX. *Arterio-venous aneurism of the occipital artery and right and left transverse sinus.*—(Rizzoli, quoted by Bramann, *Archiv für klin. Chir.*, 1886, xxxiii. p. 69). Female, aged eight years. Caused by exposure to the sun apparently. Without treatment the child died of meningitis. The post-mortem showed a defect in the skull, and the communication above stated. (This case and the two following I must cite at second hand, as the original references are not accessible to me.)

This case is the only one, besides the first case I report, of spontaneous (?) *arterio-venous* aneurism arising under twenty years that I have found. It is, at least, a curious coincidence that it apparently arose from exposure to the sun's heat as my own first case did from, or, at least after, sunstroke.

CASE XXI. *Aneurism at the elbow.*—(Jobert, quoted by Bramann, *vide antea*, p. 22). Male, aged eighteen years. Spontaneous origin. Cured by two injections of liquor ferri.

CASE XXII. *Varicose aneurism of popliteal.*—(Boling, quoted by Bramann, *vide antea*, p. 38). Male, aged sixteen years, apparently spontaneous origin. Sudden on-set. Cured by amputation. The popliteal artery and vein had been perforated by an exostosis. (Perhaps this case should be excluded by reason of its cause.)

CASE XXIII. *Spontaneous aneurism of left iliac.*—Alfred C. Post (*New York Journal of Medicine and Surgery*, iii. August 26, 1840). A blacksmith, aged twenty years, had had syphilis. Nine months previously he had first noticed the tumor, size of a filbert, with marked pulsation. It was treated as a bubo, and finally opened, when its aneurismal character was first discovered. Death. No autopsy.

CASE XXIV. *Aneurism of the arch of the aorta.*—Mr. Hutchinson (*Transactions of the Pathological Society of London*, v. 104). A girl, aged four years. No prior symptoms of aneurism. Child died after ten days' illness, of acute pericarditis. Mr. Hutchinson believed that the aneurism originated as an abscess, and had ulcerated into the vessel. The lining membrane of the aorta was smooth and perfectly healthy up to the edges of the orifice of communication (one-fourth by one-eighth of an inch) with the sac. This was the size of two chestnuts placed side by side, and hung from the arch of the aorta into the pericardium, compressing somewhat the pulmonary artery. The heart was normal, but in the lungs were tubercles, with chalky concretions in the bronchial glands. (Possibly this case should be excluded from the list as not probably arising spontaneously in the artery.)

CASE XXV. *Aneurism of the ductus arteriosus in a child a month old.*—Martin (*Bull. Soc. Anat.*, 1827, ii. 17.) Size of nut, filled with a clot, and impervious.

CASE XXVI. *Aneurism of the abdominal aorta in a fœtus, causing dystocia from the size of the tumor.*—Phänomenow (*Archiv f. Gynækol.*, 1881, xvii. 133). Breech presentation; stillborn; circumference at navel fifteen and three-quarters inches; circumference of head thirteen inches; endoarteritis of aorta; dilatation of left ventricle.

CASE XXVII. *Aneurism of the arch of the aorta in a child of eight years of age; result unknown.*—Roger (*Bull. Soc. Méd. des Hôp. de Paris*, 1863, p. 499). Child of ten years; out of health for five years. First suffocative attacks at eight years of age; tumor above and to left of sternum. Passed from under observation.

CASE XXVIII. *Aneurism of the arch of the aorta in a boy of thirteen years of age.*—Sanné (*Rev. Mens. des Malad. de l'Enfance*, Feb. 1887). Dyspnœa; death; cardiac hypertrophy; aortic arch thinned, dilated with an aneurism; aortic valves with vegetations.

The cause of spontaneous aneurism is most frequently an embolus arising from valvular cardiac disease. The most remarkable case arising in this way that I have found is the one reported by Langton and Bowlby, in the *British Medical Journal*, 1886, ii. p. 1031. This case seems to be absolutely conclusive as to the causative relation between embolism and aneurism.

The girl, aged twenty years, had ulcerative endocarditis. Three and four weeks, respectively, before her admission to the hospital aneurisms appeared at the right elbow and right popliteal space, for which the brachial and femoral arteries were successfully tied. Six weeks after admission she became hemiplegic, and died two weeks later. The sinuses of Valsalva were dilated, the arteries diseased at a large number of places, multiple emboli and aneurisms were found in the vessels of the brain, trunk, and extremities.

But we must also recognize endoarteritis as another distinct cause. That this may begin soon after and even before birth Cases XXV. and XXVI. will show. Rauchfuss in his Dissertation (1869) has collected the literature bearing on the subject and well discussed it. It is certainly very rare in early life as is natural, but when it does occur may easily give rise to aneurism. Moutard Martin (*Bull. Soc. Anat.*, 1875, p. 775) gives a striking case of atheroma of the arch and hypertrophy of the heart in a boy two years old, which presents all the needed factors for the later formation of such an aneurism had not the child's life been suddenly cut short by smallpox.

Many of the cases in the table of Mr. Parker arose also from embolism. But a few arose from

endoarteritis, as proved by the autopsies. In my first case the heart was normal. The aneurisms, I believe, arose from the diseased state of the arterial walls, which was first shown by dilatation of the smaller arteries causing the peculiar mottling of the surface nearly two years before the presumable origin of the aneurisms. The vessels being weakened, it only required some sudden strain, or possibly a blow, as in her fall when sunstruck, to cause a rupture, this rupture apparently at once breaking also into the similarly weakened coats of the neighboring veins at the elbow (the diseased state of the coats of the veins was shown conclusively at the operation), while in the innominate the second aneurism is limited to the artery alone. The first two sphygmograms seem to confirm this view, for while generally that taken on the diseased side shows lessened force, in this case the universally dilated and weakened arteries allow of a larger sphygmographic excursion. It is extremely interesting also to notice that, though the brachial had a high bifurcation and the ulnar alone was tied, yet the effect of the operation was to restore the right (diseased) radial to almost the same sphygmographic tracing as that of the left.

As to the treatment, I deemed it best to discontinue the Esmarching on both occasions by reason of her general condition of extreme restlessness and discomfort (in spite of her fortitude), and the marked variation of the left radial pulse. This showed a profound change in the increased arterial tension and altered curve (Fig. 5). The first could have been overcome by ether, but the anæsthetic might have added to the circulatory dangers. Esmarch's bandage has been applied continuously for as long as eight hours I knew, but I was unwilling to risk its further application in this case in view of the possible cure by the substitution of the tourniquet and also the good prospect of relief by an operation, as was shown later. As it was, an apparent cure was obtained for nearly three weeks by the tourniquet, digital compression, and compression by a roller bandage.

The operation was chiefly noticeable for the difficulty with which the hemorrhage was controlled on account of the diseased condition of the walls of the veins. They tore on the application of the slightest force, and at a number of points had to be tied *en masse* with the surrounding tissues to give additional firmness. The result was especially gratifying not only in the fact of a cure, but that I had no trouble from secondary hemorrhage, which I attribute to the antiseptic method. This secured the speediest possible union without any inflammatory reaction. The arm was entirely well in nine days after the operation.

ABDOMINAL SECTION FOR PERFORATED TYPHOID ULCER.[1]

BY THOMAS G. MORTON, M.D.,
SURGEON TO THE PENNSYLVANIA HOSPITAL, ETC.

IN THE MEDICAL NEWS of November 26, 1887, in an article on "Surgical Consideration of the Abdominal Complications of Typhoid Fever," by Dr. Thomas S. K. Morton, two cases of abdominal section for perforating typhoid ulcer are reported. The first operation was performed at Strasburg in October, 1885, by Professor Kussmaul, who excised that portion of the gut including the perforation; the wound was closed by Lembert sutures, the peritoneal cavity cleansed with a salicylic solution, a large drain was inserted, and the abdominal wound closed; the patient never reacted, and died eleven hours afterward.

The second case was under the care of Mr. T. H. Bartleet about a year ago at Birmingham; perforation was diagnosed, an abdominal section was made, "great fecal extravasation was discovered upon opening the peritoneal cavity, an unsuccessful hurried search was made for the bowel opening, the cavity was irrigated, a drain put in, and the parietal incision was closed; the patient died during the second day after the operation." These two cases, with the one which very recently came under my observation, constitute all the instances I have been able to find of surgical interference in the intestinal complications of typhoid.

Even the most recent works on abdominal surgery make no mention of the surgical treatment of this complication in typhoid fever, nor of the possibility of repairing the intestine after perforation.

In the Philadelphia *Medical Times* of December 11, 1886, Dr. James C. Wilson called the attention of the profession to the possible propriety of surgical interference in perforating typhoid ulcers, and says: "In point of fact, the objections which may be urged against laparotomy in intestinal perforation in enteric fever, are no more forcible than those which would have been made use of, at first, against the same operation in gunshot wounds of the abdomen," and the fact must not be overlooked, says Dr. Wilson, that "while a few cases of perforation occur in the second week of the disease while the infective process has yet some time to run, a far larger proportion take place in the period of convalescence when the condition of the patient, except for deep ulceration, often single, is tending toward recovery."

Granted that the diagnosis of perforation has been made out, shall a patient, although in a most unfavorable condition from the very nature of the malady for any operation, be allowed to perish? or ought the surgeon to feel justified in making an attempt to save life? Indeed, is it not his duty to open the abdomen and repair the perforated gut? Especially it would seem to be indicated when the accident has been early recognized, and the patient not in a sinking or moribund condition.

Although recoveries after supposed typhoid perforation have been reported, it is highly probable that there was an error of diagnosis, at least recovery must be extremely unusual, for the fatality of such a complication is universally recognized.

The following case represents, so far as I am aware, the first operation done in this country for the repair of a perforated typhoid ulcer; unfortunately it was not undertaken until many hours after the accident had occurred, but the patient's condition even at that late period gave sufficient encouragement to

[1] Read before the Philadelphia Academy of Surgery, December 5, 1887.

warrant the performance of a formidable operation under most trying circumstances, and which, I believe, in no wise hastened the fatal termination.

Lee A., aged twenty-three, enjoyed perfect health until the last week of October, 1887. He then acquired specific urethritis, but was little troubled thereby and continued his usual occupations. One week later he first presented symptoms of typhoid fever.

His was what is commonly called a "walking" case of that disease, and he was scarcely in bed at any time until the last day and a half previous to his sudden death. Dr. Lewis W. Steinbach was his physician, and so light did the case seem that he had ceased visiting him regularly. Although at most it was but the end of the third week of disease his temperature had for several days been scarcely above the normal. On the afternoon of November 12th, he felt very well, and in the absence of his family he ate a hearty meal of meat, etc.

A few hours afterward he was seized with most excruciating pain in the right lower portion of the abdomen, followed shortly by a violent chill and subsequent rapid rise in temperature and pulse and respiration rate.

The abdomen became tympanitic, and the pain more diffuse.

I saw him in consultation next morning, positively diagnosed perforated typhoid ulcer, and urged abdominal section as the man's only chance. To this advice he and his friends were sensible enough to conform, and preparations for operation were at once made.

The man was of splendid physical frame, and at the beginning of his illness had weighed 190 pounds. Just before operation his temperature was 104½°, pulse 156, respiration about 45. His face was deeply flushed. He seemed perfectly rational; being able himself to decide in favor of the proposed operation. During the night he had vomited several times, but otherwise the symptoms aggregated simply as above at this time.

A room was cleansed as well as possible; anæsthesia by ether induced, and he was transferred to the table and the abdomen shaved and made surgically clean.

Operation.—Twenty hours after perforation; condition as above. A median incision from just below the umbilicus to the symphysis pubis was made. Considerable yellowish serum poured out, and in it floated flakes of purulent lymph. A little gas and feculent material also thus made their exit. The small intestine was at once turned out, and searched from the cæcum upward. About three feet above the valve a perforation was discovered. It was about three-eighths of an inch in diameter, and occupied the lower (toward the cæcum) end of a large ulcerated Peyer's patch. This lesion was repaired by turning the whole area of ulceration into the lumen of the bowel by means of eight Lembert sutures. These were started into the two outer coats of the bowel, about three-sixteenths of an inch from the edge of the ulcer, brought out again one-sixteenth of an inch from that edge, then reintroduced in like manner upon the other side of the ulcer, paying no attention to the ulcer and bowel-tissue between. When these eight sutures were tied, the perforation, ulcer, and the bowel-tissue below it turned into the lumen of the bowel, whilst the peritoneal surfaces came into apposition above. This done, and the remaining portion of the intestine having been examined, attention was directed to a necrotic-looking ulcer which had been observed not far above the cæcum.

The ulcers were all outlined upon the peritoneal surface by a deep dusky-red, slightly swollen area corresponding to their own outlines. The one especially referred to presented in a portion of its area a gray aspect, as if of sphacelus. Although there was no actual perforation at this point, its speedy occurrence was thought likely, and that the more prudent course would be likewise to turn in this ulcer area. This was accordingly done with about six Lembert sutures. No other lesions were discovered upon further search of the intestines, etc., although ulcerations extended to quite a high point of the small gut. The whole intestine was greatly distended with gas, and quite difficult to manipulate: it was congested to a dusky-red hue throughout, while in various sized patches here and there the peritoneal covering of the gut was in a state of arterial hyperæmia, with an occasional recent ecchymosis.

The abdomen was then cleansed by very copious irrigation with water which had been boiled, and allowed to cool to a temperature of about 110° to 105°. Then the cavity was sponged dry, and the intestines returned: they had during the whole process been protected by towels wrung out of hot water, and frequently changed.

Considerable difficulty was experienced in returning the intestines from their great distention, but it was accomplished without resorting to puncture.

The parietal wound margins were then brought into apposition with a glass drain running through the lower extremity of the wound, and down to the bottom of the pelvic cavity.

The patient speedily became conscious upon withdrawing the anæsthetic, and remained so, without pain, for several hours, although the pulse, temperature, and respiration still kept very high. Six hours after operation, he suddenly sank into a collapsed condition, became cold and pulseless, and in an hour died.

Post-mortem examination, twenty-four hours after death. Decomposition far advanced. Drain-tube had been removed shortly after demise. Upon opening the abdomen by an incision parallel to the operation-wound, everything was found to be as it should. The intestines were distended with air, and also contained a small amount of yellow feculent liquid. Some few of the coils in the upper portion of the cavity were slightly adherent from the presence upon their surface of recent, healthy looking lymph. Others of the coils were congested to a bright pink color. There were no subperitoneal ecchymoses upon the intestines, but here and there, upon the surface of the mesentery, near the intestinal attachment, were to be seen such extravasa-

tions; none were of greater extent than a half inch diameter. In the deeper tissues of the intestine, however, ecchymotic spots were present at quite a number of points—one larger than a quarter inch in diameter.

Typhoid ulcers extended to a distance of probably eight feet above the cæcum; those nearest it being most marked, and, with one or two exceptions, furthest advanced. Three inches above the valve was the ulcer which had looked necrotic at the time of operation, and which had been turned into the lumen of the bowel as a precautionary measure. It was in excellent condition. Three feet above the cæcum the repaired perforated ulcer was come upon, and found in like excellent condition.

No additional perforations were discovered, and the intestine when distended even forcibly with water did not leak or give way at any point.

The lumen of the bowel at the points of suture, when moderately distended, was at least an inch. There was marked enlargement of the mesenteric glandular system. About two ounces of clear serum had collected in the hollow of the sacrum since taking out the drain tube, which had been done a few moments after death. The peritoneum was perfectly clean and free from extraneous matter, purulent lymph, or blood. The parietal incision had undergone no other change than that of simple gluing together of its surfaces.

The examination did not extend beyond the abdomen: otherwise than as above, the search of that cavity was negative.

Time for operation.—As soon as the diagnosis of perforation has been made out, the operation should be immediately performed, every moment of delay increases the danger of the situation; indeed if any successful results are to be chronicled, those operations which are undertaken immediately after the perforation will unquestionably be the successful ones.

Method.—One of three methods can be adopted, should an operation be decided upon: First, the perforation can be closed with Lembert sutures; second, a formal excision of a portion of the gut, including the entire ulcer as performed by Kussmaul; or third, the bowel can be brought to the surface and an attempt made to form an artificial anus.

Incision.—The median abdominal incision affords the best opportunity for an examination of the intestines; it should be ample and extend from the umbilicus to within two inches of the pubes; any portion of the intestine likely to be involved can thus be easily reached; the search should be thorough, and in addition to closing the perforations, the intestines should be carefully examined to determine the condition of other ulcers, and if any be found in which perforation seems likely to occur, such should be turned into the bowels by Lembert sutures in a similar manner.

Prior to abdominal closure the belly should be thoroughly cleansed with hot water. The after-treatment would not vary from the usual treatment of typhoid fever.

It is interesting to note that an examination of the specimens of the above case showed that although a considerable amount of tissue had been turned in, in both places, where the perforation existed, and where a perforation seemed likely to occur, no unsafe or marked diminution in the calibre of the bowel was found.

TREATMENT OF INTRALARYNGEAL ABSCESS FROM NECROSING CARTILAGE.

BY J. SOLIS COHEN, M.D.,
OF PHILADELPHIA, PA.

On the principles of good surgery, intralaryngeal abscess from diseased cartilage is best treated by splitting the larynx in the middle line, removing the dead structures, and thoroughly scraping the parts down to healthy tissue. This being accomplished, measures should be immediately taken to provide for drainage in case of continuation of the suppurative process and to adopt such aseptic management of the parts as the conditions found may indicate. Thorough response to these indications may require precautionary tracheotomy for respiratory purposes until subsidence of the diseased process has taken place, or for purposes of securing functional rest to the larynx when such subsidence is not going to take place.

This plan is far more judicious than to await the fragmentary discharge of carious particles, or carious cartilages by expectoration, or attempts at their withdrawal by intralaryngeal procedures through the normal apertures. When the larynx is exposed by section to direct vision, the entire extent of the disease can be determined, and fatally diseased tissues be removed at once. The impairment of voice which may follow must be regarded as a secondary matter in the great majority of instances. Prompt treatment of this kind ought to save many cases that perish because proper surgical interference is postponed so long that the hurried tracheotomy performed in an emergency merely saves the patient from impending suffocation, while he dies a few days later from septic poisoning, the result of absorption of pus which should have been evacuated by the most direct access possible, whether by intralaryngeal puncture or incision, or by cutting down upon the parts from the exterior.

A CONTRIBUTION TO THE PHYSIOLOGICAL ACTION OF THE HYDROBROMATE OF HOMATROPINE,

WITH A SUMMARY OF ITS ACTION ON THE EYE.

BY GEORGE E. DE SCHWEINITZ, M.D.,
OPHTHALMIC SURGEON TO THE PHILADELPHIA HOSPITAL AND OPHTHALMOLOGIST TO THE ORTHOPÆDIC HOSPITAL AND INFIRMARY FOR NERVOUS DISEASES.
AND
H. A. HARE, M.D.,
DEMONSTRATOR OF EXPERIMENTAL THERAPEUTICS AND INSTRUCTOR IN PHYSICAL DIAGNOSIS IN THE UNIVERSITY OF PENNSYLVANIA.

Action on the eye.—The thorough study of the action of hydrobromate of homatropine by Risley[1] and Jackson,[2] in which they prove that this drug is

[1] The Comparative Value of the Mydriatics. S. D. Risley, M.D. Trans. of the American Ophthalmolog. Soc., 1881.

[2] Homatropine Hydrobromate. E. Jackson, M.D. THE MEDICAL NEWS, July 24, 1886.

entirely satisfactory for the correction of anomalies of refraction, and that it is an efficient and reliable mydriatic, is so entirely in accord with our own experience that this communication will not be burdened with statistical facts in further confirmation of this belief.

Method of employment.—In order to acquire full control of the accommodation, frequently repeated instillations of the drug must be employed. Jackson prefers a solution of a strength equal to 1 in 50 or 1 in 40. Our own experience has been almost entirely with one equal to 1 in 80, and we have only occasionally used stronger solutions. The patient is directed to put a drop of such a solution in each eye at bedtime on the night before the measurement is to be made, and every fifteen minutes for one and a half hours the next morning. The latter instillations are most advantageously made by the surgeon himself. If the ordinary tests do not then show that the accommodation is under control, the instillations may be continued. Very occasionally it has seemed wise to repeat this procedure on the following day.

Pupil and accommodation.—As has been noted before, the effects of this drug upon the pupil and the accommodation proceed *pari passu*—in other words, dilatation of the pupil and paralysis of accommodation end together.[1] The pupil usually begins to dilate in from seven to twenty minutes after the first instillation, the average in about fifty observed cases being from ten to fifteen minutes. The drug obtains control of the accommodation in about one hour—Jackson says in from forty to ninety minutes—and begins to lose its hold in from one to two hours; in Jackson's observations in from one to six hours. Recovery takes place in from eighteen to seventy-two hours. When the duration of the drug's effects was longer than three days, suspicion was not wanting that a perfectly pure homatropine had not been obtained. Homatropine probably dilates the pupil, as atropine does, by a peripheral action. The present communication does not include experiments upon this point.

Local effects.—Slight smarting is not infrequently complained of by the patient immediately after the application. Oliver[2] states that the conjunctival irritation of hydrobromate of homatropine may be avoided by the use of a perfectly neutral salt. The smarting is of no moment, although after repeated instillations slight injection of the bulbar conjunctiva is, we think, always present. This hyperæmia is well described by Jackson (loc. cit.). We have in one instance only seen a distinct conjunctivitis follow the frequent use of the drug. The homatropine solution in this instance was freshly prepared and the applications were made with our own hand. In a few cases we have observed after the use of this mydriatic in the manner just described, that a *slight* gray haze appeared in the fundus, or that the choroid became "woolly." These appearances invariably had disappeared when the effects of the drug had subsided. Such slight changes in the eye ground are scarcely seen or not seen, according to circumstances, that this point needs verification. Jackson has noted that hypodermatic injections of homatropine produce hyperæmia and later abscess. We have no observations to add to this statement.

General effects.—The toxic effects which quite frequently appear after the use of duboisine and much less frequently after atropine and hyoscyamine are well known. The comparative great infrequency of constitutional disturbance after the use of even frequently repeated instillations of strong solutions of homatropine renders this method safe just as it is reasonably accurate. In more than two hundred cases Jackson found only three who complained of feeling a little "strange" or intoxicated. Risley[1] has observed distinct drowsiness.

Ziem,[2] by the employment of a small quantity of a one-half per cent. salve of homatropine in the conjunctiva, produced distinct intoxication. We have in our series of cases seen one instance of hallucinations and incoherency of speech. The patient was a highly neurasthenic woman nearing the menopause. A distinct *influence upon the circulation* is a phenomenon quite commonly to be noted after the frequent instillation of this drug in the conjunctival sac. Jackson (loc. cit.), in speaking of its action upon the circulation, says, "In my experience a decrease in the pulse-rate is the most constant symptom produced. Next to this is an increase in the fulness and force of the radial pulse." In our own experience a distinct decrease in the number of pulse-beats has frequently, but not invariably, been present. In order to determine experimentally the reason of this slowing of the pulse, as well as the action of the drug upon the cord and peripheral nerves, this paper was especially undertaken.

Summary.—Hydrobromate of homatropine, properly applied by frequent instillations, is a reliable mydriatic for the correction of anomalies of refraction in healthy eyes. Experience with us is not at hand to determine its value for this purpose in eyes affected with retino-choroidal disturbance. Atropine and hyoscyamine are preferred, for the obvious reason that their prolonged action is desirable as a method of treatment. The danger of systemic disturbance from homatropine is far removed, even when repeated instillations have been made. Its temporary action upon the pulse causes no inconvenience to the patient. Slight hyperæmia of the conjunctiva almost invariably follows its use; true conjunctivitis, if it occurs at all, must be excessively rare.

When a dose of homatropine amounting to three-quarters of a grain is injected into the posterior lymph sac of a medium-sized frog, there follows in the course of from one to two minutes, a peculiar change in the respiratory rhythm resembling closely the so-called Cheyne-Stokes breathing; this is followed by a marked decrease in respiratory movement, both as regards numbers and depth, the breathing becoming more and more shallow, and finally stopping entirely after the lapse of three minutes from the administration of the drug. Tests show at this time that sensation is entirely unaffected,

[2] Centralblatt f. Augenheilk., Aug. and Sept. 1887.

and that voluntary movement is well preserved. But slight changes take place in the condition of the batrachian after this for many minutes; but finally, forty minutes after the poisoning, slight tetanic spasms develop themselves, which at first seem to be due to external irritation, but which later occur entirely without cause from the periphery apparently. The stage of spasm, however, lasts but a few minutes, and the frog rapidly passes into a condition of relaxation and paralysis.

At this time electricity produces normal contractions in the muscles, while galvanizing a motor nerve trunk calls forth a response in the tributary muscles, showing that the drug in producing paralysis must act on the spinal cord or brain.

That it acts on the spinal cord is proved by the fact that if a limb be protected from the action of its power by tying its artery, reflexes fail as completely when stimuli are applied to the protected as when irritation is used to the unprotected leg, so that the influence cannot be on the sensory nerves. Further than this, if another frog have a ligature tied tightly around the limb, in such a manner that nothing escapes its grasp save the nerve trunk, and the drug be given below the ligature into the limb, reflexes remain quite as active on impulses applied to the drugged as to the normal leg. Again, we have proved that the direct application of drop after drop of a solution of six grains to the ounce of water to the bared sciatic fails to retard the passage of sensory impulses up to the spinal cord.

In one experiment, however, it appeared that when the drug was given into the body, and the limb was protected, reflexes at first were somewhat stronger on irritating the protected toes than when the unprotected foot was irritated. This condition was only temporary, and must have been due to some fallacy in the test, since the other experiments directly on the nerve trunk failed to discover any influence. When the drug is injected directly into a limb, and held there by ligature above, the muscles seem to retain their power of reacting to the electric current as normally as usual.

We may, therefore, conclude that homatropine produces, in very large dose, at first but a slight change of respiratory rhythm, followed shortly by failure of respiration, which is again succeeded after some time by a period in which tetanic spasms assert themselves, alternating with relaxations approaching paralysis, which finally deepens into absolute palsy, with failure of all nervous phenomena. The spasms are evidently, from their tetanic character, spinal, as is also the palsy, the nerve trunks and muscles being unaffected. These experiments coincide with those of Tweedy and Ringer,[1] who, carrying their experiments to a greater length of time, found that in six to eight hours the palsy was replaced by a return to voluntary movement, which was associated with tetanic spasms of greater intensity than the first.

The action of this drug on the circulatory system is, however, much more interesting to the clinician, since it almost invariably produces a slowing of the pulse when frequently dropped in ordinary solution into the eye.

The following table shows better, and more briefly than can be done by ordinary text, the effect of the drug when applied to the heart lying *in situ*:

Time.	Drug.	Pulse.	Remarks.
9.03	.....	42	
9.04	.....	42	
9.05	5 drops	42	Solution 3 grs. to ½ oz.
9.06	.....	36	
9.07	.....	30	Diastole prolonged, systole incomplete.
9.08	.....	30	Diastole very full.
9.13	.....	30	
9.15	5 drops more	.....	
9.17	.....	30	
9.19	.....	26	
9.28	.....	26	Fibres of heart muscle about apex very well marked.

From this experiment it becomes evident that homatropine slows the pulse by a direct action on the heart itself, or its ganglia, or the peripheral ends of the vagi. Tweedy and Ringer (loc. cit.) also reached identical results.

In the experiments performed by us on the higher animals (dogs), notwithstanding the fact that they were frequently repeated, we found that large amounts of the drug affected the heart but little.

When ten drops of a solution of six grains to the ounce are injected into the jugular vein, in the course of from one to two minutes there occur a slight fall of pressure, and an equally slight decrease in the number of pulse-beats. If the dose has amounted to as much as thirty drops, these symptoms occur again, but to a more marked degree, the rate falling as much as thirty or forty beats per minute, while the pressure may fall an equal number of millimetres of mercury. That the fall of pressure is not due to depression of the vasomotor system is proved by the fact that the production of asphyxia always was followed by rise of pressure; and that the slowing of the rate was partly due to vagal stimulation, was proved, we think, by the fact that section of the vagi always caused a marked increase in the pulse-rate, although not such a rise as would appear if the inhibitory apparatus were intact. These results were reached both in curarized and non-curarized dogs, and are undoubtedly correct.

The conclusions which we think may be drawn from these experiments are as follows, namely, that homatropine slows the heart of both frog and mammal, by a direct depressing effect on that viscus, aided at the very first by a stimulation of the inhibitory apparatus, as was witnessed by the effect of section of the vagi in dogs, and by the prolonged and full diastole in the heart of the frog.

It will be seen, therefore, that Tweedy and Ringer were right in their statement that homatropine acted upon the heart in much the same manner as atropia itself, although to a weaker degree. Beyer has also reached results on the heart of the terrapin similar to our own.

[1] Lancet, 1880, vol. i. p. 795.

FRAGILITAS OSSIUM.

MULTIPLE FRACTURES (THIRTY-TWO) OCCURRING IN VARIOUS MEMBERS OF A FAMILY.

BY T. D. FOREST WILLARD, M.D.,
OF PHILADELPHIA

THE father of the brittle family described below was a small, spare man; the mother, large, corpulent, and excessively hysterical. There was no history of broken bones in the ancestry of either parent. Both denied the existence of syphilis, and neither of them bore any traces of this disease. The children were all small—some of them almost dwarfs; all were puny and had notched teeth, still they rarely suffered from serious illness, and as there have been no deaths an opportunity has not been offered for an examination of the osseous tissues.

A.—Father.

1. Fracture of right clavicle. Direct and decided violence.
2. Fracture of right clavicle (several years later). Direct and decided violence.
3. Fracture of rib. Direct and decided violence.

B.—Daughter, now eighteen years old. Height, four feet.

1. Left femur, upper third, twelve months. Fell one step to pavement.
2. Left femur, upper third, two and a half years. Tripped on carpet.
3. Left femur, upper third, three years. Slipped upon oil-cloth floor.
4. Left femur, upper third, four years. Jumped from low stool.
5. Left femur, upper third, seven years. Slipped on ice.
6. Left femur, upper third, seven and a quarter years. One day, after resuming walking, turned suddenly and callus snapped.
7. Left femur, upper third, nine years. Fell two steps.
8. Right femur, upper third, twelve years. Tripped on carpet.
9. Left clavicle, seven years. Fell down stairs without other injury.

(Both femora now united with a projection anteriorly about two inches below the trochanters. The fragments are at right angles to each other; but union has been strong and serviceable for the last six years. Walks with difficulty.)

C.—Daughter.

1. Right femur, upper third, four years. Turned suddenly while standing at a window; screamed before she fell.
2. Right femur, upper third, seven years. Tripped on carpet.
3. Right femur, upper third, sixteen years. Fell on ice.

Left clavicle, six years. Fell from a chair.

Left clavicle, twelve years. Fell backward on floor.

(Femur united with right-angled deformity laterally.)

D.—Daughter.

1. Right femur, upper third, eight weeks. Cause unknown.
2. Right femur, upper third, fifteen months. Slipped on orange-peel.
3. Right femur, upper third, twenty-two months. Fell one step to pavement.

(Femur now firmly united for eighteen years, but with two inches of shortening and with anterior angular deformity.) (Dislocation of right shoulder at five years. Burned over nearly one-third of surface at fifteen, but survived.)

E.—Son.

1. Right femur, upper third, two years. Fell about eight inches.
2. Right femur, upper third, eight years. Knocked down in the street.
3. Right clavicle, three years. Fell from the top of a sewing machine.
4. Right rib, three years. Same accident.

F.—Daughter.

1. Left clavicle, at birth. (Easy labor.)
2. Left clavicle, thirteen months. Fell from a stool.

G.—Daughter.

1. Right clavicle, one week. Cause unknown.

H.—Daughter.

1. Left clavicle, at birth. (Easy labor.)

I.—Son.

1. Left clavicle, three weeks. Fell from a bed.

J.—Son.

1. Rib, seven years. Fell down stairs.

Only one child escaped. She was the largest and strongest of the family and has now two children, neither of whom has as yet received any injury.

The manufacture of this fragile ware was temporarily suspended by the demise of the male member of the firm, but seems destined to be speedily resumed, as the daughters have now commenced to bear offspring, and one grandchild has already, at four weeks, broken its thigh while being turned in bed, and at nine months has rebroken the thigh from a trifling cause.

These various fractures were treated by myself and numerous other surgeons in Philadelphia, and, as a rule, united speedily. In the femora the new line of fracture was nearly always through the old callus, although the union would seem to be perfectly firm, and an interval of several years had, in some instances, elapsed. The angle of deformity usually increased with each successive break.

Bone-forming food and medicines were given, but their influence could be only inferentially judged.

MEDICAL PROGRESS.

SUPPURATIVE PERITONITIS, WITH RECOVERY.—At a recent meeting of the Clinical Society of London, MR. BARWELL read a case of suppurative peritonitis; opening, washing, and sponging the peritoneum; recovery. The man, aged forty-two, accustomed to drink a good deal, was admitted into Robertson ward, Charing-Cross Hospital, on June 24, 1887. Six days previously he fell

and struck the left lower part of the abdomen, but seemed very little hurt. Five days afterward, he, in stooping, felt severe pain in the lower part of the abdomen; he vomited and passed a little very dark colored urine. (Absence or presence of blood cannot be verified.) He went to bed; his abdomen swelled; he passed very little urine; vomited after, and sometimes without, taking food. 24th. On admission he was placed in a warm bath; while in it he passed what may, he thinks, have amounted to a wineglassful of urine. At 2 P.M. Mr. Barwell found him with pinched, anxious countenance, pulse small, hard, and quick, and temperature 100.4°; dry skin; tongue somewhat coated; vomiting; abdomen slightly tender, save in the left iliac region, much swollen, very tympanitic, quite down to the pubes; tapping it produced a peculiar thrill not like that of flatulence. A No. 12 catheter brought away no urine, even though pressed far back, but the instrument when withdrawn was full of urine deeply stained with blood. 25th. On three occasions ten ounces of urine had been passed, at first with blood, the last sample free from blood, but slightly albuminous, sp. gr. 1.022; temperature 98; pulse 130; abdomen more distended. It being evident that the man had a bad type of acute peritonitis, Mr. Barwell opened the abdomen in the middle line below the umbilicus. A large quantity of gas, not of feculent odor, escaped. No rupture of any viscus was found, but in its lower part the peritoneum contained a quantity of thick pus; there were no adhesions; parts of the intestines were congested, and the membrane was somewhat thickened. Three sponges passed into the lowest part of the cavity were withdrawn covered with tenacious flocculent pus. A smooth-nozzled glass funnel was then deeply introduced, and the part of the cavity washed out with ten pints of distilled water, temperature 99°, bringing away quantities of pus and flocculi. After sponging, a second smaller washing and sponging was directed to the upper part. The abdomen was then sewn close without any drain. The whole operation, including giving the anæsthetic and dressing, lasted an hour. 26th. During the night and day the patient frequently vomited a brown fluid with darker concreta; pulse rather fuller, 110; abdomen scarcely distended, and tender only in immediate neighborhood of wound. Lies flat, save for a small pillow under the knees; says he is quite well, and wants to go home. 28th. The vomiting slowly decreased during the night; the bowels acted rather copiously four times. The vomiting ceased and all symptoms passed rapidly away. The rest of the history is merely that of rapid convalescence, the man being very importunate in requesting to be discharged. In his remarks, Mr. Barwell, referring to a paper by Mr. Hancock, claimed for Charing-Cross Hospital the first conception of the idea of opening the peritoneum for acute peritonitis. He also pointed out that this operation has been performed fourteen times, though the operator has not always known what was the precise nature of the case; and the circumstances have been very various—ulcers or rupture of some part of the intestinal tract, or of an ovarian cyst. He emphasized the impossibility of draining the lower part of the peritoneum through a wound in the front of the abdomen, and advised that no drainage tube should be here inserted immediately after operation, but that, if distention recurred, the lower stitches should be removed and escape permitted. The presence of a tube which cannot in that position act as a drain might be injurious rather than beneficial. In the female, drainage per vaginam would probably be the most valuable treatment.—*Lancet*, November 5, 1887.

Sodium Sulphite in Asthma.—As a modification of Bergeon's proposal to treat asthma by rectal injections of sulphurous acid gas, Battesti has employed

Sodii sulphit.	1 part.
Aquæ	500 parts.

of which a teaspoonful contains about one-sixth of a grain of the salt; this may be given several times daily, in proportion to the tolerance of the patient and severity of the symptoms.—*Revue de Thérapeutique*, November 15, 1887.

Argyriasis from Repeated Cauterization.—In the *Vratch*, No. 33, 1887, p. 635, Dr. M. S. Tolmatcheff, of the Rüza Zemsky Hospital, records a case of chronic argyriasis. The patient, a strong peasant, aged fifty-eight, had accidently pricked the sole of his foot with a nail. On his admission three months later a granuloma was found on the injured spot. This was partly cut away, partly scraped out, the whole denuded surface being subsequently "Paquelinized," and afterward cauterized with solid nitrate of silver. In the course of two months fifteen cauterizations of the kind were performed. The patient then left the Infirmary, but seven months afterward returned with a new and still larger granuloma. The same treatment was again carried out, and fifteen further cauterizations with the solid stick were performed in the course of two months and a half. About the end of that period the man began to lose flesh markedly, and to grow weak. In a few weeks left hemiplegia came on, the face became of a leaden color, with the ecchymoses under the eyelids; profuse brownish-black spots of the size of apple-pips appeared on the cheeks, forehead, neck, abdomen, hands, and feet; there was a bluish line on the gums, the sclerotics became discolored; the mouth was dry and had a bitter taste. Microscopical examination of a piece of the stained skin that was cut out showed that the brownish-black specks were situated mainly in the lower strata of the Malpighian layer, and in the upper ones of the subcutaneous cellular tissue. A month's treatment by tepid baths, iodide of potassium, and Glauber's salt, did not effect any improvement. According to Dr. Tolmatcheff's reckoning, the whole quantity of the silver salt employed in the case during a twelvemonth was not more than one drachm and a half, the average quantity used at a sitting taken at three grains.—*British Medical Journal*, Nov. 12, 1887.

For Blennorrhagia.—Ricord has prescribed with success

℞.—Aquæ rosar.	ʒ 50.
Zinci sulphat.	gr. 15.
Plumbi acetat.	gr. 30.
Tinct. catechu.	
Tinct. opii (Sydenham) . . .	āā ♏ 45.

for injection.

MAURIAC substitutes tannin for acetate of lead, and subnitrate of bismuth for tincture of catechu, and prefers the combination to the classic formula of R cord. —*Revue Générale de Clinique et de Thérapeutique*, November 24, 1887.

THE BACTERIOLOGY OF THE BREATH.—SHABLOVSKY and VARGUNIN, of St. Petersburg, conclude from the examination of expired air, that the reserve air is optically pure; that is, it does not contain any microbes (as Tyndall teaches). The negative results given by this series of experiments demonstrate also that the current of expired air does not carry away and out any microbes from the oral cavity.

But the expired respiration air does invariably contain microbes, though their numerical strength oscillates between wide limits. The average number amounts to 54.18 per cent. of all microbes floating in the surrounding atmosphere. The first moiety of the expired respiration air contains 80.54 per cent., and the other 27.82 per cent. of the atmospheric microbes.

The remaining 45.82 per cent. of the air microörganisms probably settle down for a while on the mucous membrane of the upper respiratory tract, to be subsequently expelled with expectoration, etc. Only a trifling proportion of microörganisms can penetrate into the pulmonary alveolar tissue, since the respiration air itself does not descend deeply into the lungs, the gas changes between it and the reserve and residual air proceeding by way of diffusion.

The following varieties of microbes were found by Dr. Shablovsky in the breath. (*a*) Colonies in the shape of patches of the size of a pin's head, of a rich milk-white color, with a slow growth on the surface of gelatine, the latter remaining unliquefied. They consisted of very mobile cocci and diplococci, measuring 0.5*u* in diameter. (*b*) Lemon-yellow colonies of the size of a hemp seed, with a slow superficial growth without changing gelatine. They consisted of large cocci, measuring about 1*u*, and forming groups of two or four individuals. (J. Eisenberg's yellow sarcina.) (*c*) Yellow-brown colonies, liquefying jelly, the liquefaction area having the shape of a shallow funnel, with irregularly fringed edges. Their growth was more rapid than those of *sub a* and *b*. They consisted of motionless monococci and diplococci, measuring 1*u*. (*d*) White colonies, which in the beginning had the shape of a small, irregularly fringed patch, but subsequently became surrounded by a zone of liquefaction, and then coalesced into a whitish formless mass. Their growth was fairly rapid. They consisted of motionless monococci and diplococci, measuring 0.7*u*. (*e*) Grayish colonies, swiftly spreading over and liquefying the surface of jelly. They were formed by micrococci, measuring 1*u*, chained two or three together, and endowed with a slight swinging and progressive motion. (*f*) Colonies of the bacillus subtilis. (*g* and *h*) Yellow-brown and yellow-white colonies of some yeast fungi. (*i*) Mould fungi (Penicillium glaucum and Aspergillus glaucus).—*Medical Chronicle*, November, 1887.

THE ACTION OF CHROMIUM.—DR. HEINRICH PANUM, of Dorpat, publishes an account of some researches he has made on the physiological action of chromium. The compound which he found to answer best was the double lactate of chromium and sodium. Chromic acid and its salts produced both acute and chronic symptoms, salts of chromic oxide causing only chronic or, at most, subacute forms of poisoning. The chromic acid compounds were found to be a hundred times more toxic than those of chromic oxide. The acute forms of poisoning show themselves by the disturbance of the respiration and of the central nervous system; chronic forms affect the skin and also the mucous membranes when air containing finely divided chromic oxide is allowed to come into contact with them. The heart's action was not directly affected by any of the preparations. The chief as well as the earliest morbid changes appeared in the kidneys under the form of parenchymatous nephritis, followed by the interstitial form: also in the gastro-intestinal tract, where inflammation, ecchymoses, and swollen follicles were found. There were also morbid appearances in the blood and the spleen. In chronic cases the spleen was shrunken and the hepatic parenchyma had a cloudy appearance. Chromium was found to be absorbed both when given hypodermatically and also when administered by means of the gastro-intestinal tract, at least when soluble compounds were employed. Chromic acid preparations were absorbed with great rapidity, both by the skin and the stomach. When in very small quantities chromic acid and its salts were reduced to chromic oxide. The elimination of chromium took place mainly by the kidneys, but also to some extent by the liver and bowels. Death was caused in acute cases by arrest of respiration and disturbance of the central nervous system; in chronic cases by morbid changes in the blood, the kidneys, and the digestive tract. Dr. Pander was unable to find any indication as to the value of chromium as a therapeutic agent.—*Lancet*, November 12, 1887.

A USEFUL APPLICATION DURING TEETHING.—QUINCERAT prescribes

Tannin	ʒ 2.
Tinct. iodin.	gtt. 75.
Potass. iodid.	gr. 15.
Tinc. myrrh.	℥ 75.
Aquæ rosæ.	ʒ 6¼.

A teaspoonful or tablespoonful should be used in a glass of water applied to the gums every morning, and after the mouth is cleansed after feeding.—*Revue de Thérapeutique*, November 1, 1887.

THE RELATION OF THE AIR TO COMMON DISEASES.—HENDERSON concludes an extended article on this subject in the *Glasgow Medical Journal* for October and November, 1887, as follows:

But, again, it is clear that the opinion we form of the etiological significance of organisms, must be greatly influence by the answer to the question which has been discussed in the previous pages—Do common germs normally enter our bodies? If they do, which is the opinion we consider the balance of evidence favors, then it follows that in unhealthy houses a constant excess of these potent particles must pervade the system, and the risk of their growing and multiplying by the aid of comparatively weak determining causes must be

intensified. These conditions will naturally tell most upon young children and delicate persons.

But, even if the other view be correct, that germs do *not* enter the body in health, it is proved that in consequence of slight departures from health, they enter and grow, for they become visible in the tissues. Thus, in any case, organisms *may* grow at very early stages, and in point of fact this is known to occur in some diseases. Now, the appearance of organisms implies that there has been a struggle between the life of the tissues and the living invaders, in which the latter have been victorious, and, therefore, their antagonistic influence upon tissue life must considerably precede the period when they become recognizable in the tissues. These considerations indicate that the influence of organisms may come into play at a very early stage in the genesis of our common diseases.

Antipyrin, in Various Combinations.—Capitan, in the *Revue de Thérapeutique* of November 15, 1887, gives the following useful combinations of antipyrin: In heart diseases—

Sparteine	1 part.
Antipyrin	$\frac{1}{10}$th to $\frac{1}{8}$th part.

It may be mixed with the bromides, as in

Antipyrin	2 to 3 parts.
Potass. bromidi . . .	3 to 4 parts.

In cardiac troubles with defective elimination, Antipyrin, potass. iodid., equal parts, may be given.

Antipyrin may be used in the following gargle:

Aquæ	℥12½
Potass. iodid.	gr. 15.
Tinct. iodin.	gtt. 30.
Antipyrin	gr. 30.

in pharyngitis.

It may be combined with naphthaline, as follows:

Naphthaline.	gr. ¾.
Iodoform	gr. $\frac{3}{10}$.
Tannin	gr. 1½.
Antipyrin	gr. 1½.

This may may be given in pill form, three or four times daily.

This combination is very useful in the treatment of intestinal colic, with catarrhal diarrhœa.

For Acute Tonsillitis.—Lebrun has used to advantage:

Aquæ menth. piper. . . .	30 parts.
Acid. boric.	1 part.

to which should be added 4 parts of an astringent fluid composed of

Benzoin.	1 part.
Alum.	2 parts.
Aquæ	20 parts.

The mixture resulting should be used as a gargle.—*Revue de Thérapeutique*, November 1, 1887.

Ruptured Tubal Pregnancy.—At a recent meeting of the British Gynecological Society Lawson Tait contributed notes of a further group of twelve cases of ruptured tubal pregnancy in which he had performed abdominal section, and tied the bleeding point on account of hemorrhage, which threatened life. He had already reported twenty-three such cases in the columns of the *Journal*. All of these cases had recovered except the first; of the last twelve cases eleven had recovered and one died. Every one of these operations had been performed under conditions of the utmost gravity, where life was threatened; and he had no hesitation in saying that nearly, if not quite, all these lives would have been sacrificed but for prompt interference. The first case had failed because he knew not what to do. He was too long over the operation and wasted time securing bleeding points as they arose, instead of rapidly separating all adhesions, regardless of the bleeding points, down to the base of the tumor, which was the broad ligament. A ligature placed round that and secured at once arrested hemorrhage; not a drop was ever lost afterward. In the other fatal cases the hemorrhage had already progressed too far; the patient was almost dead at the time of operation. She made a great struggle to get through, and lived five days, but then succumbed. He regretted not having employed transfusion in this case.

Mr. Lawson Tait said the diagnosis was not always possible, but it might be made correctly in probably about eighty-five per cent. of the cases. The real clew to the nature of the case was a history of sterility for some considerable time, the arrest of menstruation for weeks or even months and a sudden access of pain and collapse, with repetitions of these attacks. The operation was simplicity itself. "Open the abdomen, go at once to the seat of rupture—that is, the broad ligament—and tie it, for until you come to the ligament itself, the tissue is always so rotten and friable that any attempt to arrest the bleeding in any other way cannot succeed; then clear out the débris, and put in a drainage-tube." Of course, amputation of the ligatured mass was a matter of necessity; nobody would ever dream of leaving such a thing to putrefy in the abdomen. As to the proposal to destroy the life of the fœtus, and arrest the growth of the ovum, he had never been called to these cases until such a proposal was too late. He had never seen them until the period of rupture. Hemorrhage was then the danger with which he was concerned. Further, there was abundant proof that hemorrhage might go on after the fœtus had been dead for weeks. He doubted if a diagnosis could be made before the period of rupture. If it were possible with an electrolytic needle to piece the body of the fœtus, it might kill it, but would it kill the placenta? There was no question that in these cases the placenta continued to grow after the fœtus was dead.

All these thirty-five cases produced within the short period of seven years, confirmed the statement of Dr. Blundell that the condition was by no means uncommon, and that in many instances of women dying from internal hemorrhage, the real cause of their death was never ascertained. Thanks to the progressive emancipation of the professional mind from the thraldom of authority within the last ten years, we had now the means, if we had a reasonable time in which to act, to save at least the great majority of these cases.—*British Medical Journal*, November 12, 1887.

A USEFUL PURGATIVE FOR DIABETICS.—SEE has used

R.—Sulphur. sublimat., potass. tartrat. (pulv.), magnesiæ calcinat.; equal parts.

Dose one teaspoonful several times daily.—*Revue de Thérapeutique*, November 15, 1887.

GLOSSAL TUBERCULOSIS.—DR. L. V. ORLOFF, of the Princess Helena Pavlovna Clinical Institute, gives an account in a St. Petersburg medical journal of a case of tubercular ulceration of the tongue, the nature of which, though there were slight signs of pulmonary phthisis, was definitely decided by microscopical and bacteriological examination. The importance of this latter means of diagnosis is pointed out by Dr. Orloff. Tubercular ulceration of the tongue, when primary, as it sometimes is, might in this way, if diagnosticated and treated, perhaps be prevented from being followed up by the pulmonary affection. Some experiments were made in order to test the possibility of direct communicability by inoculation of rabbits' tongues with the secretion from the ulcer, but only negative results were obtained.—*Lancet*, November 12, 1887.

MUSTARD PAPER.—An Italian pharmacist gives the following formula for a convenient mustard paper:

Gutta percha (in scraps) . . .	4 parts.
Bisulphide of carbon	100 parts.
Ground mustard (freed from oil by pressure)	q. s.

The rubber is to be dissolved in the carbon; strong paper is to be dipped in the fluid, the mustard sprinkled upon it, and a roller passed over it to secure the firm adherence of the mustard. The paper may then be cut in convenient sizes. Heat is not needed in applying it. Moisture is generally sufficient to secure its adherence. —*Journal de Médecine*, November 20, 1887.

HYSTERIA AMONG SOLDIERS.—DR. JANSSEN gives an account, in the *Weekblad van het Nederlandisch Tijdschrift voor Geneeskunde*, of several cases of hysteria and hystero-epilepsy occurring amongst Dutch soldiers. In one of the latter class of cases occurring in a man of twenty-one, who had come of a highly neurotic family, where there were several attacks during the day characterized by semi-consciousness, extremely rapid respiration, abdominal tenderness, coldness of the extremities, with cold sweating, pulsation of the carotids and other arteries, opisthotonos, and convulsive spasm of the extremities, Dr. Janssen found that the attacks could be arrested by exerting firm and deep pressure with the closed hand on the left iliac region, or by a powerful induced current. The surface of the body was anæsthetic, and if the skin were lightly pricked with a pin, not only did the man not cry out, but no blood appeared. Various anti-epileptic and anti-hysterical remedies were tried without benefit. Different metals were applied to the surface of the forearm, but the only one which produced any effect was silver, which left a red mark. This induced Dr. Janssen to prescribe nitrate of silver for internal use, and this produced a great improvement in the patient. In another there was aphonia and aphasia, the lad being able to understand what was said to him, and to read and write, but not to speak—an example of Charcot's hysterical mutism. Treatment produced no effect on this patient, and he had to be discharged from the army.—*British Medical Journal*, November 12, 1887.

PRIMARY CARCINOMA OF THE ORGAN OF HEARING; RECOVERY.—LUCAE, of Berlin, reports in the *Therapeutische Monatshefte* for November, 1887, the case of a man, aged thirty-one years, who suffered from a growth in the meatus of the right ear, which so nearly filled the aperture as to render examination of the more distant portions of the ear impossible. Microscopic examination of portions removed gave every reason to believe it carcinoma.

The treatment consisted in douches of chlorine water, and the application, by insufflation, three times weekly, of equal parts of pulv. herb. sabin, and alum. ust.

Gradual improvement followed. Three years after his first examination the foreign growth had disappeared. Seven years after he presented himself for treatment, complete recovery, including restored function, ensued.

CHRONIC MYOCARDITIS.—DR. NEISHTAB, of Ekaterinoslavl, in some articles in recent numbers of the *Russkaia Meditsina*, details some cases of cardiac disease he has met with, which show that chronic disease of the heart muscle, myocarditis chronica, or amyoatrophia cordis, may exist quite independently of endocarditis or pericarditis. This myocarditis scarcely ever affects the whole of the heart's muscular wall, but confines itself to the right or the left side. When the diseased condition is advanced, it gives rise to definite physical signs, by which it is easily diagnosticated. These are want of rhythm and a remarkable diminution in the secretion of the urine, which, however, is of a normal character. The subjective sensations which accompany this condition are similar to those due to stenocardia.—*British Medical Journal*, November 12, 1887.

SIMON'S TREATMENT OF WHOOPING-COUGH.—In the first stage of the disease he orders

Tinct. belladonn., tinct. aconit., aquæ lauro-cerasi, equal parts, proportionate to the child's age.

After the convulsive stage has become established he employs an emetic once or twice each week, and alters his first prescription as follows:

Tinct. belladonn., tinct. aconit., equal parts, of which a carefully proportioned dose should be given morning and evening.

If food is rejected it should be repeated immediately after vomiting, when coffee may be also given with advantage. The nourishment and strength of the patient should be conserved in every possible way.—*Les Nouveaux Remèdes*, November 24, 1887.

URETHRAL ENDOSCOPY.—In the *Boston Medical and Surgical Journal* of December 1, 1887, DR. ALLEN describes Leiter's (Vienna) perfected instruments, and reports five cases of urethral disease in which endoscopy proved convenient and advantageous in treatment.

ANIMAL TANNIN.—We learn from the *Chemical News* that tannin may be obtained from the bodies of weevils, which infest granaries. 500 parts of weevils yield 15 parts of tannin.

THE MEDICAL NEWS.

A WEEKLY JOURNAL
OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance, ... $5.00.
Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters.

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, DECEMBER 24, 1887.

THE CROWN PRINCE'S CASE.

The Medical News received this week the following reassuring cablegram from Sir Morell Mackenzie, at San Remo, concerning the condition of the German Crown Prince:

"A growth the size of a split pea exists on the left ventricular band of the Crown Prince's throat, but it does not look malignant. The October growth is much diminished in size, and the ulcer on it has cicatrized. The swelling of the glands has quite gone, and there is no œdema."

It is to be hoped that this new growth which Sir Morell Mackenzie distinctly states does not look malignant, is situated *upon* the tissues and not *in* them, and that it may be simply what is known as a papilloma or warty growth, similar to that removed last June from the vocal band of the same side. The description of the present condition of the October growth seems to justify the opinion that it has been an abscess tumor and not a malignant growth.

The cablegram is on the whole quite reassuring, and presents no indication to modify the favorable points in the case expressed in our issue of December 10th.

THE TREATMENT OF TYPHOID FEVER.

In the issues of The Medical News of December 3d, 10th, and 17th, we have presented our readers with an outline of the modes of treatment in typhoid fever pursued at twelve of the chief hospitals of this country. There is a remarkable uniformity of opinion that the essential details in ordinary cases consist in hygiene, diet, and nursing. This has been one of the great gains of the century in the management of fever, and in this country the profession can never be sufficiently grateful to those courageous men, Nathan Smith, Jacob Bigelow, and Austin Flint, who, more than any others, taught us to make a knowledge of the natural history of a disease the starting-point of our medication. The possibility of arresting the course is only hinted at by one writer, but the so-called abortion of the disease is extremely doubtful, and at one clinic cases terminate spontaneously, which at another would be held to be striking illustrations of arrest by medication.

Not a suggestion is made as to specific treatment, the goal toward which, in this class of diseases, we are all working; but, except in one direction, the outlook is not very encouraging. The development of the poison in the intestine naturally suggests measures directed to the limitation of its growth, or the neutralization of its products, and the administration, as intestinal disinfectants, of naphthalin, thymol, and, perhaps, carbolic acid and iodine is an attempt to meet this indication. Experimental work may lead to the discovery of some reagent which can influence materially the growth of the typhoid bacillus, and not at the same time prove injurious to its host.

Apart from the accidents of perforation, hemorrhage, and a few complications, the important questions dealt with by the writers are how to combat the fever and how to resist the progressive asthenia. Hydrotherapy does not seem to have made much headway at American clinics, and even the recent statistics of Brand do not appear to have made a convert. Repeated spongings, with an occasional cold pack, are regarded as sufficient. Properly performed, the former measure is one of the most satisfactory which we possess for reducing fever. We should like to insist on the great importance of the cold pack, or bath, in those ataxic cases in which from the outset the nervous system is profoundly involved.

Of medicinal agents for reducing temperature, quinine, so long a favorite, has been replaced by antipyrin and antifebrin, both of which act promptly and safely. From fatal cases in which these heat-reducing agents have acted well, we have learned the lesson that it is not so much the pyrexia as the whole infectious process, of which the fever is but a feature, which constitutes the real danger, and with this we too often fight a losing battle. It is the misfortune of these recently introduced antipyretics that they do not seem to modify the course of the disease, even when the temperature has been persistently reduced by them. The use of alcohol is recommended by all the writers, and we have, as yet,

no substitute for it in the progressive asthenia of the disease. We expected a more decided expression of opinion as to the value of digitalis, spartein, and ergot, in the failing heart of fever. The administration of the first named remedy is popular with many practitioners whenever the pulse becomes weak and rapid. Ergot and strychnia are of great service also, and in the so-called cardiac cases many French writers prefer them to alcohol.

We appear to have reached a stage in the treatment of these specific fevers at which we may look back with satisfaction at what has been accomplished, and with hope look forward to a future full of bright possibilities. So far, the determination of specific organisms in connection with particular diseases has done less than might have been anticipated in modifying our therapeutics, but on the rapid progress of organic chemistry we can confidently expect not only a clearer knowledge of the manner in which these bodies act, but also combinations from the laboratory, which, if they cannot control the growth, may at least neutralize or modify the action of the substance which they produce.

THE NEW ORLEANS QUARANTINE STATION.

The report of the Committee of the College of Physicians of Philadelphia concerning the state of our quarantine defences has deservedly attracted wide attention and general commendation. In so far as the Committee confined themselves to discussion of the condition of affairs at the ports of New York, Philadelphia, and Baltimore, to which their personal investigations were limited, one of our valued southern exchanges, the *New Orleans Medical and Surgical Journal*, expresses its approbation in terms not less hearty than those coming from other quarters.

The Committee, however, in putting the question, "To what extent do the existing arrangements at the ports of New York, Philadelphia, and Baltimore fulfil the requirements for an efficient maritime quarantine against cholera?" added the following:

"[We speak of these ports only because circumstances did not permit of more extended personal investigations, and there is no reason to believe, from the published official descriptions, that the conditions of other ports of entry upon our Atlantic and Gulf coasts are in any respect superior.]"

The parenthetical classification of the quarantine system of Louisiana, with others not specifically mentioned, as, in a general way, not surpassing that existing at New York, has called forth, on the part of our esteemed friends of the Crescent City, a spirited protest, in which they say: "It is a great pity that so excellent a report should be marred by a grievous sin of commission. In inserting the passage quoted in their report, the members of the Committee proclaim their ignorance of the great strides that have been made in this locality in maritime sanitation." They admit that the Committee have evidently performed all of their duties conscientiously, for even where they make a grievous error they believe they are correct, since they base their statement upon 'public official descriptions.'" Besides, in their address to the medical societies of the United States, is the following: "According to the official description of Dr. Joseph Holt, President of the State Board of Health of Louisiana, it would appear that the quarantine in the Mississippi is, in respect of establishment, fully up to the requirements of modern science." Doubtless the Committee would have been equally complimentary to the Mississippi quarantine below New Orleans in their report, had the above official description been published before the presentation of that report. Of the "published official descriptions" to which the Committee referred, it seemed proper that they should form their opinions principally from the latest official comparative report upon the various quarantine stations of the Atlantic and Gulf Coast accessible to them, namely, that of 1886, by Dr. John H. Rauch, Secretary of the Illinois State Board of Health. This was all the more natural, since that report could in no manner be suspected of reflecting the influence of local pride or commercial interests.

In that report it is true that Dr. Rauch, whilst speaking of the Louisiana quarantine, says: "I am, therefore, enabled to endorse from personal observation the claim made that this is the most thorough and vigorous system of sanitary quarantine which has ever been enforced for the protection of a port from the introduction of foreign contagion into this country—if not in the world." But, in his concluding remarks concerning the New York quarantine, in the same report he uses the following equally commendatory language: "With reference to the exclusion of cholera and smallpox, the quarantine plant and facilities of the port of New York *are unrivalled* (italics ours), the printed regulations judicious, and with proper vigilance the service should suffice to prevent either of these diseases from obtaining access to the country through this avenue."

Undoubtedly, so far as quarantine against yellow fever is concerned, the system devised and perfected by Dr. Joseph Holt for the protection of the port of New Orleans against imported diseases, appears to be admirable. The methods and facilities for disinfection at the upper station are, as far as we know, unequalled anywhere in the world, and the associated establishments lower down the river are valuable adjuncts in efforts to keep disease at a distance.

But, however praiseworthy modes and means of disinfection may be at any quarantine station where

large numbers of immigrants constantly or may from time to time arrive, the absence there of sufficiently large and convenient buildings for the landing and separation into small groups, isolated from each other, of all the ship's inhabitants during the period of detention is, especially in quarantine against cholera, a most serious defect. Whilst it may be justly claimed that New Orleans is better prepared to disinfect a ship, crew, and passengers at the upper station, than is even New York, nothwithstanding the latter's "unrivalled plant and facilities," yet, with respect to means for the speedy termination of a ship's cholera epidemic among five or six hundred immigrants, we are still unquestionably of the opinion that, at least in this one most essential modern requirement for the efficient handling of cholera in quarantine, the plant and facilities at New York, imperfect as they undoubtedly are, should still be regarded as unrivalled at the present time in this country.

A port which undertakes to protect the country against the occasional invasion of Asiatic cholera, should provide all the essential means of rapidly discovering and destroying the contagion. Thorough disinfection is only one of these, whilst debarkation, and segregation into small isolated groups, properly housed and fed, under the strictest sanitary surroundings, are nowadays regarded as no less essential for the successful and prompt extinguishment of the germs of this disease. Had the excellent system devised by Dr. Holt been planned a year or two subsequent to an experience with cholera, instead of ten years after the last epidemic, no doubt his great knowledge and ingenuity would have enabled him to develop a scheme of very perfect defence against that disease, as well as yellow fever.

While the Louisiana system of quarantine certainly has many strong features, especially in the proper handling of yellow fever, yet it is by no means free from weak points, and, when confronted by cholera, these should justly be regarded as a source of danger to the country. The interchange between Dr. Rauch and Dr. Holt of telegrams on December 9th of this year, concerning the arrival at New Orleans, on December 4th, and the landing there three days later of 614 emigrants, brought by the steamship "Elysia," from Palermo, seems to emphasize this danger.

In his last telegram, Dr. Rauch "regrets that the 'Elysia' and her passengers were not detained longer." (Can "Elysia" be a misprint for "Alesia"?) He also takes occasion to remind the quarantine authorities that "twice has cholera been introduced into this country *via* New Orleans at this season of the year," and to make the very pertinent inquiry, "Why was the 'Elysia' sent to New Orleans instead of to New York?"

Has the tide of immigration from the recently infected districts of Sicily and Southern Italy been turned from New York on account of the unpleasant experience of the "Alesia" and the "Brittania" in that port; or, has it set in, for the moment, toward New Orleans because quarantine is known to be inactive there during the winter season?

Whatever the reason may be, we cannot but regard the circumstance as contributing additional weight to the considerations which should prompt the country to demand the establishment of an efficient and uniform direction by the National Government of quarantine at the seaboard. Our health laws should be such that the commercial interests of rival ports should be allowed neither to suffer nor profit through a transference from one American port to another of those dangers to the public health which immigrants bring to our shores. During commercial activity there should be no season in which the quarantine safeguards are not in a state of constant readiness; and the treatment of immigrants should be neither more nor less exacting at one port than at another.

That the official declaration by the Italian Government of the complete and sudden extinguishment of cholera in that country so soon after its widespread prevalence in regions where the climate is mild even in the mid of winter, should be received with due allowance. Past experience, as well as late United States consular reports of the existence of cholera in Terralba, are ample to warn us. The recurrence of cholera in South America, even before the warm season there has quite returned, should be looked upon as significant of possible danger in the spring from that quarter also.

The present situation appears, therefore, highly opportune for the earnest and unbiassed consideration by the physicians of all parts of the United States, of the serious matters embodied in the report on the existing defects of quarantine along the Atlantic and Gulf Coasts, and set forth in the address accompanying it, which the Committee of the College of Physicians of Philadelphia has been authorized to communicate to the medical societies of the United States.

REMOVAL OF A LARGE BRAIN TUMOR.

AT St. Mary's Hospital, Philadelphia, on Dec. 15th, DR. W. W. KEEN removed a tumor from the left side of the brain of a man aged twenty-six years. The patient was injured by a fall at three years of age. At twenty-three years of age he suffered from epilepsy with right-sided deviation of the head and eyes, followed by paralysis of the right arm and leg and aphasia. The initial symptoms of the epileptic fits pointed to the centre for conjugate deviation of the eyes, as discovered by vivisection,

and largely upon this was based the accurate diagnosis and surgical treatment.

The tumor measured 2 by 2⅞ inches, and was 1¾ inches thick. It extended from the fissure of Sylvius into the first frontal convolution, and from near the fissure of Rolando into the bases of the three frontal convolutions, and weighed 3 ounces and 49 grains. We learn that the patient is doing very well; so far the highest temperature having been only 100.8°, and already primary union of the flaps has followed, except at the drainage openings.

On December 12th, Dr. L. Ernest Neale, of Baltimore, Demonstrator of Obstetrics in the University of Maryland, performed the Sänger-Cæsarean section upon a patient at the Free Lying-in Hospital of the University of Maryland. The case was one of dystocia from contracted pelvis. The mother died about the third day, but the child is still living.

The Methodist Episcopal Hospital, of Brooklyn, was dedicated December 15th, with religious exercises by Bishop Hurst, of Buffalo, and others of the clergy and laity. The medical address was delivered by Dr. Horatio C. Wood, of Philadelphia. There is but one pavilion, with about seventy beds, completed at present, but the foundations are laid for accommodations for three times that number when the finances are at command for the completion of the buildings. The total cost, when finished, will have been a million and a quarter of dollars. George I. Seney, Esq., by whose name this institution is most commonly called, founded it liberally about six years ago, and thought to carry the project through entirely upon his own shoulders, but being a railroad magnate whose properties suffered a decline in value, the fulfilment of his generous plans was of necessity postponed. His gifts amounted to over $400,000; others have contributed nearly half as much more. It is stated that this is the only Methodist Episcopal institution of the kind in the world, and there can be no doubt as to its eventual success and full endowment, and that too, before many years have gone by. The beds of the "Seney" Hospital are, for the most part, free and will not be restricted to the sick and injured of any denomination.

The Medico-Legal Society, of New York City, held its annual meeting on December 14th, and the election resulted in retaining the officers of last year in their positions; with the exception that the Vice-Presidency fell to Dr. W. G. Stevenson in place of the late Dr. Carnochan. A lively debate occurred on the jurisprudence of inebriety, ex-Judge Noah Davis presiding; and alcohol received so many hard thrusts, that when the time for dinner came the banqueters paid heed to the teaching given them and wine was most sparingly ordered.

George Wiedler, the slayer of Dr. Duggan, of Brooklyn, has been sentenced to twenty years' imprisonment at hard labor. This is the full penalty for the crime of manslaughter, of which he was found guilty by the jury. But, for "good behavior," as it is called, the murderer may receive a reduction of punishment to thirteen years at Sing Sing. The judge, when sentencing Wiedler, showed very clearly that he considered the trial a miscarriage of justice. He said, "I firmly believe that if you had been dealt with according to the testimony, you would now be standing here for sentence for murder in the first degree, and not for manslaughter." This criminal has saved his neck through the exertions of his lawyers, who did not hesitate to besmirch the good name of the dead physician.

REVIEWS.

A Short Manual of Surgical Operations. By Arthur E. J. Barker, F.R.C.S., Surgeon to University College Hospital; Assistant Professor of Clinical Surgery and Teacher of Practical Surgery in University College, London. 12mo, pp. vi. 423. London and New York: Longmans, Green & Co., 1887.

We can speak well of this book. In modest compass it furnishes a fair exhibit of the set operations of modern surgery, while it also gives directions for the performance of some that have pretty much had their day. Very properly more space is given to the newer operations, but even here Mr. Barker claims to have put severe restraint upon himself so as to give a condensed account of the steps of the operations. As we have indicated, the result is very satisfactory. For while the book cannot take the place of more elaborate and extended treatises, nor, indeed, does it aim at so doing, the well-read surgeon, who is called upon to do an operation for the first time, will find in Mr. Barker's chapters just such a summary of operative procedures as is necessary to refresh his memory, and bring the salient and essential points of the operation into clear relief. Our author has had large experience with operative surgery, and by the clearness and simplicity of his style shows that he writes of a familiar subject; but while he is sufficiently decided, there is entirely absent from the book anything of unpleasant dogmatism. Indeed, we could have borne with a little more of criticism, and a fuller expression of the author's own estimate of certain operations which have attracted notice of late years. The chapter upon abdominal surgery is very full and very explicit, as is fitting in view of the well directed efforts which have made that region the field of the most daring and most successful exploits of modern operative surgery. Mr. Barker apologizes for the illustrations, most of which have been drawn by himself, but even if not very artistic they serve well to make plain his meaning, and are valuable

helps to a correct understanding of the text. Those illustrating brain surgery represent well the existing state of our knowledge as applied to the most recent practice. Altogether, the book will be found valuable for its accuracy, its brevity, and the discriminating character of its contents.

SOCIETY PROCEEDINGS.

PHILADELPHIA ACADEMY OF SURGERY.

Stated Meeting, December 5, 1887.

The President, D. Hayes Agnew, M.D., in the Chair.

Dr. Charles B. Nancrede presented the

SPECIMENS FROM A CASE OF LITTRÈ HERNIA.

During the latter part of June, of this year, a case was brought to the Episcopal Hospital, nearly moribund, in which symptoms of strangulation had been present for four days. They had not been especially acute. There had been some vomiting, but no distinctly fecal matter had been brought up. The constipation was not complete. One or two efforts at taxis had been made, but were said to have been unsuccessful. In the right groin a very small tense tumor was present. Being under the impression that this was one of the forms of hernia in which only a portion of the calibre of the bowel had been caught, he determined to try to relieve the strangulation. He cut down until he came to what seemed to be the sac. On opening it a little blood-stained serum escaped. He next reached what looked like omentum. During his manipulations the tumor suddenly became softer, and about a drachm of thick pus welled up. He made a free opening, and found in the neck of the sac a mass resembling in color and appearance the skin of a grape. This came away on the slightest touch, and he searched for an opening in the intestine, but could discover none. He then concluded that, for some cause, the peritoneal coat had sloughed off. The man died five or six hours afterward, neither benefited nor injured by the operation.

At the post-mortem the intestines were found covered everywhere with a layer of false membrane, with pockets of pus. At one portion, near the internal ring, was found a place where the false membrane was absent over a circular space, corresponding to the portion of false membrane which he had found in the ring. The portion of gut nipped in the ring appeared to have been only about one-fourth of its circumference. While this variety, although uncommon, was still quite often met with, Dr. Nancrede believed that his case was the first where a piece of *gangrenous false membrane* had been stripped off and left in the neck of the sac, thus simulating gangrene of the bowel.

Dr. William Hunt said that he was present at the post-mortem of a similar case in which a portion of the gut became strangulated in the femoral ring. There were symptoms of obstruction, but the condition was not recognized during life.

Dr. D. Hayes Agnew had seen the autopsy of one case in which the portion of the bowel strangulated was not larger than the little finger. In this case the symptoms were not very acute.

Dr. John M. Barton, a few years ago, saw a case of this kind in collapse. There were symptoms of strangulation, and he searched all the openings without finding any suspicious fulness. At the autopsy a portion of ecchymosed intestine, one and a quarter inches in length, and one-half inch in breadth, was found in the inguinal ring.

Dr. De Forest Willard had operated in one case in which the extent of the hernia was slightly more marked than had been described. The outer wall of the intestine was involved to the extent of one and one-half inches, while the inner wall was just pinched. There were symptoms of strangulation, but no tumor could be found. He performed laparotomy in order to ascertain the cause. The patient, however, died in the course of three days.

Dr. Morton reported the history of a case in which he had performed

LAPAROTOMY FOR PERFORATION OF THE BOWEL IN TYPHOID FEVER.

(See page 729.)

Dr. William Hunt said that there could not be a more perfect description of his own case than the history which Dr. Morton had given of his patient. He had been sick for three weeks with mild typhoid fever. An error in diet was followed by intense pain in the abdomen, and sudden collapse. He was treated for fourteen days on the Graves and Stokes plan—that is, opium to the full extent. A blister was placed over the abdomen, and he was nourished with liquids. Following this he had phlebitis, abscess, and other complications, and was two years in recovering. This is not the history of ordinary local peritonitis. Dr. Gerhard, Dr. William Pepper, Sr., and Dr. George B. Wood were confident that perforation had taken place.

Dr. W. W. Keen said that the only case of typhoid fever in which he had been confronted with the question of abdominal section, and the first published case, he thinks, in which this question was raised, was one seen about two years ago with Dr. James C. Wilson. The only thing that deterred them from operating was the question of diagnosis. Dr. Morton had said that the time for operation is the moment that perforation has taken place, but the difficulty is to tell positively whether or not perforation has taken place. In the case alluded to, there was sufficient doubt to lead to delay. The next day the patient being better the operation was deferred and finally was not performed, the child recovering. He thought that there is no doubt as to the propriety of the operation when the diagnosis is reasonably well made out. The sequelæ of typhoid fever which require surgical interference are not very few. A good many cases of necrosis of the larynx occur during convalescence from typhoid fever, and operation in these cases could not materially add to the dangers, for nearly every one of them dies if it is not done.

Dr. Nancrede said that some time ago he was asked by a colleague to see a case in which it was thought that perforation had occurred. He was not satisfied that such was the case, and even if there had been, the condition of the patient contraindicated operation. The autopsy showed that there was no perforation. Some time later he was asked to see another case in which it was be-

lieved that perforation had occurred. The attending physician thought that he detected crepitus in the abdominal walls. He examined the case three times, but could not find this, and the patient recovered.

Dr. Barton asked Dr. Morton to state the points on which he based the diagnosis in his case.

Dr. Morton said that the points were as follows: The patient who had a mild typhoid, soon after eating most improper food, was suddenly seized with severe localized pain, a violent chill, and a temperature of 104.5°; the pain continued and soon extended all over the abdomen; these symptoms in connection with a pulse of 146 convinced him that perforation had taken place.

Dr. S. W. Gross said that it is not so much a question of mistakes in diagnosis as it is whether or not we shall operate in a certain class of cases. In one like that just described, he should not hesitate, as the signs conclusively indicate perforation, and being a walking case, the powers of life had not been greatly debilitated. In the majority of cases of typhoid fever the operation would be out of the question. He would, however, criticise the technique of the operation as described. The insertion of Lembert sutures for the closure of the perforation was eminently proper, but, from a pathological standpoint, he considered the treatment of the second lesion improper. Ulceration was still going on, and the bringing together of the serous surfaces would certainly not arrest it. If he were to meet with an ulcer which had almost perforated the gut, he would excise it, and approximate the edges of the wound.

Dr. Morton said that in the treatment of the ulcer referred to, it would have been difficult to excise it without materially interfering with the calibre of the bowel. The ulcer had reached the peritoneal coat, and he felt better satisfied to turn it in, rather than leave it unprotected; and he could only say that if he again found the same condition, he would pursue the same plan. He would not be willing to close up an abdomen, knowing that there was simply peritoneum between the contents of the bowel and the abdominal cavity, which would probably be followed by a perforation, and necessitate a repetition of the operation.

Dr. Agnew said that he was that day called to see a case of supposed perforation in a young man in the fourth week of convalescence. Twenty-four hours before he saw him he had been seized with a sudden pain in the right iliac fossa. He fell back in a state of exhaustion and fainted. This was followed by great tenderness and abdominal distention. When he saw him he was better. The distention was not so great, and the pulse had improved. He believed that in that case there was no perforation. The time that has elapsed would have considerable weight in the diagnosis. He did not believe that we shall ever accomplish much by operation in cases of perforation from typhoid ulcers.

Dr. Nancrede related the history of a case in which he performed

LAPAROTOMY FOR EXTRACTION OF CALCULUS.

The lateral incision was two inches above the pubes. The first deep stitch was introduced one and three-fourths inches above the pubes. There was some difficulty in getting the needle, and a superficial stitch was introduced one and three-eighths inches above the pubes. The abdominal walls were unusually thick, and the needle was an ordinary glover's. A glass drainage tube was put in two and one-half inches from the pubes, and carried down into Douglas's cul-de-sac. The ligatures on the nodules were tied as close to the uterus as could be done with safety. The patient was catheterized after etherization. After the next catheterization, some three hours after the completion of the operation, about three ounces of bloody urine containing tube-casts were removed, showing that there must have been very little in the bladder at the time of operation. In forty-eight hours the blood disappeared. The drainage tube was taken out on the fourth day, and the lower stitches on the sixth day. On the twelfth day she turned on her side, and shortly afterward, on attempting to urinate, urine escaped freely through the track of the drainage tube. She refused to be catheterized, and went all night passing urine only twice, when there was some leakage through the opening. The patient is doing well; no urine escaping through the abdominal opening, owing to the use of the retention catheter. He had not been able to account satisfactorily for this complication. Was it possible, he asked, that the superficial stitch passed into the bladder wall? Did he injure a pervious urachus? In tying the broad ligaments, did he draw in a portion of the wall of the bladder and ligate it? He was inclined to the urachus view, as he thinks it to have been impossible that he could pass a superficial stitch inclosing three-fourths of an inch of tissue with an ordinary straight needle, through an abdominal wall fully one inch thick, and pick up an empty bladder one and one-fourth inches above the pubes. If he did, this should be a warning to operators not to approach even within two inches of the pubes with their incisions. [The fistula has since closed, and nothing but temporary inconvenience has resulted.]

Dr. Keen called attention to the fact that when empty the female bladder has a "Y" shape. Frozen sections show that one arm of the "Y" extends some distance up the anterior wall of the abdomen. In a case of fibroid tumor, in which he performed laparotomy for the removal of the appendages, he found the bladder adherent to the abdominal wall. He had to extend the incision as high as the umbilicus before he got above the bladder.

Dr. Hunt could not help thinking that there was some peculiarity in Dr. Nancrede's case. What practical anatomist has, in making an ordinary cut of the abdomen from the symphysis to the umbilicus, ever opened the bladder?

Dr. S. W. Gross exhibited a specimen of interest which showed one of the disadvantages of the use of the silk ligature for tying the pedicle of an ovarian tumor. Dr. Martin, of Berlin, removed an ovarian cyst and secured the pedicle with a silk ligature. Some time later the patient presented symptoms of calculus, and, on examination, a large phosphatic stone was found, and crushed by Dr. Max Nitze. The nucleus was several feet of silk thread which had ulcerated into the bladder. The lady then came to this country. She consulted him about the first of last month on account of a return of the vesical symptoms, when he detected a tone.

Prior to the removal of the stone he threw an ounce of a four per cent. solution of cocaine into the bladder, and applied the same solution to the urethra on cotton.

He then rapidly dilated the urethra, carried in a small pair of lithotomy forceps and removed this stone. It is phosphatic, weighs eleven grains, and has formed around a bit of silk ligature, about one inch of which projected from the stone.

This case is interesting from another standpoint, as it is the only case in which he has not had more or less incontinence after free dilatation of the urethra. The urine was bloody for twenty-four hours. The operation was done on Sunday, and on Wednesday the patient left the hospital.

Dr. Keen said that two years ago he dilated the urethra for the purpose of exploration and had considerable difficulty in introducing his forefinger. The procedure was followed by retention requiring the use of the catheter for four days.

Dr. Morton said that a woman aged twenty-eight years was recently admitted to the Pennsylvania Hospital with the history, that three years ago she had induced an abortion by the introduction of a hairpin into the uterus. Three months ago she attempted the same procedure. The hairpin, however, slipped from her grasp and entered the uterus. The abortion was produced, but the hairpin remained. He dilated the neck of the uterus and was able to remove the pin, which had given rise to considerable endometritis.

Dr. Agnew did not think that, as a rule, extraction of calculi through the urethra causes incontinence. In one case, after he had gotten the stone into the urethra, he found that it was larger than he had supposed, but as he could not readily push it back into the bladder, he brought it through the urethra. It was one and one-half inches in diameter. This woman recovered without incontinence.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 15, 1887.

The President, A. Jacobi, M.D., in the Chair.

Dr. T. Herring Burchard read a paper on

the modern treatment in strangulated hernia.

He said that, encouraged by the remarkable successes obtained in the treatment of non-strangulated hernia by the methods suggested by Banks, Czerny, and others, surgeons had latterly paid special attention to the radical cure operation, as applied to cases in which strangulation existed, and the results achieved had been most gratifying. The general principles upon which the operation is based, as a legitimate surgical procedure, are :

First. A more general recognition by the profession of the value of time in the earlier stages of the strangulation, so that surgical relief could now generally be rendered before pathological changes, which were irremediable, had taken place in the tissues.

Second. Modern herniotomy implied an abandonment of those uncertain and pernicious methods and practices which, founded on a false pathology, had sought to relieve the strangulation by producing a condition of systemic relaxation. It was now recognized that spasm, as a causative agent in the production of strangulation, never exists.

Third. Modern herniotomy restricted the employment of taxis to within limits that were rational and safe. Necessary as properly directed taxis is in the reduction of hernia, by its indiscriminate and reckless use irreparable damage had not infrequently been done the intestine ; and he could not but feel that it had been a misfortune to designate by a special appellation the manipulations employed in reducing hernia, since the practice had exaggerated their importance in the treatment, and been a fruitful source of abuse.

Fourth. Modern herniotomy implied the early resort to a cutting operation. Many lives had to be sacrificed before the profession seemed to realize that the gangrene and ulceration, the fecal extravasation and stercoraceous vomiting, the peritonitis and collapse were not necessary and integral factors of the primary condition of strangulation, but secondary complications developing later on in the progress of the disease, the legitimate result of delay in affording relief to the original constriction. If, however, the strangulation were relieved before inflammation of the gut or adjacent tissues had supervened, these grave dangers could be avoided.

Dr. Burchard's practice is, if possible, to operate on every case of strangulated hernia in which gently applied taxis, under anæsthesia, preceded, as a rule, by the application of ice, does not yield reasonable expectations of success within about one hour after positive symptoms of strangulation have presented themselves. In his opinion nothing is gained by delay, while everything is risked.

Fifth. Modern herniotomy is an antiseptic operation, demanding the fullest application of Listerian principles.

Sixth. Modern herniotomy requires in the disposition of the hernial sac the finest impartiality of judgment. Certain cases require incision, while in others the strangulation can be readily reduced without opening the sac; so that it would be folly thus to complicate the operation and expose the patient to unnecessary danger.

Seventh. Since Mitchell Banks, of Liverpool, had urged the possibility and expediency of perfecting the old operation of kelotomy, so as to add to the operation done for the relief of strangulation, the inestimable advantages of an operation for radical cure, the strongest possible encouragement had been given for the attainment of an early, thorough, and perfected operation.

Regarding the special treatment of strangulated hernia, Dr. Burchard said that he had nothing novel to add to the excellent recommendations that had been published on the subject. His experience had led him to the adoption of a plan of treatment substantially as follows :

First. Pain is allayed, vomiting quieted, and nervous tranquillity secured by the hypodermatic administration of morphia with atropia.

Second. As soon as practicable a careful examination is made of the hernial tumor, any attempt at reduction being studiously avoided.

Third. If evidences of local inflammation are present, or if there is much swelling of the tumor, a poultice of linseed meal and cracked ice, or the ice coil, is at once applied. These are dispensed with if the patient is feeble or the strangulation is of long standing.

Fourth. A stimulating enema of turpentine and oil, or a larger emollient one of thin flaxseed tea, is admin-

sidered, and the rectum thoroughly washed out. Should it be required, the patient is catheterized. If the tumor is still unreduced, no attempt at taxis is made until

Next. The patient is anæsthetized, permission having first been obtained to proceed with the operation in case taxis should fail.

At this point Dr. Burchard said he wished to emphasize the advantages to be gained by putting the patient under full anæsthesia (preferably by chloroform), covering the tumor with a rather large and heavy ice poultice, elevating the lower extremities, and keeping the hands entirely off for a period of from thirty to forty minutes. In a number of instances thus treated he had the satisfaction of seeing the tumor, almost imperceptibly, slip back of itself, even after prolonged taxis had been unsuccessfully employed. As to just how long the attempt at reduction by taxis is justifiable, no absolute rule can be laid down. To the practised touch a moment is sometimes sufficient to determine the possibility of a successful reduction. In other cases it is advisable that the trial should be prolonged for twenty, or even thirty minutes, provided always that only the gentlest manipulations are employed.

Taxis having proved unsuccessful, the operation should at once be undertaken. By careful dissection the sac should be fully exposed; when, if the strangulation be of recent occurrence, and the sac free from inflammation and of normal appearance, an effort may be made to secure its return by gentle taxis into the cavity of the abdomen. Should adhesions bind down the sac, they may be broken up if not too extensive; precautions being taken that all bleeding has been effectually checked before the sac is returned. If constricting bands girdle the body of the sac and prevent its return, they should, if possible, be divided. Adhesions around the neck of the sac must be treated with great deliberation. Having pointed out the complications and dangers to which such adhesions might give rise, he mentioned that serous effusion within the sac might be safely gotten rid of by puncturing the sac with a capillary hypodermatic needle.

If, now, the sac could not be readily reduced, he went on to say, it should be carefully opened. Unprejudiced surgeons, he thought, are at present agreed that in all those cases where it would be safe to replace the hernia by simple taxis, if that were possible, the same thing might be done after restraining adhesions of the sac or constricting bands around its neck had been divided by the knife. But in those cases in which the symptoms are suggestive of an aggravated condition of the bowel, and on account of which it would be dangerous to attempt to reduce it by taxis, it is necessary to open the sac. The sac having been opened, the stricture should be sought for and divided.

Dr. Burchard then alluded to some points of practical interest in connection with the return of the gut. One of these was in regard to cases of deep congestion. How far the vitality of the bowel is consistent with a change of color, drying of the secretions, emphysematous crackling, and foul odor, is a difficult matter to determine. He had seen two cases in the practice of Dr. Eric Ludlum, R. Wood in which gut that was decidedly gangrenous was replaced and in both instances with the most favorable results. In one case of his own, where a deep furrow marked the seat of the stricture, and where the gut itself was of a dark maroon shade, the condition of the gut did not warrant its reposition for nearly three hours after the operation; whereas in another case, of more prolonged strangulation, with grave constitutional symptoms (the condition of the gut being almost identical, with the exception of the furrow or groove), the circulation was restored in one-fourth the time. He said he could not feel that we are justified in returning strangulated intestine until it gives some evidence of reanimation; while it is perfectly possible to keep it enveloped in moist flannels and rubber tissue for several hours. In cases of ulceration it is sometimes advisable to practise partial excision before returning the intestine, and in some instances the condition of the gut does not warrant this until several hours after the operation. Extensive perforations and lacerations occurring in herniated bowel necessitate the formation of an artificial anus.

Treatment of adhesions.—If acute, and simply binding down the body of the sac, they may be gently broken down. If they surround the neck of the sac, binding the intestine to the upper end of the sac, or the intestine to the cord, or to an undescended testis, it is necessary to accomplish the separation with the greatest possible gentleness and circumspection, on account of the extreme friability of the tissues. Chronic adhesions may be divided with more boldness, provided no traction is made on the inflamed intestine. In all cases the intestine, both above or below the strictured portion, should be carefully examined after the operation.

The radical cure—The modern operation finds its greatest advantage in the radical cure it accomplishes, by the complete closure of the sac and permanent obliteration of the hernial canal; and it has been successfully performed upon all forms of hernia, inguinal, femoral, and umbilical, with equally satisfactory results.

In the present light of hernial surgery he thought that no operation for strangulated hernia could be said to be properly performed without the final closure of the hernial canal. By this practice five decided advantages are gained:

First. Complete isolation of the peritoneal cavity, and its permanent closure.

Second. Permanent closure of the patulous orifice through which the gut escaped.

Third. Shortening of an abnormally elongated hernial canal.

Fourth. Prevention of septic percolation into the cavity of the abdomen in case suppuration should ensue.

Fifth. The inestimable advantages that would result to the patient from a permanent cure.

In the performance of the operation, the clinical requirements are, first, a safe and satisfactory disposition of the sac; and, second, a total obliteration of the hernial rings, and an accurate coaptation of the sides of the canal.

Disposal of the sac.—The sac may be dealt with in one of several ways:

First. It may be reduced within the abdominal cavity, and the canal then obliterated.

Second. It may be left within the canal (especially when firm adhesions prevent its safe return), and the superficial tissues and the skin are firmly approximated over it.

Third. It may be ligatured, the hernial investment amputated, and the stump returned.

Fourth. It may be ligatured and amputated, and then invaginated in the canal.

Fifth. It may be drawn up upon itself and fixed as a bulwark against the internal ring, as in Macewen's operation.

Sixth. The abdominal wall may be divided longitudinally and parallel to the pillars, and the sac then woven into the fibrous structure.

DR. JOSEPH D. BRYANT said that he thought the first method should be dismissed from consideration, except in very acute hernia, on account of the danger of causing adhesions with their attendant pain and discomfort, or of lighting up peritonitis. The objection to the second method was that with the sac remaining *in situ*, complete obliteration of the canal could not be effectually secured. A canal thus treated became exceedingly sensitive, and a truss could scarcely be worn. Between the remaining methods a choice could sometimes be made only after mature deliberation.

DR. BURCHARD said he had operated in nine cases of strangulated hernia, in which he had been enabled to carry out the operation in all its details. Eight of these had recovered, and one developed delirium tremens on the second day, and died from this cause on the fourth. Having alluded to a number of interesting points in connection with these cases, he spoke, in conclusion, of two practical matters which suggested themselves: (1) In cases of stercoraceous vomiting and collapse, nothing had equalled in his experience the use of hot water employed as a stomach douche, as practised by Tait. A long, soft rubber tube was passed into the stomach, and a stream of hot water very gently injected in a continuous current. By this means the stomach was not only thoroughly washed of its fecal contents, but the best possible stimulant in cases of hernial collapse was furnished by hot water so employed. (2) As a factor in the production of acute general peritonitis concealed hernias in exceptional localities are apt to be overlooked. He had met with two instances of this kind in his own experience; one being a case of inguinal bubonocele of a direct variety, and the other one of concealed femoral hernia.

DR. R. F. WEIR made some remarks on the question

HOW SHOULD THE SAC BE TREATED IN HERNIOTOMY?

He said that Dr. Burchard had covered the ground so completely that but little remained to be said. Like Dr. Burchard, he thought that the surgeon should be guided by the circumstances of each individual case, and he did not advocate any one method of procedure to the exclusion of others. He illustrated by diagrams the operations for radical cure of Macewen and Czerny, and went on to say that while the radical operation unquestionably marked an improvement in this branch of surgery, it could not as yet be regarded as a perfected operation. Having given some statistics showing the comparative frequency of relapses, he said, in conclusion, that surgeons were everywhere practising the operation, and he feared too freely; that is, too freely in non-strangulated hernia.

DR. W. B. DE GARMO read a paper on

THE CONSERVATIVE TREATMENT OF IRREDUCIBLE AND INCARCERATED HERNIA.

He said, in opening, that his paper did not relate in any sense to strangulated hernia. He would present the histories of a number of cases which were intended to show that the two opposite opinions concerning operative interference and non-interference were both wrong. He would advocate operation in certain cases which could not be reduced, but he thought it unwise to operate in all cases. The first case which he related was one of irreducible inguinal hernia of ten years' standing. The first day he devoted one hour to making taxis (by which term he wished to be understood as meaning certain very gentle manipulations, which were quite different from the taxis usually made use of), but with apparently very little effect. By the fourth day, however, he succeeded in reducing the hernia by this means. At first a truss could be worn for only a short time; but the tolerance of it gradually increased. The second case was also of ten years' standing, and the hernial tumor was of the size of a fœtal head at full term. The hernia was complicated, as was frequently the case, with a piece of omentum, and this proved to be irreducible; but it afterward disappeared under the pressure of the truss. After the hernia was first reduced the truss could not be worn in the standing position for a time.

The third case was characterized with attacks of colic in connection with the hernia. The hernia was gradually reduced by gentle manipulations; after which a truss was worn with comfort, and by the end of a year the patient thought himself cured. As the result of jumping out of a carriage, however, the hernia became strangulated. An operation was then performed, and he made a rapid recovery. Dr. De Garmo narrated some other cases, and said that of the ten, there were seven reductions and two failures, while one case was abandoned on account of the patient having diabetes.

He then went on to speak more particularly of the manner of reducing these supposed irreducible hernias into reducible ones. The first thing was to see that the mass was freely movable in the sac, and then use compression, rather than ordinary taxis. In the second place, the tumor is to be separated from the vicinity of the testicle, if it were situated in the scrotum. In other words, it is to be perseveringly stripped from its lower adhesions and gradually worked upward; no force whatever being used. The complete separation of the omentum, so frequently forming a part of the mass, is accomplished before the reduction proper is commenced. In some cases Dr. De Garmo is in the habit of directing self-applied taxis, practised daily. After the reduction the hernial sac usually remained; but if the hernia is kept properly in place by a well-fitting truss this generally disappeared in the course of time. Taxis is to be practised from fifteen to forty-five minutes at a time, and repeated once a day. None of his patients had been confined to bed for more than one week.

In those cases in which it was found impossible to reduce the hernia the tumor was compressed by a truss, and a strong suspensory support was also employed. It was important, however, to distinguish the contents of the tumor. If only omentum was present no trouble

could result, but if bowel were present the truss would cause more or less discomfort, and would be likely to lead to strangulation.

DR. A. G. GERSTER made some remarks on

STRANGULATED HERNIA IN CHILDREN.

This he said is a very rare condition in children, and he had met with but four instances of it in his experience. There is nothing peculiar in the character of the strangulation in such subjects, and he would direct attention only to a point of difference in the treatment required, as compared with that in adults. This was on account of the difficulty of preventing infection of the wound in small children. In most instances the hernia is congenital, and the neck of the sac is usually not very wide. On account of the danger of infection he advocated an open treatment of the external wound. Primary union does not occur after suturing, and, therefore, after securing occlusion of the sac and the abdominal opening he packs the open wound with iodoform gauze, and thus secures an aseptic condition.

Dr. Gerster then proceeded to relate the history of the four cases that he had seen. In one of them, a child two years and three months old, an error of diagnosis was made. The tumor was at first mistaken for hydrocele; but the true nature of the case was determined by the hypodermatic syringe, which brought away intestinal matter. It was also found to be a strangulated hernia; but as no urgent symptoms were present no active interference was made at this time. By the next day, however, all the ordinary symptoms of strangulated hernia had manifested themselves, and the radical operation was performed. During this a slight wound was made in the gut, on account of the adhesions present, and this was sewed up with the Lembert suture. In another of the cases strangulation of the hernia occurred four separate times in connection with eclamptic attacks, to which the child was subject. It was always successfully reduced under the use of chloroform; but when the accident appeared the fifth time it was determined to perform the radical operation, after which there was no further trouble from the hernia.

DR. V. P. GIBNEY said that he should like to make some protest against the strong condemnation of taxis which Dr. Burchard had expressed, as he had seen a number of aggravated cases of strangulated hernia reduced under taxis as employed by the average practitioner. As regards strangulated hernia in children, he did not recall a single case in all his experience in which the strangulation could not be reduced with the aid of chloroform. Furthermore, if it could be reduced, it could be cured simply by the wearing of a suitable truss. As the operation was a more serious one than in adults he thought, therefore, that operative interference should never be resorted to in children; and this became still less necessary in the light of the successful results accomplished by the conservative methods advocated by Dr. De Garmo.

DR. WEIR said that he had had two cases in children like Dr. Gerster's, and both had proved fatal. In two other cases he had successfully reduced the hernia by resorting to the expedient of inserting the finger into the rectum, and thus combining internal with external pressure.

DR. DE GARMO said that he had met with only temporary incarceration in children. No bad results had ever occurred, and he had never found it necessary to resort to taxis in such cases. In reply to a question from Dr. Weir as to just what he meant by the term taxis, he said that the gradual working of the tumor loose by passing the fingers around it was not taxis proper, but rather pressure. By taxis he meant the manipulation of the neck of the sac, but employed in such a way as to avoid pressure backward against the abdominal rings, which was apt to be resorted to in taxis as commonly practised.

CORRESPONDENCE.

IS THE QUESTION OF SILK OR SILVER LIGATURES STILL BEFORE US?

To the Editor of THE MEDICAL NEWS,

SIR: In the number of THE NEWS for December 3, 1887, I see a letter from Dr. Martin, of Ann Arbor, advocating the use of "braided silk suture in lacerated cervix and perineum," and I must beg of you the permission of adding a few lines upon the subject.

A year or so ago I called attention to the advantages of catgut in three cases—in a short correspondence in these same columns. Since then catgut has become quite popular through the efforts of Martin, who lauds the juniper preparation, and I have continued the use of the bichloride gut, which I esteem as highly now, as I did then, and my object in addressing you now is to call a halt in the discussion as to the merits of the various sutures in gynecological work.

I have tried them all faithfully, and I have come to the conclusion that *it matters not*, in the great mass of cases, *what the material be, provided it be* of sufficient strength and—*thoroughly antiseptic*. I do not object to the whale or kangaroo-tail tendon, but practically we must limit ourselves to silver, silk, or catgut.

Silver is more expensive and cannot be handled with the same rapidity, hence it is rarely used, and we are brought down to silk and catgut. Catgut possesses the great advantage over silk, that the surgeon need not trouble himself about the removal of the sutures; it possesses no disadvantage, is inferior in no way to silk, unless it be desirable that the suture remain longer than ten days. The catgut prepared in corrosive sublimate and alcohol, or in juniper oil, is as agreeable and convenient to handle as silk, and the surgeon will soon learn by experience for how many days he can trust his suture; the time varies with the thickness of the gut, method of preparation, and location of suture.

I prefer catgut for the reason that I need not trouble myself or patient with the removal of sutures, and that I can resort to buried sutures without change of material, but I claim no other advantage for this material. Silk, silver, kangaroo-tail tendon, horsehair, or any other antiseptic material is just as good.

As a matter of convenience, I have now used catgut continuously for over two years, externally and internally, on cervix, vagina, perineum, and other integument. I have even in one instance used catgut exclusively in an ovariotomy, for ligatures and sutures.

Indifferent as is the kind of material, so is the kind of suture with which we unite vaginal or perineal structures, provided the suture be drawn sufficiently tense, and firmly knotted, and we no longer trouble ourselves about the kind of knot with which the suture is tied—provided it holds. I might add, that in the hard tissues of the cervix, or, more correctly, in the tissues of an indurated cervix, the interrupted suture, as ordinarily used, is preferable.

Whilst all that Dr. Martin says as to the relative value of silk and silver sutures in cervix and perineum is correct, I find fault with the complete omission of catgut, and with any discussion regarding that material. I shall never forget the lesson I learned in a smoking-room on an express train, with my honored friend Dr. Parvin, when he told me, years ago, of a labor case with ruptured perineum, far out in the country, and no silver wire on hand; he took a hair from his horse's tail and sewed up the perineum, did not tie the legs, and scored a perfect success!

I could not but think of this case whenever I heard the relative merits of silk and silver discussed. Practice has confirmed the inference I drew, and I believe that gynecologists who are in the habit of operating, and operate frequently, will say with me, that, as a rule, in the usual gynecological operations *one suture is as good as another*, and *convenience alone should guide us* in the choice of material.

Frequently it is a great advantage if the annoying procedure of removal can be dispensed with, thus when cervical and perineal operations are performed in one sitting, or in an operation for cystocele and for rectocele in combination with a cervix or a perineum; in these cases catgut is to be decidedly preferred, but, as a rule, the operator can suit his convenience, the result is not dependent upon material or kind of suture. I do not object to the preferences of individual operators, and do not laud catgut[1] as superior to silk in anything but convenience. I claim no superiority for it, but neither do I admit the superiority of any other material in general for sutures; individuals have their preference, the result of habit and long continued experience, and now and then under circumstances certain materials are unquestionably indicated, but with the recent progress in surgery, with the development of antiseptic technique, these questions, formerly so important, as to material for suture, kind of suture, and kind of knot, have been blended in that of surgical cleanliness—antisepsis—this is the requisite. I may, perhaps, add, sufficient strength to permit of a perfect coaptation of the parts until union has taken place.

Several years ago, when I first took this position, I repeatedly used silk, silver, horsehair, silkworm gut, and whale tendon indiscriminately in one and the same operation, stitching with some, tying with others, to demonstrate to students of how little importance the material was, but for over two years I have used catgut only and prefer it, as a matter of convenience; let this then, and not superiority determine our choice—as there is no superiority.

Respectfully yours,

GEORGE J. ENGELMANN.

ST. LOUIS, December 5, 1887.

[1] I refer, of course, to the catgut of modern antiseptic surgery, a very different article from old time catgut.

THE EYESIGHT OF SCHOOL CHILDREN.

To the Editor of THE MEDICAL NEWS,

SIR: A notice in the Medical Progress columns of your journal of this date, as to a new apparatus devised by Prof. Cohn, for testing the eyesight of school-children, contains the comment that this is a matter which is scarcely attended to at all in this country. This would indicate an opinion that relatively less importance is accorded to this question by oculists here than abroad. As this is a somewhat prevalent mistake, a correction of it, and of several kindred errors may be in place.

Of about 140 investigations of the eyes in the schools thus far recorded, 21 have been made in the United States (more than in Great Britain, France, and Scandinavia combined); and while none of these are inferior in value to many of the often-quoted German studies, some are among the best of the kind. The earliest, Callan's study of negro pupils in New York (*American Journal Medical Sciences*, April, 1875), has few equals anywhere. But comparisons, though tempting, are dangerous.

So far as any special apparatus is required to supplement the test-letters of Snellen, it has been furnished by Green, Dennett, and others; and Prof. Cohn's card, which has long been in the hands of some of us, is simply a set of the E like "haken," which Snellen gave us long ago. There has been no trouble from lack of efficient means for such examinations, were the opportunities only afforded.

The American investigations have been comparatively unnoticed for several reasons: First, they have been scattered about in school reports, society transactions, and our countless journals, in a way that has made them extremely difficult to find, even for one who has for years been seeking them. Then the public interest in them is less. We have no compulsory military service, and our Government has not been forced to recognize the number of conscripts who have to be rejected because of defective vision or high degrees of near-sight—a point of no small concern to the military authorities of the Continent. So too, in our educational methods, we have little of the rigid grading of the German schools, which enforces some ten or twelve years of school before the University can be entered—each year crowded with an amount of work that casts our public school cramming in the shade. The increase in the percentage of nearsight from the lower to the higher classes, which sends the young Germans out more than half of them myopic before they go to the universities, must needs challenge the attention of educators and of the general public. The educated classes are, themselves, the victims; all professional men having to pass through this preliminary training—so that the facts are patent to the whole body of medical men, however much familiarity may have lessened the force of their lesson. Then, the status of the investigators on the Continent, often semi-official, has lent weight to their utterances and has aided in disseminating their results.

Doubtless the European investigators have had many difficulties in pursuing their studies, and are subjected to much criticism; but in America has there not been too often an unfortunate jealousy in the medical profes-

sion which has looked askance at all such examinations, lest they should bring the examiner into undue public notice? The most scrupulous conduct on the part of the investigator will not free him from the imputation of sordid motives in his undertaking; and the publication of results or the enforcing of their teachings will almost always arouse antagonism and invidious criticism. Among parents and educators there has been an indisposition "to have notions put into the children's heads that there is anything wrong with their eyes." The teachers have often all that they can do to carry out the curriculum entrusted to them, and naturally deprecate any investigations which may add hygienic duties to their tasks. Many of them are already laboring in the most self-sacrificing way to save their pupils from damage in school; but the majority ignore the matter in most of its aspects. The parents are too often inclined to resent as an invasion of their American liberties any investigation of their children's eyes, and oppose it as vigorously as the railway employés do the color-tests. All remote advantage is wholly overshadowed by present inconvenience, real or fancied. Under these conditions a self-respecting student of the subject must be zealous indeed to carry out such a piece of work; and not a few who have done so have withheld their results from publication.

There are among us dozens of competent men who, looking for no other reward than the right to utilize the scientific results of their studies for the instruction of themselves and others, would investigate in all our schools this crying need of our civilization, if only the opportunity were afforded them. The amount of labor involved is known only to those who have experienced it; but the importance of the data which remain to be obtained would nerve many to the task. Every such study will be of value to the school where it is made and to the individuals examined; and if regularly repeated at intervals, doubly so; while if well done its value will be much more enduring and far-reaching. A careful study of each investigation thus far made, has shown in most of them imperfections, grave, indeed, but readily avoidable; and vast as is the work already done, much remains to be elucidated by future examinations. The evil, though less crying among us than in Germany, is none the less real and menacing here, as numerous studies show. A great step would be gained if only a card of Snellen's letters or any other suitable test were to be placed in every school-room where the children could test their own vision and compare it with our standard; and for this purpose Dennett's card (*Transactions of American Ophthalmological Society*, 1886) is probably one of the best. But is it not time that the medical profession, at least, if not the general public, should be aroused to the importance of the subject and to a belief that it can be investigated, as it deserves to be, in a purely public spirit?

It is doubtless true that insufficient attention is given to the subject in this country, as you suggest, but I would protest that the fault is not to be ascribed to the oculists, who have already, in face of many obstacles, done excellent work, and stand prepared to continue it whenever their services are desired.

Very respectfully yours,

B. ALEX. RANDALL.

PHILADELPHIA, December 10, 1887.

NEWS ITEMS.

THE BOSTON MEDICAL LIBRARY ASSOCIATION has authorized its Executive Committee to purchase land on St. Botolph Street, on which at some time in the future to erect a library building. In order to secure the new lot it has been necessary to place a mortgage upon the newly purchased land, and also upon the present library building.

DR. THOMAS F. WOOD, editor of the *North Carolina Medical Journal*, is recovering from aneurism. His treatment has embraced his confinement to his bed for over a year.

MR. LAWSON TAIT has been appointed to a recently established Chair of Gynecology in Queen's College, Birmingham.

THE COLLECTIVE INVESTIGATION OF SYPHILIS is about to be undertaken by a committee of the various specialists interested in this study, in the German hospitals.

COLLECTIVE INVESTIGATION OF SCARLET FEVER.—The success which followed the collective investigation regarding the practical value of "swill milk," instituted by *Science* in June last, has led that journal to begin, in its issue of December 16, 1887, a similar investigation regarding scarlatina, as met by physicians in general practice. A list of inquiries has been prepared which covers the recently raised questions regarding scarlatinal contagion, and the replies of physicians, to these inquiries, in various portions of the United States will be published from time to time.

THE TOWN COUNCIL OF WONSACKET, RHODE ISLAND, recently held a conference with the physicians of the town to devise the best means of restricting scarlatina. Other municipalities could imitate the example with profit.

THE CROWN PRINCE OF GERMANY.—According to the *Lancet* of Dec. 10th, the physicians in attendance upon the Crown Prince are giving a trial to the treatment suggested by Dr. Freund, of Vienna, and based on his analyses of the blood of patients suffering from cancer which showed an excess of sugar. By a rigid exclusion of sugar from the diet, and the substitution of saccharin, it is attempted to reduce the amount of sugar in the blood, and by that means to prevent the malignant growth. Dr. Freund's views have not won general acceptance, and one fact which is strongly adverse to them is that the subjects of diabetes mellitus are not specially liable to be attacked by cancer. We are glad to learn that there has been an improvement noted in the Crown Prince's condition during the last fortnight, and we hope it may continue. The period of improvement corresponds with the adoption of Freund's treatment, and very naturally this has excited hopes that a further continuance of it may be attended with still greater success.

BLACK UPON GREEN, FOR OCULAR HYGIENE.—Several of the French railway companies and other public bodies have resolved on having their printing done on

green instead of white paper. The reason for the alteration is, that they believe the combination of white paper with black characters endangers the eyesight of their workpeople. Black on green has always been recognized as a good combination, and many railway tickets are so printed.

THE CHROTOGRAPH is a pencil manufactured in Germany for writing on the skin. It is made in various colors, and affords legible writing, which can be easily removed without the use of water. It is designed for the use of physicians, to make memoranda upon their patients.

VENTILATION OF SICK BEDS.—DR. WYMAN, of Cambridge, Mass., describes his method in a recent number of the *Lancet*, as follows:

In the Cambridge (Mass.) Hospital there is an arrangement for the ventilation of the beds not generally known; it is so effective that I wish to describe it. Beneath each bed is a ventilating tube of about eight inches diameter, fifty square inches area, leading directly through the floor to a foul-air trunk, beneath which it communicates with the main ventilating chimney. About 2000 cubic feet of air an hour is thus drawn from beneath each bed. This ventilating tube is connected with the bed above by a four-inch pipe of tinned plate, with a proper cover and joints, which passes around the side or foot of the bed and into it beneath the clothing. This pipe is lengthened with one of the same size of pasteboard or other substance, a non-conductor of heat, reaching to any part of the bed. By this simple means foul air is removed as fast as formed, the bed kept free from odor, and the patient's body is no longer surrounded with contaminating gases. As the air presses inward through the porous bed-clothing none escapes into the ward. Further, a two-inch flexible pipe is adjusted to that just described, and slipped over the hollow handle of the bed-pan when in use, carrying off odor from that also. In the same hospital similar means connect the beds in the private wards with the chimney of an ordinary fireplace, up which the pipe reaches about four feet to insure a good draught with a moderate fire; the part in the chimney is of black iron. The advantages of such an arrangement in cases of sloughs, foul ulcers, cancers, and in fevers with frequent fecal dejections, are obvious. It may be supposed that the passage of air through the bed would cool it too much. Practically it does not; probably the quantity of air passing is about the same as in beds ordinarily at the same temperature of the room, but in a different direction.

AN INDIAN'S BRAIN.—The College of Physicians of Vienna were greatly interested, at a recent session, by the examination of the brain of an Indian. They found the cerebrum inferior to the cerebellum in development, and in the former a tendency to the formation of a convolution in the frontal lobe, which is characteristic of the horse and ox.

A RED CROSS PRIZE.—This Society has offered a prize of $1400 for the best design for a portable hospital.

THE DESTRUCTION OF ANIMALS BY INTENTIONAL INOCULATION WITH TUBERCULOSIS.—From the *British Medical Journal* of December 3, 1887, we learn that the rabbits introduced into Australia a generation ago have increased at such a rate that the Government of New South Wales has offered a prize of £25,000 to any one who will discover a means of checking their further multiplication. M. Pasteur has come forward with a suggestion which belongs to the same order as one made some years ago and already carried into practice on several runs, without, so far as has yet been announced, any very great success. The older proposal was to inoculate a number of rabbits with tuberculosis, and to turn them loose to infect the rest; M. Pasteur's plan is to use the virus of the so-called fowl cholera in the same way. The disease can be communicated to fowls by giving them food sprinkled with cultivation fluids in which the bacterium of fowl cholera has grown; and he assumes that the disease could be communicated to rabbits, which are very susceptible to it when inoculated in the same way. He also assumes that it would spread from rabbit to rabbit by infection through the droppings.

CREMATION OF GARBAGE.—The cremation of garbage is a question of great interest to all cities at the present moment. It is, as yet, an experiment, but one upon which several cities are working with pardonable enthusiasm. Montreal and Wheeling, W. Va., are, on this continent, the pioneers in this movement. At Montreal, Dr. La Berge, the medical health officer, reports that the garbage is consumed in a perfectly satisfactory manner by the Mann furnace under a contract made by the year. There is no evidence as to the actual cost of the consumption to the contractor, as he, very properly, refuses to disclose the amount which he makes on his contract. At Wheeling, where the Smith furnace is used, we believe, reports vary as to its utility. It is evident that the municipal management of it is not the best which could be given it. At Des Moines, Ia., a small Engle furnace is in experimental use, and is working very satisfactorily. At Pittsburg, Pa., a Rider furnace has been in use about two weeks, which is too short a time to allow any judgment to be made as to its efficacy. In Chicago a Mann furnace is being constructed. It will soon be completed, and will be managed entirely by our very competent health department, and under such management it is very evident that we shall know its absolute cost and merits. Dr. De Wolf, health commissioner, promises to read a paper on the subject of garbage cremation at the next meeting of the American Public Health Association, in Milwaukee, in 1888, and we may rest assured it will furnish the facts which municipalities most wish to know.—*Sanitary News*, November 19, 1887.

THE DETECTION OF TRICHINÆ.—If the suspected meat be dissolved in pepsin and hydrochloric acid, and allowed to settle in a conical glass, the sediment may be removed by a pipette, and examined microscopically at the convenience of the observer.

MECHANICAL VENTILATION AND MICROORGANISMS.—HALDANE, in a recent paper read before the Sanitary Institute of Great Britain, reports the results of his investigations on the air of school-rooms, as follows:

Wishing to test more thoroughly the results of mechanical ventilation, we made a number of comparative

experiments on different days in the same room. The circumstances were as nearly as possible the same, except that on some days the mechanical ventilation was in operation, and on other days not, open windows, etc., being used instead. We found, to our surprise, that, whereas the carbonic acid present in the air was increased from 12.6 to 18.6 volumes with the mechanical ventilation not in operation, the average number of microörganisms remained almost exactly the same. Even when the mechanical ventilation was kept off for a week, this had no distinct effect in increasing the number of microörganisms. These anomalous results did not lead us to doubt the effects of mechanical ventilation in diminishing the number of microörganisms in air, as we found the number very small even in rooms where every other condition except the ventilation seemed to favor a large number. We were, therefore, forced to conclude that while the ventilation at the time is the decisive factor in influencing the amount of the gaseous impurities, it is not, other things being equal, the habitual state of the ventilation which influences the microörganisms. This led us to inquire into a number of points regarding the sources of the microörganisms.

It had previously been proved by Tyndall and others, that physical disturbances of any kind, such as those caused by the presence of human beings, have a great effect in disseminating microörganisms in air, and that air left perfectly still gradually deposits its microorganisms. We naturally, at first, expected that varying amounts of physical disturbance would very much obscure other differences. It turned out, however, that this is not the case. Although the influence of difference in physical disturbance is well marked, under ordinary circumstances other influences have a much greater effect, as we shall see.

That the microörganisms do not come from the breath, but are on the contrary filtered off by respiration, we showed by means of some experiments, the details of which need not be described here (see *Phil. Trans.*, vol. 178, B. page 92). That they do not come in any large number directly from the clothes or skin of the person present in a room, was shown by a number of observations made in the two chemical lecture rooms. Even during a course of crowded popular lectures there was found to be an average of only four microörganisms per litre, as compared with an average of about three when the room had remained empty. Nor did the number rise beyond six per litre when the room was left unventilated during the lecture, and the carbonic acid rose to nearly 40 volumes per 10,000. This observation alone shows strikingly, I think, that the carbonic acid is no measure of the number of microorganisms in the air of a room.

The microörganisms thus do not come to any large extent from the bodies of the persons present at the time. Nor do they come from the outside air, which is comparatively free from microörganisms during winter, as shown both by our own experiments and by the more recent and systematic ones of Dr. Percy Frankland. We must, therefore, conclude that they come from the floor and other parts of the room itself. If this is really so, the state of a room as regards cleanliness ought to have an effect on the number of microörganisms. This we found to be actually the case.—*Sanitary News*, November 12, 1887.

JAMBUL.—According to the *Pharmaceutical Record* (November 15, 1887), jambul is the fruit of the Indian syzigium jambul (Eugenia jambulanum), and is given for diabetes, in doses of five grains, three or four times daily.

THE VENTILATION OF SLEEPING ROOMS.—DR. BROWN-SÉQUARD, who has been preaching that bad ventilation of sleeping rooms and poor and monotonous food are great causes of phthisis, discussed the subject at the last meeting of the Academy of Sciences, Paris, taking many of his examples from England. Wherever population is dense and sleeping rooms ill-aired or overcrowded, consumption prevails. A room in which a consumptive person sleeps is reeking with contagion if the air he exhales is not carried off. Dr. Brown-Séquard exhibited an apparatus of his invention. A reversed funnel the shape of a lamp-shade is placed at the end of a tube, so arranged that, when it is placed beside the bed, the reversed funnel will be above the sleeper, and draw up the air he breathes. The other end runs into the chimney of the room. If there is none, it is taken through a heating apparatus to an airhole. In either case the contagion is destroyed by heat, after the manner suggested a few years ago by Dr. Burdon Sanderson and others.—*British Medical Journ.*, December 3, 1887.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM DECEMBER 13 TO DECEMBER 19, 1887.

HARRIS, H. S. T., *First Lieutenant and Assistant Surgeon.*—Ordered from Fort McIntosh to Camp Pena, Colorado, Texas.—*S. O. 283, Department of Texas*, December 12, 1887.

CLENDENIN, PAUL, *First Lieutenant and Assistant Surgeon.*—Ordered from Camp Pena, Colorado, Texas, to Fort McIntosh, Texas.—*S. O. 283, Department of Texas*, December 12, 1887.

OFFICIAL LIST OF CHANGES OF STATIONS AND DUTIES OF MEDICAL OFFICERS OF THE U. S. MARINE HOSPITAL SERVICE, FOR THE WEEK ENDING DECEMBER 19, 1887.

MURRAY, R. D., *Surgeon.*—Granted leave of absence for fourteen days, December 8, 1887.

GASSAWAY, J. M., *Surgeon.*—Granted leave of absence for fifteen days, to take effect when relieved, December 17, 1887.

IRWIN, FAIRFAX, *Surgeon.*—Relieved from duty as Acting Chief Clerk, Office of Supervising Surgeon-General, and to await orders.

CARRINGTON, P. M., *Assistant Surgeon.*—Ordered to examination for promotion, December 14, 1887.

BROOKS, S. D., *Passed Assistant Surgeon.*—Granted leave of absence for thirty days, to take effect when relieved, December 15, 1887.

MCINTOSH, W. P., *Assistant Surgeon.*—To proceed to Wilmington, N. C., for temporary duty, December 13, 1887.

A CLINICAL ANALYSIS OF SIXTY-FOUR CASES OF POISONING BY LEAD CHROMATE (CHROME YELLOW), USED AS A CAKE-DYE.[1]

BY DAVID DENISON STEWART, M.D.,

CHIEF OF THE MEDICAL CLINIC IN THE JEFFERSON MEDICAL COLLEGE; ASSISTANT PHYSICIAN TO ST. CHRISTOPHER'S HOSPITAL FOR CHILDREN.

IN presenting to the profession through THE MEDICAL NEWS of June 18, 1887, some hastily prepared notes on several cases of lead-poisoning, whose source I had traced to the use of lead chromate as a food adulteration, I was unaware of the rather extensive use of this substance as a food color and of the wide prevalence of lead-poisoning through this means. The present paper is an analysis of the symptoms of sixty-four of these cases, fifty-seven of which I have personally carefully examined. All of them had consumed, for a considerable period, large quantities of the cakes containing the lead chromate and all showed some unmistakable signs of plumbism, which, by diligent inquiry, I was unable to trace to other sources. I have excluded some cases which I have no doubt are due to lead, presenting none of what are ordinarily regarded as the essential symptoms of plumbism, such as the blue line on the gums, colic with constipation, arthralgia, etc., time not permitting examining the urine for the metal. I prefer to deal here almost solely with the class presenting the ordinary symptoms more or less pronounced, concerning which, there can be no question as to diagnosis. I have found that there is a much larger class with symptoms more or less obscure and not especially suggestive of plumbism, but whose condition is, nevertheless, due to the action of lead and deserves most careful consideration and study. They make a far more instructive group than these here considered, since, because of the obscurity of their symptoms, serious mistakes in diagnosis are constantly being made.

I have met a number of these cases recently, which, though I believe there can be no doubt as to the nature and source of the symptoms, I prefer not to discuss as a group until I can, at the same time, present the results of the urine analysis which Dr. Leffmann is now carrying out. In the present group are a few, for example, one of the cases of encephalopathy (Mrs. V. G.), that approach those that present so-called "classical" symptoms of lead-poisoning, there being some few features in common; yet of them, those in the latter are obscured by more prominent symptoms not generally considered suggestive of plumbism. In a subsequent paper, the material for which is being collected, some cases of this sort will be discussed and the results of the tests for lead in the urine given.

The sixty-four cases here considered include nearly all that first came to my notice due to the introduction of lead chromate into the food furnished by the two bakers, Palmer and Schmid, who were recently held by the coroner to await the result of a judicial inquiry. They do not by any means include the whole number affected. From subsequent observation I am convinced they are only a modicum and that the extent of the evil is not yet fully known

Of these 64 cases 32.81 per cent. (21) are males and 67.18 per cent. (43) are females. This large excess of females affected may be explained by their greater fondness for the food containing the lead salt. Both sexes appeared to be equally susceptible to the metal and each suffered with equal severity. Of five women who exhibited symptoms of plumbism during gestation, none aborted, but all at full term gave birth to living children; one had, however, two convulsions at the termination of the seventh month of pregnancy, believed to be of saturnine origin, though a small amount of albumen was present in the urine. Four of these five infants had convulsions within two months after birth, in which two died.

78.21 per cent. (50) of the cases exhibited the saturnine cachexia, displaying an anæmic appearance with an earthy-yellow hue to the skin; a sallow tint without yellowness was present in the remaining 21.87 per cent. (14). In 10.93 per cent. (7) the skin became intensely yellow at one time or another, notably when colic was present. The dull, anæmic, somewhat listless look, associated with a peculiar fulness of the cheeks, of which Oliver[1] speaks, and which is considered by him as quite suggestive of plumbism, I noticed in but three cases. Emaciation was present in nearly all who had been affected for several months and in some was marked.

In a large number neurasthenic symptoms antedated for a considerable period the outbreak of colic, arthralgia, or encephalopathy. Many recalled that for days and weeks prior to the development of marked symptoms of plumbism they were affected with progressive muscular weakness, the slightest exertion causing fatigue, and often aching in the lower extremities; they had vague pains in various parts of the body, loss of flesh, mental depression, the skin had become sallow, they had passed restless nights, were affected with insomnia and arose in the morning totally unrefreshed.

Among the neurasthenic symptoms to be especially noted are: the mental depression, which was a

[1] Brit. Med. Journal, Oct. 17, 1885, p. 732.

prominent symptom in 54.68 per cent. (35), in several it approached melancholia; marked impairment of memory present in 17.18 per cent. (11); great prostration and weakness, the slightest exertion causing fatigue, present in 54.68 per cent. (35) —the fatigue was especially marked on rising in the morning, and may have been caused in part by obstinate insomnia, with nocturnal restlessness, of which the same number complained; vague neuralgic pains as a portion of the neurasthenia—apart from severe arthralgia—were present in 9.36 per cent. (6); 7.81 per cent. (5) made complaint of general pruritis, unassociated with icterus, and the same number of cutaneous and muscular hyperæsthesia. These symptoms were, in nearly all classes of cases, associated with those indicative both of disordered primæ viæ and of the specific action of the metal on the gastro-intestinal apparatus. There were very few of the sixty-four that had not more or less pronounced anorexia, associated with a heavily furred tongue, and a very fetid breath, which in some cases was so peculiarly so as to deserve the name metallic. 32.81 per cent. (21) spoke of a bad taste, which 2 described as persistently sweetish; 1 as metallic; 1 as sulphurous, and 4 as sour; 13 were unable to describe theirs intelligently. Nausea was present in a large number, and in several who vomited very little, if at all, and had no colic. Colicky pains of all sorts, severe and light, and attended by more or less constipation, were present in 76.56 per cent. (49), and 60.93 per cent. (39) exhibited the phenomena of pronounced lead-colic. These pains were felt most often about the umbilicus, and following that in frequency about the epigastrium; they were in 53 per cent. (26) of the (49) cases relieved by firm pressure when applied gently and were accompanied by obstinate constipation in 55.10 per cent. (27); and moderate in 34.68 per cent. (17); obstinate constipation, alternating with severe diarrhœa, was present in 1.55 per cent. (1). Agonizingly severe loin pains coexisted with 19 cases of pronounced colic.

The peculiar character of the pulse—diminished in frequency and increased in strength and volume —usually considered one of the characteristic features of lead colic, I did not find present in the five cases I saw in the paroxysms; in these it was frequent and of only moderate strength and volume.

One of these cases was a patient of my own and was of peculiar interest because of her symptoms closely resembling hepatic colic. She is a woman weighing over two hundred pounds, whose first noticeable symptom of plumbism was attacks of exceedingly severe colic always appearing suddenly, and having their seat in the right hypochondrium and thence radiating to various parts of the abdomen and back. They were usually preceded for a day or two by slight colicky pains in the region of the gall-bladder and epigastrium, with constipation, anorexia, and an icteroid hue of skin. There was always during the attacks tenderness on superficial or deep pressure over the hypochondriac region, and the abdomen was distended rather than contracted; constant nausea and frequent vomiting were present, the vomited matter consisting largely of bile; the bowels were much constipated and the scybalæ voided were clay-colored; the urine was concentrated, scanty, and contained a large excess of urates, but no albumin or casts. The attacks rarely lasted over eight or twelve hours, being checked without much difficulty by free use of morphine and atropine hypodermatically. Because of her general condition, habits of life, and her known fondness for sweets and fats, colic due to the passage of gall-stones was at first suspected and treatment was instituted for that affection, her feces being carefully washed and strained, but no stones were ever detected. Her gums, which were much retracted, showed a faint bluish streak along the lower incisors. She subsequently developed more marked symptoms of plumbism, but under potassium iodide made a rapid and continuous recovery, entirely regaining color and losing the constipation.

The frequency of the presence of vomiting in all classes of cases, and particularly in those with epigastric and umbilical pains deserves more than passing notice, and would seem to indicate a special irritant action of the lead chromate. It occurred in 81.63 per cent. (40) of the forty-nine cases of light and severe colic, and in eleven (17.18 per cent of the sixty-four) cases in which other symptoms than colic were present. It was present, therefore, in 79.68 per cent. (51) of the whole number of cases and was nearly always severe. The vomited matter had a greenish-yellow or greenish hue. Nausea preceded vomiting and was a quite constant symptom in a few of the sixty-four who did not vomit. Tanquerel, who saw a very large number of cases of plumbism, recorded 1217 carefully studied cases of lead-colic; he found vomiting present in only 33 per cent. (412) of the 1217, and rarely if ever observed it with other manifestions of lead disease than colic. I believe the abdominal pains in all of the 49 cases were colicky and not inflammatory, though I am unable to be as positive regarding this point as I should like. Against it in a minority were the facts that firm pressure seemed to aggravate them greatly, and the abdomen in several cases was distended during the paroxysms. The pulse, too, during the paroxysm in at least 5 cases was far from being characteristic of lead colic. The color of the vomit was probably due to bile and not to the lead chromate, for Tanquerel mentions a somewhat similar colored vomit in his cases which were not due to poisoning by this particular salt of lead, and this same character of vomit continued in many of the cases, at intervals, for several weeks after the poison had ceased to be ingested.

It has been ordinarily supposed that lead chromate is soluble to a very limited extent in the intestinal juices, and hence its ingestion in small quantities cannot give rise to serious symptoms, though Schuchardt[1] states that it appears to act as a corrosive poison and more powerfully even than the acetate, while Wharton[2] and Stillé suppose it is more or less insoluble, though they believe it sometimes gives rise to acute poisoning owing to its decomposition

[1] Maschka's Handbuch der Gerichtlichen Medicin.
[2] Medical Jurisprudence.

after it enters the body. Owing to this fancied insolubility and the number of cases now indubitably traced to its use as a food-dye, it might be thought that the samples used by bakers contained lead carbonate as an adulterant and that the poisoning was due to the latter more soluble salt, but Dr. Leffmann has recently ascertained by experiment that, while the commercial samples do not yield lead to distilled water or carbonic acid water under pressure, notable quantities are dissolved in a short time by dilute solutions of the ordinary household acids, citric and acetic, and also by very dilute solutions of hydrochloric acid, or by very dilute solutions of hydrochloric acid and pepsin. The non-solution of lead from commercial lead chromate by carbonic acid under pressure indicates that the samples tested, which include that obtained from Palmer, do not contain lead carbonate. These facts set at rest the question of insolubility, and explain the ease with which poisoning occurred; especially when one reflects that the lead was taken with the food, at a time when it could most readily meet the agents necessary for its solution. No doubt, decomposition rapidly follows its ingestion, and soluble chromium and lead salts are formed which diffuse into the blood.

That the various salts of chromium do act as local and systemic irritants, there can be no reasonable doubt, one has but to consult the various works on toxicology and jurisprudence[1] for abundant evidence on this point. Lead chromate, because of its supposed non-solubility in the stomach, has been thought less toxic than any of the other chromium salts, though Von Linstow[2] and Leopold[3] report 3 cases of acute poisoning due to it, occurring in very young children,[4] and terminating in death in a very few days, in which the autopsy revealed extensive signs of the action of a corrosive poison, such as softening, ulceration and perforation of the stomach and duodenum, etc., though the amount of lead chromate ingested in each of Von Linstow's cases was said not to have exceeded the one-fifth of a grain. In these latter cases, from the character of various symptoms present and such marked signs of the action of a corrosive poison found post-mortem, as well as from the smallness of the quantity of lead chromate taken, it may be that potassium bichromate, and not lead, was the active toxic agent. In the recent fatal cases it is unfortunate that the viscera were not examined with reference to the action of a corrosive poison. Of the two under my charge, in one, the gastric symptoms were apparently almost nil, in the other, though lead poisoning was suspected to be the cause of death, the source of the poisoning not then being ascertained, the particular salt ingested was not known, and the viscera were removed with as little handling as possible, exclusively for chemical examination.

The abruptness of the seizures in many of the recent cases might suggest acute poisoning, but in all of them, by careful inquiry, I succeeded in eliciting a history of some signs of failing health for at least a brief period prior to the onset of the seizures, and in many of slight colicky, arthralgic or head pains suggestive of plumbism. All, too, showed the sallow skin, and none of this class was without at least a faint blue line on the gums. The four members of the Helm family, whom I saw through the kindness of Dr. Hellyer, were notable examples of this; it was ascertained that in these some of the abovementioned symptoms had been present in a slight degree for the space of a week or ten days prior to the marked outbreak of their trouble, which occurred on June 18th. They were then within a day or so of one another taken suddenly ill; their principal symptoms being, collectively, nausea and frequent vomiting, often uncontrollable, the vomited matter having a yellow or greenish-yellow hue; heavily coated tongue; exceedingly fetid breath; severe, paroxysmal colicky pain above the umbilicus, aggravated by food and apparently by pressure, but decreased by warmth and poultices; severe pains in the loins. Very obstinate constipation was present in all save Annie Helm, whose bowels could be moved without trouble by mild purgatives and whose passages were described to be exceedingly yellow. All had very severe pains in the knees and ankles unattended by heat, redness, or swelling in any save Mr. Helm, who, after a few days, had an attack of acute articular rheumatism as a complication. Violent continuous cephalalgia was present in Annie[1] alone and was the precursor of convulsions, which appeared on the fifth day. The convulsions were at first local but soon became general, violent, and long-continued; in the intervals she lay in a comatose state and died on the eighth day. The skin of all was sallow, Mr. H. and Annie becoming quite jaundiced, and on the gums of all could be seen a slate blue line.

In some of the Palmer cases, for example, the first two children, Charles, æt. 7 years, William, æt. 10 years, which, from not being able to get detailed histories, I have excluded from the cases here analyzed, symptoms were present indicating the action of an irritant poison. They were seized, one on May 9th, the other on June 27, 1884, suddenly with nausea, vomiting, abdominal pains, great prostration, and continuous convulsions, and died within 24 to 36 hours after the onset of the symptoms. They were both, from all I can learn, thought to be in good health on the morning of the day of seizure, and were known to have eaten largely of the baker's colored cakes on that day, while one, in addition, drank quantities of lemonade. I have notes of a case resembling these as regards the abruptness of the onset, which, however, did not have a fatal termination. It was that of a boy of 12 years, who, some hours after a hearty meal of dyed cakes procured from Palmer, was seized with identical symptoms. He has since come under my observation

[4] Leopold's case was æt. 2 weeks; Von Linstow's were æt. 1¼ and 3½ years respectively.

[1] Notable quantities of lead were found in her viscera by Drs, Reese and Leffmann, vide THE MEDICAL NEWS, Aug. 27, 1887. p. 231, Case v.

suffering with lead cephalalgia and arthralgic pains in the knees and ankles. Six cases, similar to the last, exhibiting symptoms of acute poisoning due to the same cause, were reported in the *Medical Times and Gazette* of December 24, 1859.

Arthralgia was present in 73.43 per cent. (47); in 56.25 per cent. (36) it affected the inferior extremities, including the loins, only; in 17.18 per cent. (11) it was more or less general. In 64 per cent. (41) it was severe, agonizingly so in a few; in the remaining (6) cases it was slight, and in all the pains in the lower limbs were of greater severity than in the upper. In 37.50 per cent. (24) it was associated with headache, which, in most of the instances, appeared simultaneously; in 20 of these the headache was severe, in 4 mild. Severe arthralgia, without any preceding or following colic, but with usually cachexia, disordered primæ viæ, and (in two) constant diarrhœa, occurred in 8 of the 47. In 10 cases the arthralgia preceded for a considerable period the colic and other symptoms, save cachexia and debility; in 29 cases it occurred coincidently with or following colic. The flexor surfaces of the knees and ankles and usually the flexor muscles about these joints, were most affected; cramps in the calves and posterior and outer aspect of the thighs were frequent accompaniments of the pains. In several burning pain was felt in the soles of the feet and in the toes, accompanied by a hyperæsthetic condition of the skin of the same parts. In the 11 cases in which the superior extremities in addition to the inferior were affected, the pains were less severe above than below, and here, too, showed a preference for the flexor surfaces. The pains of all were acute and burning, or dull and aching in character, were always worse at night and never accompanied by inflammatory conditions, such as heat, redness, or swelling, save in the case of Helm, mentioned on page 755. They were in all assuaged by pressure and friction, but in many, increased by motion, and their onset was often preceded by ataxic symptoms in the limbs.

Many made complaint of a dull aching throughout the whole body, referring it especially to the osseous system. It was particularly marked at night and usually antedated colic and arthralgia.

Paralysis of the extensor muscles of the forearm, typical wrist-drop, occurred in only two; in both it was bilateral and seemingly complete. I was unable in either case to get the electrical reactions, because of ignorant opposition on the part of the subjects and their friends. In three cases there was slight ataxia of the extensors of the wrists and fingers, but paralysis did not occur.

Headache was present in 73.43 per cent. (47); in 67.18 per cent. (43) it was more or less constant for a considerable period, with exacerbations and remissions, and of sufficient severity to indicate involvement of the deep cranial structures. In 35.93 per cent. (23) it was present without arthralgia. It was felt most severely and frequently in the frontal regions, and, following that, in the occipital; in a few it was equally severe and constant in both regions. Some, in addition, complained of pain in the nucha, and in a small number the pains were equally distributed about the head.

Encephalopathy was present in 23.43 per cent.[1] (15); in 17.18 per cent. (11) it was manifested as eclampsia; in 2 (3.12 per cent.) as delirium; in 1 as a modification of the delirious form, melancholia with accompanying hallucinations and delusions; and in 1 as coma. The eclamptic seizures were of epileptiform type, and were preceded in 10 of the 11 cases for days or weeks by other manifestations of saturninism, such as cachexia, colic, arthralgia, or severe continuous headache; and in at least 5 of these they occurred primarily, during or immediately subsequent to an attack of colic and arthralgia. In at least 4 of the 10, excruciating cephalalgia preceded for several days their outbreak. The convulsions were in all, general, severe, and in several, violent. The duration was longer than that of idiopathic epilepsy, the clonic stage often continuing upward of a half-hour, during which the tongue was known to be bitten in at least 6. The intervals in the 8 fatal cases were exceedingly brief, the convulsions rapidly recurring, until death took place in from eight hours to four days. In these, too, after the first few seizures, consciousness was entirely lost, and stupor or coma persisted until dissolution. I was unable to discover that an aura preceded the convulsive attacks in any of the 11 cases save 1, yet it may have in all; in this one it preceded only three spasms out of several. In 7 of the 11, I was able to discover the probable time existing between the first exposure and the appearance of the convulsions, during which lead was constantly ingested. In one it was 15 days; 32 in another, and 33 in a third; $2\frac{3}{4}$ months in a fourth; 4 months in a fifth, and $4\frac{2}{3}$ months in a sixth—these were all members of one family; in a seventh it was about $2\frac{1}{2}$ months.

This last case presents several points of interest. It may be one of a type which is occasionally overlooked. It is that of Mrs. S., aged thirty years, of good previous health, who had eaten from early in April, 1886, for a period of fourteen months, almost daily of the dyed cakes. For one-half of this period she ate daily from four to six of the buns, frequently then partaking of nothing else at the morning or evening meal. For two or three months anterior to her confinement on May 23, 1886, she began losing strength, was restless and sleepless at night, rising in the morning weak, enervated, and listless; she had anorexia, occasional nausea, vomiting, colicky pains, and constant dull aching in the knees and ankles; her skin became sallow and pruritic, and the bowels constipated. About June 15, 1886, during an attack of severe headache and of what presented the phenomena of mild lead-colic, save that diarrhœa alternated with constipation, she had a violent epileptiform convulsion, lasting nearly an hour, during which she severely bit her tongue, as she did in all subsequent convulsions; no aura preceded. On July 6, 1886, all the less pro-

[1] If three of the earlier Palmer cases, the two boys before mentioned and the first Mrs. Palmer, were added to these, this percentage would be raised to 26.86 or 18 cases out of 67, and that of the eclampsic variety to 20.89 or 14 cases out of 67. They were undoubted cases of lead eclampsia, and are excluded from this paper only because the lack of detailed history renders them unavailable for statistical purposes.

nounced lead symptoms continuing, she had three convulsions in the space of three hours; severe headache and slight colic preceded for two or three days. On the 25th of the same month, after a day or two of colic and headache, she had a number of convulsions lasting four and a half hours, with intervals of unconsciousness. In December, 1886, and March, 1887, they recurred, preceded by the same symptoms, and now, for the first time, prior to these and the last convulsions occurring at midnight on May 28, 1887, she had a distinct sensory aura of numbness and tingling throughout the body immediately preceding, and she felt a seizure imminent. The spasm of May 28th was very violent, and was preceded for a few hours only by abdominal cramps, which appeared during the evening after eating a number of particularly yellow cakes at her noon lunch.

I saw her early in August last for the first time, she then had been for months under the treatment of irregular practitioners, who had been unable to discover the nature or source of her malady; she presented marked symptoms of plumbism with pronounced lead cachexia. There were present in addition, frequent attacks of syncope by day, and at night delirium accompanied by limited clonic spasms. There was a pronounced blue line along the lower gum, which was much retracted from the teeth; in the upper gum where no teeth existed, no blueness could be discovered. Her heart was over-acting with a ringing, apical second sound. The urine was found to contain lead in notable quantities, but though repeatedly carefully examined for albumin and casts none were at any time found. She was under treatment for a short time and improved; I then lost sight of her. I have since understood that she has developed delusional mania.

One of the two cases of the delirious variety of encephalopathy has been already described;[1] the other was a more pronounced one. It was that of a girl, E. B., aged eighteen, who was profoundly saturated with lead through baker Schmid's cakes. Preceding a marked outbreak of arthralgia and encephalopathy she had symptoms indicating mental and physical exhaustion; she entirely lost her memory, was incapable of exertion, and was constantly wearied; there were present well-marked lead-cachexia, total anorexia, coated tongue, fetid breath, frequent nausea, and vomiting of a greenish-yellow fluid, obstinate constipation, an intense blue line on both gums, so marked that it was noticed by her acquaintances, but at no time did she have colic. She had three or more seizures, lasting two or three weeks at a time (with a number of minor ones), in which she was almost constantly delirious with very brief lucid intervals. They were always preceded for a day or two by intense frontal headache and exceedingly severe pains in the knees, calves of the legs, ankles, soles of the feet, and, occasionally, the loins. There were intermissions of about a week between the attacks, and all her symptoms were aggravated at night.

The case of melancholia with accompanying delusions deserves at least brief consideration. It was referred to on page 753 and is of interest because the absence of the more pronounced symptoms of lead-poisoning caused it to be mistaken by two physicians for several quite different affections. The following are the points briefly given:

Mrs. V. G., aged twenty-two; no children; had been for months a hearty eater of Palmer's dyed buns; in excellent health up to three and a half months ago, then began to grow progressively weak, was easily wearied, the slightest exertion causing great fatigue; she suffered with insomnia, was depressed mentally, and there were constantly present such disorders of the digestive apparatus as coated tongue, foul breath, bad taste, frequent nausea with occasional vomiting, especially after food, mild constipation, and occasional slight colicky pains in the left lumbar and inguinal regions. There were also total anorexia, and earthy-yellow hue of skin, and severe, constant, dull, aching pains in the knees, with a feeling of soreness in the feet. Violent occipital and frontal headache appeared shortly after she began to fail in health and soon became constant with remissions and agonizing exacerbations often associated with transient amblyopia. About the same time she was affected with subjective and objective vertigo, the slightest exertion causing giddiness. Since the headache and vertigo have been present she has frequent hallucinations and delusions of sight and hearing, among others, she would imagine she was approached by persons, who did not exist, with whom she would carry on lengthy conversations. During and following these spells she becomes exceedingly despondent and has dismal forebodings.

At the present time, in addition to the above symptoms, she complains of slight ataxia of the forearms, though the muscles respond normally to faradism and galvanism. The heart is overacting with an accentuated second sound at the apex and high tension in the pulse at the wrist. Various specimens of her urine were carefully examined for albumin at different times, but always with a negative result.[1] As her sight had recently failed somewhat, the eye-ground was examined by Dr. Hansell, who reported that "in the right eye the nerve is oval; the upper and outer quadrant is lined with pigment; the lower part is clear and sharply bounded. There is venous pulsation; the arteries are slightly swollen, more so than normal. The above conditions are even more pronounced in the left eye." The gums of this case did not show what is ordinarily regarded as a "blue line," but within the thin margin of gum grasping the neck of the upper left central incisor could be seen by careful inspection with the naked eye, and more easily with a single lens of moderate power, a number of bluish-black dots which were undoubtedly lead. A piece of white paper pushed up under this edge of the gum, between it and the neck of the tooth, brought out the dots with great distinctness. The thin edge of gum about the necks of the lower

[1] The Medical News, June 18, 1887, p. 679; Case VII.

[1] Her urine was not examined for lead until she had almost entirely recovered, and had discontinued the potassium iodide. It was then resumed for a few days, and a sample collected. Several tests were made of it by Dr. Leffmann, and distinct traces of lead found.

central incisors showed this pigmentation somewhat more plainly.

The patient[1] with the comatose variety of encephalopathy presented very much the same symptoms prior to the full development of the encephalopathy as the cases whose histories I have just related, so no detailed description need be given. He was profoundly affected by lead. With him, intense frontal headache, which he described as "deep-seated," and very severe arthralgia of the lower limbs preceded, for a short period, the coma. Though there had been marked gastric derangements, with the various manifestations of lead-colic, it was less evident at that time. So far as I could learn, he had but one attack of coma, very prompt treatment preventing a repetition; this appeared suddenly, during severe headache and arthralgia; he was totally unconscious and remained in this condition for seventeen hours. A careful examination of the urine showed there was no associated kidney trouble.

Encephalopathy is undoubtedly the severest and probably the most infrequent of all the manifestations of lead-poisoning. It has been met with almost exclusively among those whose work favors a copious absorption of the metal. There seems slight doubt, from the large percentage among these 64 cases which are probably but a small part of the number poisoned by the two bakers, that the affection has been more than once overlooked and attributed to other causes. There is now no question, from recent developments, that the poisoning has been going on unsuspected in various sections of the city for years. Since my attention has been directed to the matter, I have been surprised, in looking over the mortuary records of the past few months, to see the large number of deaths returned as convulsions. The matter seems to deserve more attention from the profession than it has yet received.

The gums of 89 per cent. (57) of the 64 showed the "blue line" and it probably existed also in 6 of the remaining 7 cases, but was not looked for. In 24 of the cases the "line" was very marked above and below on the labial and lingual surfaces of the gums, about the necks of the teeth, and was accompanied by more or less retraction of the gum, which bled readily when subjected to even light friction. In 8 of these, who were intensely saturated with lead, the retraction was extreme and the borders of the affected gums looked as if fringed, displaying much of the neck surface of the teeth, which were usually of a brown color. In 16 there was a moderately well-marked "line," either below or above, in the edge of the gum about the necks of the incisors, canines or bicuspids. In these the retraction of the gum was not great, but the thin edge of the mucous membrane grasping the neck had become atrophied, and the edge of the gum containing the deposited metal could be readily separated from the neck and a portion of the fang of the tooth. In 17 the "line" consisted of either a faint, bluish-black streak, limited to the mucous membrane grasping the neck, or of a number of fine bluish-black dots as described in the case of Mrs. V. G., irregularly distributed within the same portion of gum; these dots, or the streak which seemed to be simply an aggregation of them, were most frequently limited to a portion of gum grasping a single tooth, often one of the bicuspids or anterior molars, so that care had to be taken that it was not overlooked. The "line" in most instances was more marked below than above, and much more pronounced on the labial than on the lingual surface. A severe case was seen in that of the wife of one of the bakers, who was thoroughly saturated with the metal. The labial surface of the whole gum in the upper and in the lower jaw was deeply dyed, beside there being a deep line in the gums at their junction with the teeth.

The mortality in the 64 thus far is 12.5 per cent. The 8 deaths were among the eclamptic cases, making a death-rate in the latter of 72.72 per cent. If with these 8 the 3 were included, mentioned in the foot note on page 756, the general mortality would be raised to 16.41 per cent., or 11 deaths out of 67, and the mortality in the eclamptic cases would reach 78.57 per cent., or 11 deaths out of 14.

It is worthy of note that in the viscera of all of the 5 fatal cases examined by Drs. Reese[1] and Leffmann lead was found, and in 4 in notable quantities. It was encountered in large quantities in the liver. In only 2 of the 5 were the brain and spinal cord examined; these organs yielded to several tests distinct evidence of its presence, which indicates that it would probably have been found in the same organs in all had they been examined.

In conclusion I desire to express my thanks to Dr. Leffmann for examining the urine of several of the cases for lead, to Dr. Hansell for eye examinations, to Drs. E. Hellyer, Isaac MacBride, and W. K. Brown, for permitting me to see and study their cases, and to Drs. A. A. G. Starck and W. G. Bobb for histories of their cases, some of which I have used in the preparation of this paper.

A NEW CHROMOGENIC BACILLUS—BACILLUS COERULEUS.

BY ALLEN J. SMITH, M.D.,
ASSISTANT DEMONSTRATOR OF PATHOLOGY IN THE UNIVERSITY OF PENNSYLVANIA.

IN a cultivation of the organisms in water from the Schuylkill River (Belmont Reservoir), planted January 15, 1886, there appeared a fungus of intense blue color, which, on examination and further culture, proved to be an unknown species of chromogenic bacillus.

It grows well on boiled potato at ordinary temperatures, with at first a beautiful dark blue hue, deepening into an intense blue-black, as the coloring grows old. The colonies when developed fully are marked by numerous cup-shaped depressions with elevated borders. It is aërobic so far as its color is concerned, the cultures in the mass of gelatine-peptone in tubes invariably developing as colorless growths, while the upper or surface part of the same culture shows a bluish tinge, faint because of the thinness of the stratum. Liquefaction of the surface invariably attends the cultures in peptone

[1] Vide report in THE MEDICAL NEWS, Aug. 27, 1887.

gelatine. The color of the bacillus is contained in the cells, and cannot be dissolved out by water or alcohol; nor is it affected by acids. On potato, where the color is best seen, the bacillus foci grow only on the surface, not penetrating to any depth, as is the case with the micrococcus cyaneus.

The bacillus, as seen under the microscope, is from 0.002 to 0.0025 mm. in length, and 0.0005 in width. It frequently develops in leptothrix-like chains. Some few of the individuals on the specimens mounted present a comma shape, although this is probably accidental, due to overheating in the preparation. An excellent stain for it is the ordinary methyl-violet. For its recognition the higher powers of the microscope should be employed, although the individuals can be discovered with a good $\frac{1}{4}$th inch lens.

It is possible that this form might be confused with bacillus syncyaneus, bacillus violaceus, or micrococcus cyaneus. The color, however, is so intense and in old colonies so dark that it alone should differentiate in every instance.

The coloring matter of *bacillus syncyaneus* (*Beiträge z. Biologie d. Pflanzen*, vol. iii. p. 187) is of a lighter shade, and is changed by soda or potash to a peach-blossom pink, ammonia changing it to a violet color—to none of which reactions the color of *bacillus coeruleus* responds. The *bacillus violaceus* (*Ann. Societ. Nat. Moden.*, xiv. 1880, and *Botanisch. Centralblatt*, 1, 1528) grows best on solution of egg albumin, and the coloring is of a characteristic hue, and the color readily soluble in alcohol. The *micrococcus cyaneus* (*Cohn, Schröter*) grows well on boiled potato, as does bacillus coeruleus, but penetrates with its blue color deep into the slice; its color is soluble in water, the solution at first green and later blue. This micrococcus very readily produces softening and liquefaction, while the bacillus coeruleus produces but a comparatively small amount of such change; and microscopically the diagnosis is readily made. The *micrococcus violaceus* is distinguishable from the bacillus coeruleus by its characteristic hue and its mode of growth (in gelatinous drops of a violet color), and later by the microscope.

Like the other chromogenic bacilli generally, the bacillus coeruleus seems to be non-pathogenic, and is interesting only so far as being an addition to our knowledge of microscopic botany.

#23 SOUTH SEVENTEENTH ST., PHILADELPHIA.

EFFECT OF BERGEON'S TREATMENT ON THE URINE OF PHTHISICAL PATIENTS.

BY R. C. HUTCHINSON, M.D.,
PHYSICIAN TO THE NEW JERSEY STATE PRISON,
AND
C. F. ADAMS, PH.G., M.D.,
OF TRENTON, N. J.

WE have the theory that hydrogen sulphide, when administered by rectal injection, is not absorbed by the system, but that, being carried by the venous system to the lungs and there exhaled, it acts only locally on the mucous membrane; such being the case, it would have no effect on the urine, but if it was absorbed the amount of sulphates would be largely increased. With the object of ascertaining the fact we made a series of quantitative analyses of the urine of patients thus treated.

The sulphates were estimated by means of a standard solution of baric chloride and proved by a solution of potassic sulphate, as recommended by Neubauer and Vogel; the chlorides, by Mohr's nitrate of silver method.

The phosphates were estimated by means of a standard solution of uranic acetate in the presence of an acidulated solution of sodic acetate, with potassic ferrocyanide as indicator.

The urea was measured by mixing a solution of sodic hypochlorite with the urine, thus decomposing the urea, and then measuring the nitrogen given off, and estimating from that by means of Lyon's apparatus.

Hydrogen sulphide was detected by heating acidulated urine, and allowing the vapor to come in contact with blotting paper moistened with a solution of plumbic acetate, and also by adding some of the lead solution to the urine, which would give a black precipitate.

The ammonia was detected by hydrochloric acid giving white fumes, as well as by red litmus paper, which would be turned blue by the urine, when by the application of heat it would return to its original color.

In selecting cases we endeavored to obtain the different types and stages of the disease represented, as well as possible.

No. 1 was in the third stage, a cavity in each lung, sonorous and crackling râles, copious expectoration and night-sweats, anorexia; pulse 115–150; respiration 50; temperature 102°; urine scanty; herpetic eruption on the face, and confined to his bed.

In six week he was able to exercise in the yards, night-sweats ceased, cough and expectoration slight, good appetite, eruption on face had disappeared.

No. 2, when admitted to the hospital, had a severe hemorrhage; pulse 118; cavity in right lung, expectoration thick and yellow, not profuse. After three months' treatment night-sweats have ceased, cough slight; pulse 90; appetite very good; is gaining strength. The disease was not checked before a cavity formed in the left lung also, but now both lungs are clearing up rapidly.

No. 3, when admitted, had a cough, subcrepitant râles, dulness on percussion. All symptoms generally improved, and is comparatively well.

No. 4 was admitted to the hospital, suffering from a severe hemorrhage from the rectum, weak and fainting. Cough, expectoration thin, dulness on percussion at both apices; large, cold abscess on his neck below lower jaw.

July 21. Lanced abscess.

Oct. 14. Cough and night-sweats ceased; slight discharge from abscess; gain in flesh and strength.

No. 5 commenced treatment July 19, 1887. Troublesome cough; free expectoration of thin sputa; night-sweats, hemorrhage, anorexia.

Oct. 22. Cough and night-sweats ceased; lungs cleared up; good appetite; gaining flesh; slight expectoration in the morning.

No. 6 commenced treatment June 22d. He was in the second stage of the disease; very troublesome cough, requiring about two grains of morphia through the night to control it.

July 25. Morphia and gas stopped. He has only a slight cough and expectoration in the morning; has gained in weight thirty pounds.

Up to June 20th, we made the gas from sodic sulphite, not being able to get sodic sulphide before that time. On examining the urine of four patients a week after the sulphide was substituted, we found that the percentage of sulphur was markedly decreased in them all; on resuming the sulphite, it again increased. There seemed to be much less pain from gas from the sulphite than from the sulphide.

After being on the treatment five or six weeks, the patients do not seem to be able to retain the gas so well; although it be repeated several times a day, and a marked fall in the percentage is noticeable, yet they continue to improve.

The urine of about one-half of the patients at the beginning of the treatment was alkaline, two of them ammoniacal. In all but one case, it became *acid* in from four to six weeks. Of seventeen cases, but one has died. He was very ill when the administration of the sulphuretted hydrogen was begun; he survived a month, growing rapidly worse until he expired. Six were discharged free from cough. All have gained in flesh. All types were benefited, the most markedly being those complicated with bronchitis.

The action of the gas on the bowels is to constipate rather than to relax. It has a slight action on the heart, tending to slow but not to depress it. It seems to have a specific action on the skin, rendering it smooth and clear.

From the effect it has on the urine, we believe it would be of service in certain diseases of the urinary tract.

By reference to the tables it will be seen that the sulphates are largely increased in amount, and that the sulphuretted hydrogen was frequently detected in a free state in the urine; in fact, much oftener than in the breath.

The toxic action of this gas causes an increased secretion from the gastro-intestinal canal and skin, and is laxative, finally impairing the red blood-globules, causing great anæmia, wasting, debility, and a feeble circulation. These symptoms all accompany phthisis.

If sulphuretted hydrogen has no toxic action on microörganisms, is it then an instance of *similia similibus curantur?*

MEDICAL PROGRESS.

THE TREATMENT OF HEADACHES BY NITRO GLYCERINE.—DR. TRUSEVICH publishes in the *Ejenedêlnaya Klinischeskaya Gazeta* a series of observations on the effect of nitro-glycerine on headaches. He adopts, in the main, the classification of headaches made by Dr. Day, whose work he translated into Russian, in which language it has already gone through two editions. The preparation generally used was the 1 per cent. alcoholic solution, though in a very obstinate case the 10 per cent. solution was used, two drops being first given, and, after an interval of two minutes, three more. The result of this heroic medication was that the patient, a girl of fifteen, became pallid, and her pulse very weak; however, a little water and some smelling salts quickly revived her, and she was none the worse. The nitro-glycerine had no effect on the headache, which was of a persistent character, and was probably due to some organic lesion, perhaps an affection of the cranial bones. As a rule, two or three one-drop or two-drop doses of the 1 per cent. solution placed on the tongue at intervals of a very few minutes sufficed to arrest the headache. The conclusion arrived at was, that all cases which depend entirely, or almost entirely, on a vaso-constrictor neurosis are immediately curable by nitro-glycerine. In cases where the cerebral anæmia is partly due to deficiency or poorness of blood, milk, iron, arsenic, quinine, and other tonic remedies are, of course, required in addition to the nitro-glycerine. The chief indications for the successful treatment of migraine by nitro-glycerine are pallor of the face and a paroxysmal character of the pains, also their augmentation on pressure of the carotids, and their diminution when the head is lowered. In "nervo-hyperæmic headaches" nitro-glycerine is useful, but it only acts indirectly by dilating the vessels in other parts of the system, and thus relieving the congestion in the cerebral vessels. It is positively injurious in headaches depending on passive hyperæmia. On this subject, however, Dr. Trusevich promises a future article. As a rule, he thinks that if nitro-glycerine fails to relieve, the prognosis is probably bad, as the pain is generally due to some organic lesion, such as thickening of the fibrous coverings following chronic alcoholism or syphilis, or to some osteophyte caused by periostitis, or, lastly, to morbid changes in the cranial bones. In some headaches of rheumatic origin, nitro-glycerine appears to have some effect, but Dr. Trusevich thinks that in others massage would probably be more beneficial. Where headaches are due to heart, lung, or to hepatic disease which causes passive congestion in the cerebral vessels, nitro-glycerine cannot be expected to do much good.—*Lancet*, Dec. 3, 1887.

ICHTHYOL.—The *Lancet* of December 3, 1887, speaks as follows regarding the value of ichthyol:

Ichthyol has now been in use some years, and bids fair to maintain its original reputation as a valuable medicament of very wide application. It is employed pure in rare cases, but more frequently in solution in water, oil, or a glycerine of the strength of 20 to 50 per per cent., for external applications in bruises, sprains, rheumatism, burns, chilblains, etc. It may be administered internally in 1 per cent. solution, or in the form of pills, in cases of chronic skin disease, gastric affections, and rheumatism. As a spray in 10 per cent. solution it has been employed in the treatment of throat and nasal affections. Ointments of various strengths are compounded for external inunction in erysipelas and rheumatism. An alcoholic ethereal solution of the strength of 10 per cent. has been successful in relieving neuralgia when sprayed on the painful region; stronger solutions are used for sciatica and lumbago. Plasters and fomentations of ichthyol are also used, and a soap is made for

preserving the skin and relieving chapped hands and kindred ailments.

STROPHANTHIN.—Among the various chemical tests and reactions of this substance the following are interesting:

Strophanthin gives, with strong sulphuric acid, a brilliant green color, changing to yellow and to brown.

With sulphuric acid and potassium bichromate a blue color is produced.

Nitric and hydrochloric acids, caustic potash and ammonia, and other alkalies produce a yellow color.

Nitrate of silver produces a reddish brown color, followed by a black precipitate.

Tannic acid gives an abundant white precipitate soluble in excess.

Chemical tests prove the existence in strophanthin of an organic body; whether it is a glucoside or alkaloid is not known.—*Journal de Médecine*, Nov. 27, 1887.

MYOMA OF THE FEMALE BLADDER; REMOVAL BY SUPRAPUBIC INCISION; RECOVERY.—At a recent meeting of the Clinical Society of London, DRS. GIBBONS and PORTER reported the following case:

The patient was a girl aged eighteen, of good general health, and the daughter of healthy parents. The earliest symptoms noticed were inability to retain the urine, and pain on making effort to do so. She was treated "for stone in the bladder, but without any relief." When admitted into the Grosvenor Hospital for Women and Children, she was found to have lost all control over the urine, which dribbled away from her; she experienced a dull aching pain in the perineum. There was no blood in the urine at the time. On bimanual examination a tumor was detected in the bladder; rapid dilatation of the urethra was accomplished with a view to a more accurate examination of this tumor. A week subsequently, the patient being under an anæsthetic, the tumor was removed by means of a galvanocautery écraseur; the loop of platinum wire was introduced through the urethra, and fitted over the tumor with the aid of the fingers passed into the bladder through a suprapubic incision which had been previously made for this purpose. When the platinum loop had been fixed round the base of the tumor, it was tightened up, and the current turned on. In five minutes the division of the tumor was complete; there was no hemorrhage during, or subsequently to, the operation. After removal the base of the growth and the interior of the bladder were carefully examined by the eye, a small incandescent electric lamp being introduced for the purpose; the advantages of this method were at once very apparent, for every part of the bladder could in turn be seen. The wound in the bladder was carefully sutured. There were no subsequent bad symptoms. The girl quickly and completely recovered, and had since remained well.—*British Medical Journal*, Dec. 3, 1887.

A CASE OF RETRO-STERNAL ABSCESS, WITH PARTIAL RESECTION OF THE STERNUM; RECOVERY.—RUSTIZKY, of Kiew, reports in the *Centralblatt für Chirurgie*, No. 48, 1887, the case of a man aged twenty-three, previously healthy, who was admitted to the hospital suffering from pyæmia. Beneath the lower jaw were three openings from which pus flowed. The percussion note over the anterior thorax was dulled; auscultation revealed the movement of imprisoned fluid. A median incision in the jugular fossa was made to the sternum, and the anterior mediastinum was washed out with a solution of salicylic acid, by an elastic catheter. Only partial relief followed this procedure, and finally resection of the manubrium and upper portion of the sternum was performed. Strict antiseptic and stimulant treatment was carried out, and the patient made a good recovery. The thoracic wall was sufficiently replaced by scar tissue to enable the patient to be about with comfort.

A PERFECT SOLUTION OF CHLORIDE OF ZINC.—The *Journal de Médecine* of November 27, 1887, gives the following formula for a stable solution of chloride of zinc:

Zinc. chlorid.	ʒ 10.
Aquæ destill.	♎ 2.
Acid. hydrochlor. pur.	♏ 45.

This will be found a clear and permanent solution for external use.

ŒSOPHAGOTOMY FOR THE EXTRACTION OF AN IMPACTED TOOTH-PLATE.—DR. WRIGHT reports, in *The Medical Chronicle* for December, 1887, the case of a woman, aged twenty-two, on whom he performed the following operation. The usual incision on the left side of the neck from the thyroid cartilage downward nearly to the sternum was made. The operation itself presented little difficulty. After division of the omohyoid and the deep fascia, the handle of the scalpel passed readily in separating the carotid sheath from the thyroid gland and exposing the gullet. A short-beaked sound passed down the œsophagus from the mouth made it very easy to open the tube, and the tooth-plate was then felt with the finger, lying well below the cricoid, but it was only after a good deal of manipulation and traction applied in various directions that the plate, which was exceedingly firmly fixed, could be extracted. It was disengaged at last, mainly by a forcible twisting movement in the long axis of the gullet. The œsophagus was closed with four or five catgut sutures, and the wound, after being well dusted with iodoform, was plugged with iodoform gauze. The gauze was removed on the following day, and a large drainage tube substituted for it. The patient was fed by enemata for a week, and then an œsophageal tube was passed, and she was fed for two days partly through this. So much pain, however, was caused by the tube that she was allowed to swallow her food in the ordinary way on the next day. No escape of fluid from the gullet ever took place through the wound, and convalescence was uninterrupted. The wound healed somewhat slowly, and it is only now—two weeks after the operation—that practically perfect swallowing power has returned.

The size of the tooth-plate is 1⅜ inches in length, 1¼ inches in breadth; it carries two incisor teeth, and has a sharp hook at one side by which it was kept in place. The other hook had broken off, and hence the plate became insecure.

VESICATION OF THE HEPATIC REGION FOR CROUP.—MOROT, of Vichy, believes and has practised the theory that puncture and vesication of the skin just beneath

the gall-bladder relaxes the spasm and dyspnœa of croup. He accounts for the effect by a diversion of the blood current from the larynx, and a slight abstraction of blood.—*Revue de Thérapeutique*, Dec. 1, 1887.

Koumissed Peptones.—Dr. Anderson, in the *British Medical Journal* of December 3, 1887, describes this substance which he has prepared, as follows:

It is milk, or milk and other foods; first, by the action of pepsin, of pancreatine, or of both, almost completely digested, and thereby converted into peptone, or still further split up, and then made into koumiss. In the process of peptonizing about twenty-five per cent. of water is driven off, and none is previously added. Koumissed peptones are, therefore, of about fifty per cent. greater food value than ordinary koumiss. They are more fluid, have a sediment of far greater impalpability, and are incomparably more digestible and easily assimilable than ordinary koumiss, or even than Russian fermented mare's milk. While the author of this paper claims to be independently a discoverer of ordinary koumiss, he is the acknowledged inventor and institutor of this, the highest expression of a perfect koumiss. It is of especial use in the most irritable and adynamic types of wasting diseases; and can be, and has been taken and retained, when all other foods, ordinary koumiss not excepted, have been rejected. Valuable lives have been saved which would have been lost but for its administration.

Hitherto I have spoken of the use of cane sugar in the making of koumiss, etc. I now come to speak of the substitution of honey. For years past seldom has cane sugar been used by me. In the preparation of ordinary foods, grape sugar, and sometimes sugar of milk, has replaced cane sugar on the ground of the disagreeable eructative and fermentative action the latter exerts when administered. This cannot be so great in the matter of koumiss; yet I have substituted honey for cane sugar, and principally for the following reasons: honey is more wholesome, more nourishing, more digestible, and more physiological food than cane sugar. It produces a koumiss having a finer sedimentary deposit, increases the beauty and delicacy of flavor, and delays or prevents its becoming caseous.

Koumissed peptones are, equally with koumiss, the vehicles for the administration of such of the most important therapeutic agencies as are of use in particularly wasting diseases. But such medicinal agents are not added where the beauty and delicacy of flavor of either the koumiss or koumissed peptones are in any appreciable degree interfered with.

The Strength of Tea.—Considering its universal use as a beverage, it is surprising how little is known about it, or any standard tests of its quality. The quality of tea generally spoken of under the term "strength" is very vaguely defined, and as yet no relation has been ascertained between it and the amount of any particular constituent of tea. Considering the physiological properties of theine, the characteristic and essential alkaloid of tea, it might be supposed that the "strength" of tea depended to a considerable extent upon the amount of this substance present in it, and this view assumes some probability in consequence of the variable statements that have been made as to the quantity of theine obtained from various kinds of tea, which estimates range from one to two to nearly six per cent. A recent investigation undertaken by Paul and Cownley, the results of which have been published in the *Pharmaceutical Journal*, has shown, however, that the variable yields previously obtained were probably due to imperfect methods of analysis, and that theine is a much more constant constituent of different kinds of tea than had been supposed. It was, in fact, found that in upward of twenty samples of Indian and Ceylon teas, commercially valued by the brokers at prices ranging from 7*d.* to 3*s.* per pound, the proportion of theine varied only from 3.22 per cent. in the lowest to 4.66 per cent. in the highest. In the case of two samples of tea selected by experienced judges as representing extreme differences in "strength," the proportion of theine was practically the same in both. It is evident, therefore, that neither the market value nor "strength" of a tea is dependent upon the quantity of theine it contains. Paul and Cownley consider that it is much more probable that the "strength" is chiefly determined by the amount and condition of the astringent constituent comparable to a tannin, but before pronouncing definitely upon this point, it will be necssary to acquire a better knowledge of the chemical nature of that constituent. The results of this investigation are of additional interest to the medical practitioner, because they furnish him with data concerning the approximate quantity of theine introduced into the system by habitual tea-drinkers. An ordinary modern teaspoon would contain about sixty grains of tea, and, according to the housewife's well-known rule, would be the quantity allotted to each person sharing in the tea-brewing. If the tea contained the average quantity of theine—say four per cent.—it would represent two and a half grains of theine. According to experiments made by Paul and Cownley, infusion in boiling water during five minutes, which does not exceed the time tea is usually allowed to "stand," is sufficient to remove at least half of the theine from the leaves, so that in a case such as that supposed each tea-drinker would ingest at least a grain of theine, or equal to a medicinal dose, as indicated by the *Pharmacopœia*. —*British Medical Journal*, December 3, 1887.

The Treatment of Blepharitis Following Measles.—Trousseau, in the *Journal de Médecine*, of November 27, 1887, employs compresses or fomentations of boric acid solution in the acute stage of blepharitis following measles. At night he orders the borders of the lids anointed with—

Vaselin.
Lanolin. . . . . āā gr. 75
Zinc. oxid. . . . . gr. 7½
Or,
Hydrarg. ox. rubr. . . . . gr. ¾

when the inflammation has become chronic.

Antifungin.—Under this title Oppermann has used borate of magnesia as an antiseptic, in a 15 per cent. solution, of which five to twenty drops internally may be given in typhoid fever and diphtheria. The powder is soluble in four parts of boiling water, and precipitates in cold water. It is decomposed by light.—*Monatshefte für Praktische Dermatologie*, No. 22, 1887.

THE TREATMENT OF LEPROSY.—UNNA is quoted by *The Medical Chronicle* for December, 1887, as advising the following treatment:

Chrysarobin	5 parts.
Ichthyol	5 parts.
Salicylic acid	2 parts.
Vaseline	100 parts.

which he applies to the nodules. On the face, neck, and hands, pyrogallic acid is substituted for the chrysarobin, in order to avoid the irritating effect of that drug, and avoid any danger of conjunctivitis. The nodules disappear or drop out, and the general condition improves.

SALOL IN TABLETS.—LOMBARD has found the following a convenient prescription:

R.—Gum. tragacanth.	gr. 15.
Gum. arabic.	gr. 45.
Aquæ	3ij.
Salol	3iss.
Sacchar.	3ij.
Essen. citron.	gtt. 5.

In 100 tablets, each containing between three and four grains of salol.—*Revue de Thérapeutique*, December 1, 1887.

PYRIDINE IN THE TREATMENT OF ASTHMA.—GERMAIN SÉE employs a teaspoonful of pyridine, put in a hot vessel or plate, by inhalation for twenty minutes, three times daily. He also prescribes iodide of potassium, with syrup of tolu and opium.—*Revue de Thérapeutique*, December 1, 1887.

ANTIPYRIN AS AN ANODYNE.—JENNINGS, in the *Lancet* of December 10, 1887, reports his experience with antipyrin as an anodyne as follows:

If antipyrin is not an unfailing specific, I have certainly seen it allay pain as speedily and more radically than a hypodermatic injection of morphia. Whether any evil results are likely to follow its prolonged use remains, of course, to be seen. There is a good deal of talk at present about the possibility of benzine poisoning resulting from the admixture of this substance with the drug, owing to imperfect preparation, but I must confess that every solution I have used hypodermatically has smelt of benzine, and until the end of September, when I purchased an inodorous sample in London, I was under the impression that this was always the case. Like others I have frequently seen giddiness, vertigo, and nausea follow the administration of antipyrin, and ecchymoses and induration at the seat of injection. In one instance where I had associated it with cocaine, according to a formula much used in Paris, the patient felt prostrate and miserable for four or five days. This had never occurred with antipyrin alone.

THE TREATMENT OF HEPATIC COLIC BY OLIVE OIL.—Olive oil in large quantity is vaunted as a certain cure for hepatic colic due to gall-stones. DR. JUST TOUATRE, of New Orleans, has written an interesting account of self-cure of biliary colic and gall-stones, in the second number of a bi-monthly Roumanian journal (*Archives Roumaines de Medecine et de Chirurgie*), whose editor is M. Georges Assaky. The method of procedure was as follows: At seven in the evening a blue pill of the weight of 2¼ grains was taken, and this was followed twelve hours later by the taking in one draught of twelve tablespoonfuls of olive oil; a quarter of an hour later a similar dose of olive oil was taken, and then the patient addressed himself to sleep on his right side. At nine o'clock the blue pill acted, producing a copious biliary evacuation, but no gall-stones. Three o'clock in the afternoon saw another bilious stool without stones, but from seven in the evening till midnight six stools were passed; the first two contained seventeen calculi of the size of a large pea of conical shape, grayish-yellow aspect, and soft consistence. Altogether sixty stones were evacuated, and six of these had the volume of an olive, and were of a black color. The passage of these calculi by the cystic and biliary canals was for the most part unattended with pain, a few spasms being felt probably at the time of the movement of the large calculi. An inexpressible relief was obtained from the pains over the liver and shoulder, which had previously caused much distress; the liver also diminished in size. For three months Dr. Touatre enjoyed perfect health, when the trouble commenced again; the olive oil was repeated in similar fashion, and with the result that eighteen more calculi were discharged by the bowel. Since then he has enjoyed excellent health. He admits that some courage is required to swallow the large doses of olive oil.—*Lancet*, December 10, 1887.

PASTEUR'S METHOD SIMPLIFIED.—DR. HÖGYES, of Buda-Pesth, has published in the *Orvosi Hetilap* an account of some researches he has made on the protection of dogs from rabies by a somewhat simpler method than that employed by Pasteur. He, too, makes use of the spinal cord of an infected rabbit, but instead of drying it to a gradually increasing extent to obtain various degrees of activity, he merely rubs it up with water containing chloride of sodium so as to make solutions varying in strength from 1-10th to 1-500th. The dog to be protected is injected successively with these, beginning with the weakest. The results appeared to be quite satisfactory, and a complete immunity from rabies to be secured by six of these injections.—*Lancet*, December 10, 1887.

A SIMPLE METHOD OF DISLODGING IMPACTED GALL-STONES.—LAWSON TAIT describes the following simple procedure, which he has used in one case successfully. It consists in passing a fine needle through the wall of the intestine from below (that is, from the empty part of the intestine) into the gall-stone. The stone is thus easily and immediately split up into fragments and passes readily along the intestine, and the grave complication of opening the intestine is rendered unnecessary. The operation is, in fact, little more than an exploratory incision.—*Lancet*, December 10, 1887.

LEMON JUICE IN EPISTAXIS.—GENUIL has had excellent results in checking epistaxis by first syringing out the nares with cold water and then following this by injecting the nares with lemon juice; the coagulation of the blood followed promptly.—*Bulletin Général de Thérapeutique*, November 30, 1887.

THE MEDICAL NEWS.

A WEEKLY JOURNAL

OF MEDICAL SCIENCE.

Communications are invited from all parts of the world. Original articles contributed exclusively to The Medical News will be liberally paid for upon publication. When necessary to elucidate the text, illustrations will be furnished without cost to the author. Editor's Address, No. 1004 Walnut St., Philadelphia.

Subscription Price, including Postage,

Per Annum, in Advance, ... $5.00.

Single Copies, ... 10 cents.

Subscriptions may begin at any date. The safest mode of remittance is by bank check or postal money order, drawn to the order of the undersigned. When neither is accessible, remittances may be made, at the risk of the publishers, by forwarding in *registered* letters

Address, LEA BROTHERS & CO.,
Nos. 706 & 708 Sansom Street,
Philadelphia.

SATURDAY, DECEMBER 31, 1887.

RELATION OF DISEASES OF THE REPRODUCTIVE ORGANS IN WOMEN TO INSANITY.

It is hardly ten years since it was deemed important for the proper care of insane women in hospitals for the insane, that physicians who were women should have a place on the medical staff. No question as to their right to become applicants for such positions, or as to their legal qualifications, had arisen, but it was urged as an important consideration that from their inherent constitution they might exhibit more sympathy in the care of their afflicted sisters than might be expected from the so-called sterner sex; and that a woman could not give that assent to a personal examination that she may give in a sound mental state; and if she felt disposed to resist an examination, it was highly improper for any but a female physician to make it, if ever necessary, under these circumstances.

The departure was urged by some from an honest assumption and belief that a large proportion of insanity among women was due to those diseases and disorders that are peculiar to their sex. Non-professional persons, politicians, and others actuated by purely sentimental reasons, who profess to believe in equal rights, in the elevation of women to a higher plane, and that seeming disabilities should be removed, so that they might not be debarred from having a fair chance, also united in invoking legislation to make the appointment of female physicians in the asylums compulsory. In the absence of any legislation, such appointments were always considered within the scope of the appointing power; and, since the agitation of the question, female physicians have been appointed in several asylums without legislative requirement, for reasons considered good and sufficient. In the State of Pennsylvania, the women's wards of two hospitals have been in the sole charge of female physicians, and wherever they have been connected with an asylum service, no obstacle has been placed in the way of the study of the relation of diseases of women to insanity, so that we ought now to be in a fair way of arriving at some established results. From published reports and expressions of opinion thus far, and the absence of any expression on the subject where we might have looked for it, we cannot conclude that these diseases form such an important factor in the production of insanity as has been alleged. In a total population, where women form nearly an equal part, we might infer that if diseases of the sexual organs of women were a prolific cause of insanity, the number of insane women would greatly outnumber the insane males, whereas the reverse is true. As a matter of fact, if we trust to official reports, so-called women's diseases figure among the least of the agencies in the production of insanity. What is a frequent concomitant coincidence is too frequently mistaken for a cause. How far do these reports sustain this allegation?

According to the Report of the Committee of Lunacy of Pennsylvania for 1885, an even one thousand women were admitted to the various asylums of the State. In the published table of causes three of the thousand are reported to have become insane from uterine disorder and disease. In the Report for 1886, of 733 women admitted, the number reported is the same. Dr. Margaret A. Cleaves, Physician, Female Department, Harrisburg Hospital for Insane, in the 33d Annual Report, says: "My own actual experience convinces me that at least thirty per cent. of insane women are the subjects of lesions of the reproductive organs" . . . "The whole subject is one of much interest to me, but I cannot yet clearly discern the full extent of the influence that diseases of the reproductive organs have upon the insanity of women." In reference to treatment: "My experience does not justify me in the belief that the percentage of recoveries will be increased by such special treatment as I had hoped." Dr. Alice May Farnham,[1] with an idea of arriving at some conclusion in regard to the relative value of uterine disease as an etiological factor in the production of insanity, conceived the idea of comparing the result of the pelvic examination of a certain number of patients in the Willard Asylum with the same number of mentally healthy women of the same social class. "The result was somewhat surprising. Out of thirty mentally healthy women but four were found in whom the pelvic organs were in a condition of health. Out of the same number of insane

[1] Uterine Disease in the Production of Insanity. Alienist and Neurologist, Oct. 1887.

women, taken *seriatim* from the patients of two wards, six were found in whom the pelvic organs were in a condition of health. Were uterine disease really so powerful an agent in the production of insanity it would be a matter for wonder that, with the alarming prevalence of such disorders, so few women exhibit profound nervous disturbances."

The testimony of Dr. Skene, and others, in the same direction, could be adduced, but enough is cited to show that there is much professional as well as non-professional sentiment among physicians and the community at large on this subject that has no other foundation than conjecture. Disorders of the reproductive organs, like those of other organs with intimate relations to the nervous system, may have an influence in lowering the natural standard of health, but as an active, direct agent in the production of insanity they are greatly overestimated.

THE DANGER OF OCCUPYING NEWLY BUILT HOUSES.

THE town of Bâsle, in Switzerland, has adopted a regulation which prevents newly built houses from being inhabited until four months after their completion. It would be well if such a restriction were extended to other places. The reasons for the practice are obvious. The chief objection to the early use of newly built houses lies in the great danger to health of wet walls. The quantity of water used in constructing an ordinary house of brick and mortar would surprise any one who has not investigated the subject. According to Pettenkofer's estimate, the walls of a building in which 100,000 bricks are used, such as a modern brick dwelling of medium size, will require about 10,000 gallons of water in their construction, which must be gotten rid of before the house becomes habitable. This large quantity of water is held in the pores and spaces of the bricks and mortar, until dispelled in the form of vapor, which is a gradual process, unless its removal is hastened by artificial means.

Damp or wet walls are injurious to health by impeding ventilation and the diffusion of gases, through the closing of their pores by water. Spontaneous ventilation through the walls of a building plays no inconsiderable part in the change of air of our dwellings. Märker and Schultze found that the spontaneous ventilation through one square yard of free brick wall, at 9.50° Fahr. difference of temperature between the outside and inside, amounted to about eight cubic feet per hour.

Another way in which wet walls are injurious is by disturbing the heat-economy of our bodies. Damp walls absorb heat by their evaporation, and act like rooms insufficiently warmed; they are much better conductors of heat than dry walls, and add considerably to our heat-losses by a one-sided and increased radiation. It is not surprising that diseases commonly attributed to cold, such as rheumatism, catarrhal affections, and Bright's disease, are of frequent occurrence in damp dwellings.

In order to render new houses habitable, the excessive amount of moisture stored in the pores of the walls must first be removed. There is only one way in which this can be accomplished, and that is by spontaneous evaporation into and by the air. This evaporation depends on the temperature, humidity, and the velocity of the air. Under ordinary circumstances it is a gradual process, but a condition of dryness may be more quickly brought about by the heating of all the stoves, furnaces, and flues, and the continual ventilation of all the rooms of the house. In the absence of knowledge of proper measures having been taken to insure dryness, it is illusory to trust to appearances. The walls may have lost just enough of the building water to allow the air to occupy their superficial pores. They appear dry, while in fact they are not. When such a house is occupied, and the fires lighted, damp spots quickly appear upon the walls. The heat from the fire evaporates water from the surfaces in its vicinity, and this watery vapor, together with that given off from the bodies of the occupants and that produced by the manipulations of the household, such as cooking, washing, etc., is precipitated as dew upon the walls at a distance from the fire, for the reason that their pores are already surcharged with moisture, and cannot pass the water on through them to the outer air. A dry, porous wall, on the contrary, is capable of absorbing and transmitting a good deal of moisture without any evident signs of dampness.

A statement of these plain facts seems to be demanded, for it is a matter of everyday observation that people recklessly occupy houses almost before completion, without regard to their dryness or other conditions of fitness for habitation. The present time is one of great activity in building operations. In Philadelphia alone more than five thousand buildings were constructed in 1885, a larger number in 1886, and this number will be far exceeded the present year. The same activity prevails elsewhere. The eagerness with which new houses are sought after shows that the supply is not equal to the demand, and, in their haste to secure possession, people are apt to overlook features in construction and conditions of the buildings which may be most prejudicial to health.

DR. R. A. F. PENROSE, after an incumbency of a quarter of a century, has tendered his resignation of the Professorship of Obstetrics and the Diseases of Women and Children in the University of Pennsylvania, to take effect at the close of the current session.

The physicians of the two easternmost counties on Long Island, N. Y., have agreed to consolidate in one body, to be named the Queens and Suffolk County Medical Society. Dr. W. P. Overton, of Cold Spring, is President, and Dr. W. Thorne, of Farmingdale, is Secretary. There will be a meeting in March, 1888, at Farmingdale, and scarlet fever has been appointed as the scientific subject for discussion.

The preparation called "Rough on Rats" is nearly pure arsenious acid, and yet in many localities it is sold without restriction to every purchaser. No record of the sales of this form of poison is kept, and when it is used for criminal ends it is most difficult to trace it to its source. Suicide by this substance has occurred quite frequently in Brooklyn, of late, and Coroner Rooney has declared war upon its free and unregistered sale. It would be well if other coroners would unite with him in finding means to suppress the sale of this deadly nostrum.

The British Medical Association, at the instance of Mr. Ernest Hart, has started a medical library and reading room at the office of the Association, in London, for the use and convenience of the members generally.

The King's County Medical Society, at Brooklyn, N. Y., having become settled in their new home, recently purchased, now propose to float a monthly medical journal, the first issue of which will appear about the first of January next. It will probably be entitled *The Brooklyn Medical Journal.* It is, in some sense, the lineal descendant of the *Proceedings* of the society above named—a publication that subsided a few years ago, after an interesting existence of nearly a decade. Some of the old editorial talent will be enlisted for the new publication. Dr. Joseph H. Raymond will be editor-in-chief, and will be assisted by Drs. Hutchins, Hunt, Butler, and Bailey. At the outset, each issue will contain not less than one hundred pages, which will be open to the transactions of various local societies.

At the January meeting of the King's County Medical Association, Brooklyn, to be held on the 3d proximo, the subject for discussion will be "Fever," to be based upon Prof. Austin Flint's Address upon that subject, at the recent International Congress; papers by Drs. W. McCollum and T. M. Rochester, will review the therapeutic and physiological sides of the subject. Dr. Flint has signified his acceptance of an invitation to attend and will be invited to participate in the discussion.

Dr. Alonzo B. Palmer, Professor of the Practice of Medicine in, and Dean of the Medical Faculty of the University of Michigan, died at his home in Ann Arbor, last week, aged seventy-two. He was the author of a text-book on the *Science and Practice of Medicine*, which was published about five years ago, and of numerous contributions to periodical literature, and from 1852 to 1859 he was one of the editors of the *Peninsular Journal of Medicine.*

The English weeklies, just received, announce the death, last week, aged eighty-six, of Sir George Burrows, formerly Physician to the St. Bartholomew's Hospital, and Physician in Ordinary to the Queen.

REVIEWS.

A Manual of Organic Materia Medica. By John M. Maisch, Phar. D. Philadelphia: Lea Brothers & Co., 1887.

This little hand-book of Professor Maisch having reached its third edition, needs from us no words of recommendation, and our duty is the pleasant one of announcing the advent of the book revised up to date, and containing descriptions of those remedies which, as the author states it, are new, or else are old ones revived within the last few years.

The boon to the student who is forced to learn a large amount of that dry subject, materia medica, which this book affords, can only be appreciated by those for whom the book was chiefly written, namely, students of pharmacy; and while condensation of knowledge in a convenient form for "cramming" is, as rule, a faulty method of book-writing, in this instance it is not only justifiable but necessary, since a vast mass of unnecessary descriptive statements is weeded out.

Altogether, the third edition surpasses in its advantages and completeness its predecessors, and will doubtless reward both the writer for his thoroughness as to important details, and the publishers for their care in the printing and binding of the book.

CORRESPONDENCE.

BERLIN.

The Friedrichshain Hospital—Extirpation of Larynx—The Bacillus of Cancer.

To the Editor of The Medical News,

Sir: The physician who comes to Berlin thinking that the hospitals are open to him for bedside work and personal examination of the sick, is destined to be disappointed. There are hundreds of courses (in general medicine), where one can waste any amount of time, while a German student excludes *every* organ in the body before he makes a diagnosis of arterial insufficiency. But, bedside work, as a rule, is not to be had here. "The Berliner Krankenhaus, Friedrichshain," is the most extensive hospital here. It is built on the pavilion system, with no connection whatever between the buildings, of which there are fourteen; six medical and seven surgical, with a total of about seven hundred beds. The eleven resident physicians receive their appointment largely on account of their record in the University and elsewhere; and their term of service is as long or short as they choose to make it.

The surgical wards are under the direction of Fürbringer, formerly professor extraordinary at Jena. The distinguished position he occupies here needs no words from me—personally he is a charming man, and beloved by all about him. Prof. Fürbringer's latest publication is a monograph "Ueber die Desinfection der Hände des Arztes," a timely contribution to an important subject; it would well bear translation for American readers.

The surgical wards are under Hahn, who is considered by many to be a greater surgeon than Bergmann. And, indeed, the purpose of this letter is to describe his (Hahn's) last successful operation for extirpation of the larynx. This operation is at present much discussed here in connection with the case of the Crown Prince, about which one hears so much gossip and so little that is reliable. And the German physicians and surgeons, though differing, are at heart one in their sweeping condemnation of Morell Mackenzie. It is currently reported here that from the time he was called to the case, up to a few weeks ago, no German was allowed to examine the Prince's throat; and that this was not even permitted to Langraf, who accompanied his Highness to England, and remained with him until September 15th. Much comment has also arisen from Mackenzie calling Krause in consultation, as it is claimed that he does not represent Berlin medicine.

Again, Virchow now declares that he never said that the growth was *not* malignant; only that the *piece* sent him was not. However this may be, the growth is now said to be cancer, and medical Germany rejoices in the triumph of German diagnosis, and declares that the radical operation should have been performed at first, as was advised by Bergmann, Gerhardt, Tobold, etc. But then comes the question, "How far is this operation justifiable? Does it tend to prolong life?" I have before me Hahn's last two papers on the subject:

"Extirpation of the Larynx," and "The Results of Extirpation of the Larynx for Carcinoma," also the record of his 18 operations. The detailed record of those of Bergmann I could not get.

These figures are valuable, for they enable me to give a complete history of this operation till to-day. They are, moreover, entirely reliable; having been kindly given me by the distinguished professor himself.

There have been 103 partial and total laryngectomies done to date, with 21 recoveries. These figures, however, must not be taken as absolute; for in many we have no record beyond that of their supposed recovery at the time the case was reported.

We can obtain a fairer idea of the success of the operation in question by an examination of Hahn's record.

Professor Hahn has classified his operations as follows:

	No.	No. living
I. *Total* extirpation of larynx, on account of carcinoma and sarcoma	10	1
on account of stricture	2	2
II. *Partial* extirpation for cancer	4	3
for stricture	1	1
III. *Partial tracheal* extirpation on account of cancer	1	—
Total	18	7

Here, then, we have a total of 7 recoveries in 18 operations. In the partial operations the record is very good; for, as will be seen, we have here a record of 4 recoveries out of 5 operations. I had the pleasure of seeing the only surviving case of *total* extirpation. The patient is now seventy-five years of age, and was operated upon seven years ago. A very beautiful result; the old man having quite a respectable voice, and one can understand every word he says. Professor Hahn does not consider the operation a dangerous one, provided it is performed *early*, and the *cancer* shows no tendency to a *soft* variety.

In the Crown Prince's case, as is known, it was proposed to do a partial extirpation—and if we can judge anything by the above figures his chance of surviving was very great. The distress of the German people at his critical condition is very deep, for the Crown Prince is greatly beloved; and I am told that Bergmann had received three letters, from different men, begging that he should take their healthy larynx, if such a thing was possible, and transfer it to the Prince—for they would gladly die to save his life.

Two partial laryngectomies have been done here in the last month. One by Bergmann, upon a healthy man of about forty years, whose larynx had been involved for two months only, and who died a few days after the operation. The second was by Hahn, upon whose invitation I was present at the operation.

The patient was a fine looking fellow of thirty-six. The cancerous growth, of one and a half years standing, had destroyed the left vocal cord. He was operated upon exactly one month ago. He did well from the first, and is now rapidly recovering. I had the pleasure of seeing him a few days since, sitting up and able to swallow liquid food.

The operation was rapidly performed under perfect antisepsis—the only thing calling for special mention, is the use of a large tracheotomy tube,[1] wrapped with iodoform gauze; this is of a size which completely fills the lumen of the trachea, and absolutely prevents the entrance of blood into the lungs, besides enabling chloroform to be administered.

The other subject of general discussion here is, or was the announcement of the discovery of the *bacillus of cancer* by a young man, Scheurlen, an assistant of Leyden.

Scheurlen brought forward the results of his investigation on Monday last at the *Verein für Innere Medicin*. Of course, all medical Berlin was present, and the paper was listened to with great interest, which eventually gave place to greater disappointment. Scheurlen is only twenty-five, and graduated last spring from the University. The tremendous importance of this subject—a cancer bacillus—justifies a *résumé* of the latter's paper, the text of which comes to me this morning in the *Berliner klinische Wochenschrift*. Briefly: He took twenty carcinomas from various sources, and as a vehicle for pure cultures he first used the serum from a pleurisy. This was coagulated in sterilized tubes after Koch's method, and vaccinated with the "cancer milk" from the original cancers—and in three days occurred different changes indicative of the development of bacilli.

From each of ten tumors twenty vaccinations were

[1] An inferior tracheotomy was done.

made, and seven were successful. Microscopic examination of these showed a peculiar bacillus and spores, which, under sufficient power, showed movement. The bacilli colored with Gram's method, but only the ends. The spores colored with nitric acid and water only. He claims that no other bacilli and spores have the same form or movement, or color in the same way. The bacilli were found eight times out of ten when colored after Gram's method.

When cultivated from the serum in agar-agar, the bacilli appear in ten hours, the spores after ten days. A first coloring of these spores with fuchsin aniline, and afterward with violet or blue, makes a very striking picture.

In gelatine, the growth of the bacillus is very slow.

Direct cultivation from the tumors in agar-agar or gelatine, gave six results from seventy cultures. Two potatoes gave infusion of peptones. From cabbage, after twelve to twenty-four hours, he got the characteristic microbes.

The mammary glands of six dogs were injected with cultures from potato, or agar-agar. In four days there were circumscribed hardness and swelling of the glands. The tumor was removed from two of the dogs, and microscopic examination showed considerable cell proliferation, with large granular epithelioid cells, among which moving bacilli spores could be seen. Finally, he claimed to have discovered the cause—*i. e.*, the bacillus of cancer.

On this claim the criticisms have been very severe. But it is only fair to await his further investigations.

F. Donaldson, Jr.

Berlin, December 9, 1887.

NEWS ITEMS.

The New York Quarantine.—The State Board of Health of New York has forwarded to the Governor of the State a lengthy report on the New York Quarantine Station, which concludes as follows:

"It is the unanimous opinion of those posted on such matters that it would be difficult to imagine a worse state of affairs than now exists at the Quarantine station. It is hard to realize in this age of civilization that the harbor of the city of New York should be so inadequately provided with facilities for the prevention and extinction of an epidemic. The State Board of Health does not consider it within its province to pronounce upon the actions of the Quarantine authorities."

Refusal of a Physician to Treat Wealthy Patients in a Charity Hospital.—Dr. Norman Bridge, one of the attending physicians to Cook Co. Hospital, has been recently made the object of severe criticism by the *Chicago Tribune*, for refusing to treat as charity patients, persons able to pay, but admitted to the hospital under political favoritism.

Localization of an Imbedded Needle by a Magnet.—The *Chronique Industrielle* of November 6, 1887, is quoted by the *Sanitary Engineer* as relating the following incident:

The daughter of a Mr. Preece accidentally stuck a small steel needle into her hand which broke into three parts. Two of these parts were easily found and extracted, but the third could not be located. The Hughes' induction balance plainly indicated that the piece of needle was there, but not its position. Mr. Preece highly magnetized a fine needle and suspended it by a single fibre of silk. The deviations of the suspended needle always plainly indicated one particular spot when the sore hand approached it. After a number of trials with the same result, this point was marked, an incision made, and the third piece of the broken needle four millimetres long was found and easily extracted.

Hypnotism and the French Laws.—The *Lancet* reports that a schoolmaster has recently been charged, at the assizes of the Nièvre, with indecent assaults upon children under his care. At the previous sessions he had admitted the offence, but declared he had acted under the influence of an irresistible impulse. The court had in consequence postponed their decision pending the medical examination of the accused. The medical witnesses have concluded that the case is one of hysteria, and that hypnotic sensibility being developed to a high degree, the subject is only responsible to a limited extent; and an intelligent jury pronounced a verdict of acquittal. It would be interesting to know whether these enlightened experts would have come to the same conclusion had the assaults in question been made upon their own children, and what would then have been their views on hypnotism.

Lead Poisoning from Flour.—The *British Medical Journal* reports that a very remarkable epidemic of lead poisoning has recently been investigated in three communes in the north of France. Upward of one hundred persons were suddenly attacked with violent symptoms, among which severe colic predominated. So serious did the condition of some of the sufferers become, that medical aid was obtained, and the presence in several patients of a characteristic blue line on the gums gave rise to the suspicion of lead poisoning. The water supply was derived from so many different sources that it could not be incriminated, and suspicion ultimately fell on the flour.

It was ascertained on inquiry that the affected persons had all obtained their flour from the same mill, but those who had partaken of rye bread were most severely attacked. The mill was gone over, and after a very long and painstaking examination, attention was directed to the tin buckets of the elevator which served to transport the rye flour from the grindstones. Several of these buckets had a dull, leaden appearance, and were found to have been "tinned" with lead. As doubts were entertained whether the quantity of lead from this source was sufficient to give rise to such severe symptoms, they were carefully weighed, and were found to have lost upward of five ounces of their weight. The wheaten flour, which passed through another elevator, was free from lead, and this was evidently due to none of these "leaded" buckets having been employed in its construction. The accuracy of the discovery was confirmed by the observation that those who ate rye bread exclusively were most severely attacked, while the others, who mixed the two flours, escaped with comparatively slight symptoms.

A REVOLT OF VENEREAL PATIENTS IN AN ITALIAN HOSPITAL.—At the hospital of Santa Maria, at Naples, where a number of women suffering from specific diseases are under treatment, the authorities had forbidden the friends and paramours of the patients from calling upon them. This was followed by an open revolt for eight hours, during which the furniture of the hospital was demolished, windows and doors broken, and twenty-two of the Sisters of Charity in attendance were injured more or less severely. The patients attacked the police, and wounded several. Order was finally restored, and twenty-eight arrests were made. A reform in hospital management is evidently needed.

A PRACTICAL TEST OF A CLIMATE FOR A PHTHISICAL PATIENT.—DR. OTIS, of Boston, concludes in an article in the *Boston Medical and Surgical Journal* of December 15, 1887, that in whatever climate one finds his lung trouble improving steadily, there he should remain, not only until all signs of mischief disappear, but, in many cases at least, as long as he lives. I feel convinced that this is the safest and wisest plan, and I think that physicians of experience are gradually growing to this opinion. This is especially true of the Colorado climate, which is such a radical change from the one the patient is likely to come from. I believe the slow improvement, or lack of any improvement, in many cases is due, partly, at least, to the worry over the enforced exile, and eager watching for the time when they think they will be able to return to their homes. It is often noticeable how quickly and permanently those improve and recover who take up their residence in Colorado, and settle down to permanent living there, with their friends and family about them. The contrary is also observed with those who make it a mere health resort, and are separated from their family and friends; as, for instance, a wife from her husband, or a daughter from the rest of her family.

SEWER GAS POISONING IN A YOUNG WOMEN'S SCHOOL.—The *Sanitary News* of Dec. 10, 1887, reports a recent instance where a large and well-built and expensively built house, in a particularly exclusive and perfectly well-cared for thoroughfare of an eastern city, was taken as the home of a young ladies' school. Before its occupancy plumbers were set to work to tear out and renew wherever tearing-out and renewing were necessary to constitute perfect safety from sewer emanations. Even the stationary wash-bowls were removed from all the rooms, and bowls with pitchers substituted as a special precaution. At last the plumber—one of the largest, and wealthiest, and most reputable in the city—who had not been limited in any necessary expense, pronounced the plumbing-work in the house as good as it could be. The school moved in and for a considerable time all went well. After a while, one of the young ladies, and then another, then a third, was taken suddenly and mysteriously ill with violent headache, fever, vomitings, and other unmistakable typhoid symptoms. The school was at once closed, and a New York sanitary engineer of much more than local reputation, was commissioned to discover the cause. He found it in sewer-gas, escaping here and there about the building through leaky joints, ill-made connections, and criminal botch work of many descriptions, which, by the aid of plaster-of-Paris, or behind wood-work, or under floors, had been covered up and left to breed disease by the conscienceless plumbers. It is significant to note, notwithstanding all the defects found by the engineer on detail examination, that the well-known and so-called perfectly reliable peppermint test, which was first made by him, revealed no leaks whatever, except a scarcely perceptible odor in the bath-room.

THE CONTAGION OF DIPHTHERIA.—The *Sanitary News* of December 10, 1887, reports cases of diphtheria in Michigan, in which the health officer has traced the contagion which caused a severe attack of diphtheria in St. Joseph's Orphan Asylum, and has found that a mother and child had diphtheria in Sault Ste. Marie last spring. The mother died. The woollen dress which the child had worn was packed in her trunk and brought to Marquette. After being unpacked a short time ago diphtheria soon appeared.

DR. ARTHUR D. BEVAN, a member of the Faculty of the Medical Department of Wilamette University, Portland, Oregan, has been appointed to the Chair of Anatomy in Rush Medical College, Chicago.

WHAT IS A DRUG?—From the *Boston Medical and Surgical Journal* of December 8, 1887, we learn that a case came up in the Superior Criminal Court, December 6th, before Judge Bacon, on the interpretation of the Sunday law passed at the last session of the Legislature, as to the meaning of the word "drug," and what it includes. An apothecary was tried for a violation of the law. It appeared in the evidence that the violation consisted in selling a cigar. Counsel for the defendant claimed that a cigar was a drug, and came within the section of the law relating to drugs and medicines. In support of his view of the case, he cited various authorities, and quoted freely from Worcester and Webster as to the definition of tobacco. In his instructions to the jury, the judge said that if they found that tobacco was a drug or a medicine, then they must acquit; but if they found that it was not a drug, then the defendant would be guilty. The jury, after being out a short time, returned a verdict of not guilty.

OFFICIAL LIST OF CHANGES IN THE STATIONS AND DUTIES OF OFFICERS SERVING IN THE MEDICAL DEPARTMENT U. S. ARMY, FROM DECEMBER 20 TO DECEMBER 24, 1887.

BIART, VICTOR, *Captain and Assistant Surgeon.*—Relieved from further duty in the Department of Dakota.—*S. O. 293, A. G. O.*, December 17, 1887.

SWIFT, EUGENE L., *First Lieutenant and Assistant Surgeon.* Ordered for duty at Fort Spokane, Washington Territory.—*S. O. 293, A. G. O.*, December 17, 1887

THE MEDICAL NEWS *will be pleased to receive early intelligence of local events of general medical interest, or of matters which it is desirable to bring to the notice of the profession.*

Local papers containing reports or news items should be marked.

Letters, whether written for publication or private information, must be authenticated by the names and addresses of their writers—of course not necessarily for publication.

All communications relating to the editorial department of the NEWS *should be addressed to No. 1004 Walnut Street, Philadelphia.*

INDEX.

ABDOMEN, gunshot wound of, 302, 375
  pistolshot wound of, laparotomy for, Kinloch, 66
  stab-wound of, 544
Abortion, treatment of, 423
Abscess, cerebral, 129
  Wilson, 675
  intralaryngeal, J. S. Cohen, 731
  liver, 342, 391
  perihepatic tubercular, 122
  psoas, treatment of, 342
  retro-sternal, 762
  subdiaphragmatic, Shepherd, 700
Acetanilid, 582
Acetphenetidin, 424, 452, 547
  Mays, 204
Acid, boric, 682
  carbolic, influence of, upon bodily temperature, 423
    creolin versus 545
  salicylic, influence of, upon bodily temperature, 423
Acne, treatment of, 270, 391
Actinomycosis, 101, 659
Adams, effect of Bergeon's treatment on urine of patients, 759
Agaricin, 13
Agnew, death during administration of ether, 589
Air-passages, treatment of diseases of, 452
Albumen, use of tallow to settle urine examined for, 152
Albuminuria, cyclic, Canfield, 118
  incidence of, among the sick, 547
  intermittent, 428
  of pregnancy, 191
  pathogenetic condition of, Semmola, 441
Alcohol, influence of, on action of pepsin, 687
  use of, during Arctic explorations, 492
Alexander's operation, 366
Almén's test for sugar, 43
Amaurosis, quinine, 153
American Public Health Association, annual address before, Sternberg, 537, 585
Amputation, Chopart's, 154
  Murdoch, 57
Amygdalitis, simple, treatment of, 99
Amyl hydrate, 240, 244, 457
Anæmia, pernicious, 153
  gall-stones and, 686
  treatment of, 426
Anæsthesia by chloroform and oxygen, 270
  rapid, 544
Anæsthetics, use of, 80
Anatomist, a veteran, 168
Anencephalia, 218
Aneurism, Keen, 725
Angina tonsillaris, treatment and prophylaxis of, Hoffmann, 616
Anthrax, value of inoculation against, 452
Antidote, a common, 44
Antifebrin, 107, 195, 213, 423, 425, 541, 543, 573
  in typhoid fever, J. S. Cohen, 422
Antipyrin, 15, 104, 166, 213, 269, 270, 362, 423, 499, 596, 681, 682, 711, 737, 764
Antisepsis, surgical, 570
Antiseptics, importance of, in private obstetric practice, 493
  Weir, 697
Antiseptic liquid, a non irritant, 544
Apex-beat, cardiac, in children, 683
Arches, palmar, wounds of, 477
Argyriasis from repeated cauterization, 735
Arm, base-ball pitcher's, Leuf, 62
Arsenical poisoning, 668
Artery, central retinal, embolism of, 162
  innominate, spurious aneurism of, Hare, 388
Asepsis, ocular, 571
Asphyxia of pneumonia, treatment of, 477
Asthma, treatment of, 122, 482, 735, 764
Ataxia, Mastin, 225
Atkinson, forms of typhoid fever simulating remittent malarial fever, 174
Atropia, cocaine and, in iritis, 151
Atropine for sea-sickness, 267

BACILLI, chemical tests for, 453
  tubercle, and flies, 453
    action of eucalyptol on, 362
  typhoid, persistence of, 43
Bacillus, cholera, chemical tests for, 542
  new chromogenic, A. J. Smith, 758
  of scarlatina, 508
  tubercle, sulphuretted hydrogen versus, Trudeau, 570
Bacteria, antagonism among, 268
  dirty floors as breeding grounds of, 667
  effect of essences upon, 151
  in intestinal diseases, 123
Bacteriology in Spain, 463
Baldness, 464
Baldwin, horny growth of penis, 449
Ballou, Ariel, death of, 106
Bandage, a good, 434
  material, sterilized, 76
Bandages, flannel versus rubber, 364
Barium chloride in vascular diseases, 123
Bartholow, some respiratory neuroses, 669
Basiotribe, Tarnier's, 574
Bath, individual, in public hygiene, 251
Baths, hot-air, in syphilis, 152
  permanent, 408
Battey's operation, 402
Beds, sick, ventilation of, 751
Beer, comparative value of malt extract and, 479
Belladonna, antagonism between, and opium, 271
Bergeon's treatment at Ventnor, 13
  effect of, on urine of patients, Hutchinson and Adams, 759
  enemata, physiology of, 149
Beyer, influence of tropin hydrochlorate and sodium tropate on bloodvessels of dog, 231
  problems to be solved by pharmacophysiology, 169
Biggs, germicide power of sulphur dioxide, 702
Billroth, Prof., 584
Birth during maternal syncope, 213
Bismuth sub-benzoate, A. J. Smith, 653
Bites, insect, applications for, 214
Bladder, antisepsis of, 714
  laparotomy for rupture of, 687
    Fox, 673
  myoma of female, 762
  tuberculous disease of, 665
  tumors of, Wenning, 493
Blandford, treatment of recent cases of insanity, 353
Blennorrhagia, treatment of, 574, 735
Blepharitis, treatment of, 763
Blindness, increase of, in the United States, 159
Blood, alkalinity of, in certain diseases, 650
  diagnosis of cancer by examination of, 75
    of neoplasms by examination of, 334
  effect of antifebrin on, 425
  peptones in the, 71
Bond, test for sugar in urine, 146
Bone, development and repair of, 481, 600, 718
Books, contagion from, 463
Brain, injuries of, 136
  primary actinomycosis of, 659
  railway, 273
  removal of tumor from, 550
  sarcomatous tumor of, 137
Breast, analysis of 207 cases of carcinoma of, Gross, 613
  proper method of examining, 212
  tumors of, treatment of, 318
Breath, bacteriology of, 736
Bright's disease, chronic, mental affections associated with, 603
Brinton, horny growth of penis, 141
Bromidia, 140, 251
Bronchial tubes, treatment of diseases of, Westbrook, 113
Bronchitis, antipyrin in, 423
Bruen, Bergeon's method of treating phthisis, 2
Burns on eyeball, preparation for, 479
  treatment of, 42, 454
Burow's fluid, 75

CÆSAREAN section, 25, 75, 316, 370, 548, 621, 659
  prognosis of, Lusk, 413
Caffeine, citrate of, in cardiac disorders, 152
Calcium, hypophosphite of, 597
Calculi, cystine, 664
  large, 720
  preputial, 151
Calculus, peculiar shaped, 632
Calomel, 426
Canal, spinal, removal of tumor from, 12
Cancer, analysis of a "cure" for, 612
  bacillus of, 710, 768
  diagnosis of, 75
  of stomach, 215
  pylorectomy for, 656
  uterine, treatment of, 100, 318, 376, 400, 598
Candles, disinfectant, 380
Canfield, cyclic albuminuria, 118
Cannabis indica in diarrhœa, 184
Carbolic acid, creolin versus, 545
Carcinoma, extirpation of uterus for, 376
  of the descending colon, 659
Cardiac disorders, citrate of caffeine in, 152
  medication, 713
Carminatives, action of, 44
Carnochan, John Murray, death of, 549
Carpenter, Henry, death of, 80
Carpenter, J. S., fracture of skull, 706
Cartilage, cricoid, perichondritis of, Jurist, 540
Caruncle, urethral, 377
Casein, 239
Castor oil, emulsion of, with casein, 334
Cataract, concussion, 624
  extraction, 132, 133, 190
Catheter, a capillary, 451
Cattle, tubercle in, 242

Cavity, peritoneal, Mikulicz's method of draining, 43
Cerebral lesions, study of localized, 22
Cervix uteri, amputation of, 435
lacerated, 220, 507
rapid dilatation of, 307
treatment of, with nitrate of lead, 452
Chancroid, precautions to be enjoined upon patients suffering from, 574
Charcot's disease, 596
Children, apparatus for testing eyesight of, 682
bacteria peculiar to diseases of, 13
dietary of, inheriting a tendency to phthisis, 14
mutilation of, 611
of the English poor, 379
rectal injections for convulsions of, 14
treatment of febrile disorders of, 543
Chloral hydrate, a preventive of rabies, 655
Chloroform, administration of, 362, 506
Chlorosis, 681
clinical diagnosis of, 571
sulphur in, 390
Cholera, 186, 251, 463, 491, 505, 554, 584
and quarantine, 393, 455, 462, 521, 528
bacillus, chemical test for, 542
germ, effect of iodoform vapor upon, 541
infantum, treatment of, 38, 70, 97, 122, 213
in South America, 723
nitrate of amyl in, 598
Chopart's amputation, 134
Murdoch, 57
Chorea, 168
and heart disease, 509
Osler, 437, 495
laryngealis, 578
treatment of, 43
Choroid, coloboma of, 191
Chrome yellow, 166, 190
Chromium, action of, 736
Circumcision, a substitute for, 309
Clark, Alonzo, death of, 337
Climate, artificial, for invalids, 167
Clothing, light and dark, 408
Cocaine, 15, 16, 42, 149, 151, 184, 186, 241, 267, 268, 451, 518
Coccyx, treatment of pain about, 43
Coffee, in coryza, 124
roasted, value of, as an antiseptic, 508
Cohen, J. S., antifebrin in typhoid fever, 422
appearance of larynx twenty years after extirpation of an epithelioma from, 652
hernia of laryngeal sac, 707
removal of morbid growths of vocal bands, 265
intralaryngeal abscess, 731
Cohen, S. S., treatment of pulmonary consumption, 381
College of Physicians of Philadelphia, bequests to, 245
Collodion for gouty joints, 267
Coloboma of iris, choroid, and optic nerve, 191
